PART I Fundamentals

1 Analysis of Algorithms	3
<i>Sartaj Sahni</i>	
2 Basic Structures	23
<i>Dinesh P. Mehta</i>	
3 Trees	35
<i>Dinesh P. Mehta</i>	
4 Graphs.....	49
<i>Narsingh Deo</i>	

PART II Priority Queues

5 Leftist Trees.....	69
<i>Sartaj Sahni</i>	
6 Skew Heaps.....	77
<i>C. Pandu Rangan</i>	
7 Binomial, Fibonacci, and Pairing Heaps.....	85
<i>Michael L. Fredman</i>	
8 Double-Ended Priority Queues	97
<i>Sartaj Sahni</i>	

PART III Dictionary Structures

9 Hash Tables	117
<i>Pat Morin</i>	
10 Bloom Filter and Its Variants	131
<i>Shigang Chen</i>	
11 Balanced Binary Search Trees	151
<i>Arne Andersson, Rolf Fagerberg, and Kim S. Larsen</i>	
12 Finger Search Trees	171
<i>Gerth Stølting Brodal</i>	

13	Splay trees	179
	<i>Sanjeev Saxena</i>	
14	Randomized Dictionary Structures.....	197
	<i>C. Pandu Rangan</i>	
15	Trees with Min Weighted Path Length.....	215
	<i>Wojciech Rytter</i>	
16	B Trees.....	233
	<i>Donghui Zhang</i>	

PART IV Multidimensional/Spatial Structures

17	Multidimensional Spatial Data Structures.....	251
	<i>Hanan Samet</i>	
18	Planar Straight Line Graphs.....	277
	<i>Siu-Wing Cheng</i>	
19	Interval, Segment, Range, Priority Search Trees	291
	<i>D. T. Lee and Hung-I Yu</i>	
20	Quadtrees and Octtrees	309
	<i>Srinivas Aluru</i>	
21	BSP Trees.....	329
	<i>Bruce F. Naylor</i>	
22	R-Trees	343

25	Online Dictionary Structures.....	389
	<i>Teofilo F. Gonzalez</i>	
26	Cuttings.....	397
	<i>Bernard Chazelle</i>	
27	Approximate Geom Query Structures	405
	<i>Christian A. Duncan and Michael T. Goodrich</i>	
28	Geometric and Spatial Data Structures in External Memory	419
	<i>Jeffrey Scott Vitter</i>	

PART V Miscellaneous

29	Tries	445
	<i>Sartaj Sahni</i>	
30	Suffix Trees and Suffix Arrays	461
	<i>Srinivas Aluru</i>	
31	String Searching	477
	<i>Andrzej Ehrenfeucht and Ross M. McConnell</i>	

32	Binary Decision Diagrams	495
	<i>Shin-ichi Minato</i>	
33	Persistent Data Structures	511
	<i>Haim Kaplan</i>	
34	Data Structures for Sets	529
	<i>Rajeev Raman</i>	
35	Cache Oblivious Data Structures.....	545
	<i>Lars Arge, Gerth Stølting Brodal, and Rolf Fagerberg</i>	
36	Dynamic Trees.....	567
	<i>Camil Demetrescu, Irene Finocchi, and Giuseppe F. Italiano</i>	
37	Dynamic Graphs	581
	<i>Camil Demetrescu, Irene Finocchi, and Giuseppe F. Italiano</i>	
38	Succinct Representation of Data Structures	595
	<i>J. Ian Munro and S. Srinivasa Rao</i>	
39	Randomized Graph Data Structures	611
	<i>Surender Baswana and Sandeep Sen</i>	
40	Searching and Priority Queues in $o(\log n)$ Time	627
	<i>Arne Andersson</i>	

PART VI Data Structures in Langs and Libraries

41	Functional Data Structures	639
	<i>Chris Okasaki</i>	
42	LEDA, a Platform for Combinatorial and Geometric Computing.....	653
	<i>Stefan Naeher</i>	
43	Data Structures in C++.....	667
	<i>Mark Allen Weiss</i>	
44	Data Structures in JDSL.....	679
	<i>Michael T. Goodrich, Roberto Tamassia, and Luca Vismara</i>	
45	Data Structure Visualization	697
	<i>John Stasko</i>	
46	Drawing Trees.....	707
	<i>Sebastian Leipert</i>	
47	Drawing Graphs	723
	<i>Peter Eades and Seok-Hee Hong</i>	
48	Concurrent Data Structures.....	741
	<i>Mark Moir and Nir Shavit</i>	

PART VII Applications

49	IP Router Tables	765
	<i>Sartaj Sahni, Kun Suk Kim, and Haibin Lu</i>	
50	Multidimensional Packet Classification.....	783
	<i>Pankaj Gupta</i>	

51	Data Structures in Web Information Retrieval	799
	<i>Monika Henzinger</i>	
52	The Web as a Dynamic Graph	805
	<i>S. N. Maheshwari</i>	
53	Layout Data Structures	817
	<i>Dinesh P. Mehta</i>	
54	Floorplan Rep in VLSI.....	833
	<i>Zhou Feng, Bo Yao, and Chung-Kuan Cheng</i>	
55	Computer Graphics.....	857
	<i>Dale McMullin and Alyn Rockwood</i>	
56	Geographic Information Systems	871
	<i>Bernhard Seeger and Peter Widmayer</i>	
57	Collision Detection	889
	<i>Ming C. Lin and Dinesh Manocha</i>	
58	Image Data Structures	903
	<i>S. S. Iyengar, V. K. Vaishnavi, and S. Gunasekaran</i>	
59	Computational Biology	917
	<i>Paolo Ferragina, Stefan Kurtz, Stefano Lonardi, and Giovanni Manzini</i>	
60	Data Structures for Cheminformatics.....	935
	<i>Dinesh P. Mehta and John D. Crabtree</i>	
61	Elimination Structures in Scientific Computing.....	945
	<i>Alex Pothen and Sivan Toledo</i>	
62	Data Structures for Databases.....	967
	<i>Joachim Hammer and Markus Schneider</i>	
63	Data Structures for Big Data Stores.....	983
	<i>Arun A. Ravindran and Dinesh P. Mehta</i>	
64	Data Mining.....	997
	<i>Vipin Kumar, Pang-Ning Tan, and Michael Steinbach</i>

67	Computational Geometry: Generalized (or Colored) Intersection Searching.....	1043
	<i>Prosenjit Gupta, Ravi Janardan, Saladi Rahul, and Michiel Smid</i>	
	Index	1059

Preface to the Second Edition

It has been over a decade since the first edition of this handbook was published in 2005. In this edition, we have attempted to capture advances in data structures while retaining the seven-part structure of the first edition. As one would expect, the discipline of data structures has matured with advances not as rapidly forthcoming as in the twentieth century. Nevertheless, there have been areas that have seen significant progress that we have focused on in this edition.

We have added four new chapters on Bloom Filters; Binary Decision Diagrams; Data Structures for Cheminformatics; and Data Structures for Big Data Stores. In addition, we have updated 13 other chapters from the original edition.

Preface to the First Edition

In the late 1960s, Donald Knuth, winner of the 1974 Turing Award, published his landmark book *The Art of Computer Programming: Fundamental Algorithms*. This book brought together a body of knowledge that defined the data structures area. The term data structure, itself, was defined in this book to be *A table of data including structural relationships*. Niklaus Wirth, the inventor of the Pascal language and winner of the 1984 Turing award, stated that “Algorithms + Data Structures = Programs.” The importance of algorithms and data structures has been recognized by the community and consequently, every undergraduate Computer Science curriculum has classes on data structures and algorithms. Both of these related areas have seen tremendous advances in the decades since the appearance of the books by Knuth and Wirth. Although there are several advanced and specialized texts and handbooks on algorithms (and related data structures), there is, to the best of our knowledge, no text or handbook that focuses exclusively on the wide variety of data structures that have been reported in the literature. The goal of this handbook is to provide a comprehensive survey of data structures of different types that are in existence today.

To this end, we have subdivided this handbook into seven parts, each of which addresses a different facet of data structures. Part I is a review of introductory material. Although this material is covered in all standard data structures texts, it was included to make the handbook self-contained and in recognition of the fact that there are many practitioners and programmers who may not have had a formal education in computer science. Parts II through IV discuss Priority Queues, Dictionary Structures, and Multidimensional structures, respectively. These are all well-known classes of data structures. Part V is a catch-all used for well-known data structures that eluded easy classification. Parts I through V are largely theoretical in nature: they discuss the data structures, their operations and their complexities. Part VI addresses mechanisms and tools that have been developed to facilitate the *use* of data structures in real programs. Many of the data structures discussed in previous parts are very intricate and take some effort to program. The development of data structure libraries and visualization tools by skilled programmers are of critical importance in reducing the gap between theory and practice. Finally, Part VII examines applications of data structures. The deployment of many data structures from Parts I through V in a variety of applications is discussed. Some of the data structures discussed here have been invented solely in the context of these applications and are not well-known to the broader community. Some of the applications discussed include Internet routing, web search engines, databases, data mining, scientific computing, geographical information systems, computational geometry, computational biology, VLSI floorplanning and layout, computer graphics and image processing.

For data structure and algorithm researchers, we hope that the handbook will suggest new ideas for research in data structures and for an appreciation of the application contexts in which data structures are deployed. For the practitioner who is devising an algorithm, we hope that the handbook will lead to insights in organizing data that make it possible to solve the algorithmic problem more cleanly and efficiently. For researchers in specific application areas, we hope that they will gain some insight from the ways other areas have handled their data structuring problems.

Although we have attempted to make the handbook as complete as possible, it is impossible to undertake a task of this magnitude without some omissions. For this, we apologize in advance and encourage readers to contact us with information about significant data structures or applications that do not appear here. These could be included in future editions of this handbook. We would like to thank the excellent team of authors, who are at the forefront of research in data structures, who have contributed to this handbook. The handbook would not have been possible without their painstaking efforts. We are extremely saddened by the untimely demise of a prominent data structures researcher, Professor Gísli R. Hjaltason, who was to write a chapter for this handbook. He will be missed greatly by the computer science community. Finally, we would like to thank our families for their support during the development of the handbook.

Editors

Dinesh P. Mehta has been on the faculty of the Colorado School of Mines since 2000, where he is currently professor in the Department of Computer Science. He earned degrees (all in computer science) from the Indian Institute of Technology Bombay, the University of Minnesota, and the University of Florida. Before joining Mines in 2000, he was on the faculty of the University of Tennessee Space Institute, where he received the Vice President's Award for Teaching Excellence in 1997. He was a visiting professor at Intel's Strategic CAD Labs for several months in 1996 and 1997 and at the Tata Research Development and Design Center (in Pune, India) in 2007. He has also received graduate teaching awards at Mines in 2007, 2008, and 2009.

He was assistant department head from 2004 to 2008 and interim department head from 2008 to 2010 in the former Department of Mathematical and Computer Sciences and served as president of the Mines Faculty Senate in 2016–2017.

Dr. Mehta is the coauthor of the book, *Fundamentals of Data Structures in C++* and coeditor of the *Handbook of Algorithms for VLSI Physical Design Automation*. He serves as associate director of the ORwE (Operations Research with Engineering) PhD program at Mines and is currently an associate editor of *ACM Computing Surveys*. His current research interests are in cheminformatics, computational materials, and big graph analytics.

Sartaj Sahni is a distinguished professor of computer and information sciences and engineering at the University of Florida. He is also a member of the European Academy of Sciences, a Fellow of IEEE, ACM, AAAS, and Minnesota Supercomputer Institute, and a distinguished alumnus of the Indian Institute of Technology, Kanpur. Dr. Sahni is the recipient of the 1997 IEEE Computer Society Taylor L. Booth Education Award, the 2003 IEEE Computer Society W. Wallace McDowell Award, and the 2003 ACM Karl Karlstrom Outstanding Educator Award. Dr. Sahni earned his BTech (electrical engineering) degree from the Indian Institute of Technology, Kanpur, and MS and PhD in computer science from Cornell University. Dr. Sahni has published over 400 research papers and written 15 books. His research publications are on the design and analysis of efficient algorithms, parallel computing, interconnection networks, design automation, and medical algorithms.

Dr. Sahni is the editor-in-chief of the *ACM Computing Surveys*, a managing editor of the *International Journal of Foundations of Computer Science*, and a member of the editorial boards of 17 other journals. He is a past coeditor-in-chief of the *Journal of Parallel and Distributed Computing*. He has served as program committee chair, general chair, and a keynote speaker at many conferences. Dr. Sahni has served on several NSF (National Science Foundation) and NIH (National Institutes of Health) panels and he has been involved as an external evaluator of several computer science and engineering departments.

1.1 Introduction

The topic “Analysis of Algorithms” is concerned primarily with determining the memory (space) and time requirements (complexity) of an algorithm. Since the techniques used to determine memory requirements are a subset of those used to determine time requirements, in this chapter, we focus on the methods used to determine the time complexity of an algorithm.

The time complexity (or simply, complexity) of an algorithm is measured as a function of the problem size. Some examples are given below.

1. The complexity of an algorithm to sort n elements may be given as a function of n .
2. The complexity of an algorithm to multiply an $m \times n$ matrix and an $n \times p$ matrix may be given as a function of m , n , and p .
3. The complexity of an algorithm to determine whether x is a prime number may be given as a function of the number, n , of bits in x . Note that $n = \lceil \log_2(x + 1) \rceil$.

We partition our discussion of algorithm analysis into the following sections.

1. Operation counts
2. Step counts
3. Counting cache misses
4. Asymptotic complexity
5. Recurrence equations
6. Amortized complexity
7. Practical complexities

See [1–4] for additional material on algorithm analysis.

[★] This chapter has been reprinted from first edition of this Handbook, without any content updates.

1.2 Operation Counts

One way to estimate the time complexity of a program or method is to select one or more operations, such as add, multiply, and compare, and to determine how many of each is done. The success of this method depends on our ability to identify the operations that contribute most to the time complexity.

EXAMPLE 1.1

[Max Element] [Figure 1.1](#) gives an algorithm that returns the position of the largest element in the array $a[0:n-1]$. When $n > 0$, the time complexity of this algorithm can be estimated by determining the number of comparisons made between elements of the array a . When $n \leq 1$, the `for` loop is not entered. So no comparisons between elements of a are made. When $n > 1$, each iteration of the `for` loop makes one comparison between two elements of a , and the total number of element comparisons is $n-1$. Therefore, the number of element comparisons is $\max\{n-1, 0\}$. The method `max` performs other comparisons (e.g., each iteration of the `for` loop is preceded by a comparison between i and n) that are not included in the estimate. Other operations such as initializing `positionOfCurrentMax` and incrementing the `for` loop index i are also not included in the estimate.

```
int max(int [] a, int n)
{
    if (n < 1) return -1; // no max
    int positionOfCurrentMax = 0;
    for (int i = 1; i < n; i++)
        if (a[positionOfCurrentMax] < a[i]) positionOfCurrentMax = i;
    return positionOfCurrentMax;
}
```

FIGURE 1.1 Finding the position of the largest element in $a[0:n-1]$.

The algorithm of [Figure 1.1](#) has the nice property that the operation count is precisely determined by the problem size. For many other problems, however, this is not so. [Figure 1.2](#) gives an algorithm that performs one pass of a bubble sort. In this pass, the largest element in $a[0:n-1]$ relocates to position $a[n-1]$. The number of swaps performed by this algorithm depends not only on the problem size n but also on the particular values of the elements in the array a . The number of swaps varies from a low of 0 to a high of $n - 1$.

```
void bubble(int [] a, int n)
{
    for (int i = 0; i < n - 1; i++)
        if (a[i] > a[i+1]) swap(a[i], a[i+1]);
}
```

FIGURE 1.2 A bubbling pass.

Since the operation count isn't always uniquely determined by the problem size, we ask for the best, worst, and average counts.

EXAMPLE 1.2

[SEQUENTIAL SEARCH] [Figure 1.3](#) gives an algorithm that searches $a[0:n-1]$ for the first occurrence of x . The number of comparisons between x and the elements of a isn't uniquely determined by the problem size n . For example, if $n = 100$ and $x = a[0]$, then only 1 comparison is made. However, if x isn't equal to any of the $a[i]$'s, then 100 comparisons are made.

A search is *successful* when x is one of the $a[i]$'s. All other searches are *unsuccessful*. Whenever we have an unsuccessful search, the number of comparisons is n . For successful searches the best comparison count is 1, and the worst is n . For the average count assume that all array elements are distinct and that each is searched for with equal frequency. The average

count for a successful search is

$$\frac{1}{n} \sum_{i=1}^n i = (n+1)/2$$

```
int sequentialSearch(int [] a, int n, int x)
{
    // search a[0:n-1] for x
    int i;
    for (i = 0; i < n && x != a[i]; i++);
    if (i == n) return -1;    // not found
    else return i;
}
```

FIGURE 1.3 Sequential search.

EXAMPLE 1.3

[Insertion into a Sorted Array] [Figure 1.4](#) gives an algorithm to insert an element x into a sorted array $a[0:n-1]$.

We wish to determine the number of comparisons made between x and the elements of a . For the problem size, we use the number n of elements initially in a . Assume that $n \geq 1$. The best or minimum number of comparisons is 1, which happens when the new element x

```
void insert(int [] a, int n, int x)
{
    // find proper place for x
    int i;
    for (i = n - 1; i >= 0 && x < a[i]; i--)
        a[i+1] = a[i];

    a[i+1] = x;    // insert x
}
```

FIGURE 1.4 Inserting into a sorted array.

is to be inserted at the right end. The maximum number of comparisons is n , which happens when x is to be inserted at the left end. For the average assume that x has an equal chance of being inserted into any of the possible $n+1$ positions. If x is eventually inserted into position $i+1$ of a , $i \geq 0$, then the number of comparisons is $n-i$. If x is inserted into $a[0]$, the number of comparisons is n . So the average count is

$$\frac{1}{n+1} \left(\sum_{i=0}^{n-1} (n-i) + n \right) = \frac{1}{n+1} \left(\sum_{j=1}^n j + n \right) = \frac{1}{n+1} \left(\frac{n(n+1)}{2} + n \right) = \frac{n}{2} + \frac{n}{n+1}$$

This average count is almost 1 more than half the worst-case count.

1.3 Step Counts

The operation-count method of estimating time complexity omits accounting for the time spent on all but the chosen operations. In the *step-count* method, we attempt to account for the time spent in all parts of the algorithm. As was the case for operation counts, the step count is a function of the problem size.

A *step* is any computation unit that is independent of the problem size. Thus 10 additions can be one step; 100 multiplications can also be one step; but n additions, where n is the problem size, cannot be one step. The amount of computing represented by one step may be different from that represented by another. For example, the entire statement

```
return a+b+b*c+(a+b-c)/(a+b)+4;
```

TABLE 1.1 Best-Case Step Count for [Figure 1.3](#)

Statement	s/e	Frequency	Total Steps
int sequentialSearch(...)	0	0	0
{	0	0	0
int i;	1	1	1
for (i = 0; i < n && x != a[i]; i++);	1	1	1
if (i == n) return -1;	1	1	1
else return i;	1	1	1
}	0	0	0
Total			4

TABLE 1.2 Worst-Case Step Count for [Figure 1.3](#)

for (i = 0; i < n && x != a[i]; i++);	1	$n+1$	$n+1$
if (i == n) return -1;	1	1	1
else return i;	1	0	0
}	0	0	0
Total			$n+3$

TABLE 1.3 Step Count for [Figure 1.3](#) When $x = a[j]$

Statement	s/e	Frequency	Total Steps
int sequentialSearch(...)	0	0	0
{	0	0	0
int i;	1	1	1
for (i = 0; i < n && x != a[i]; i++);	1	$j+1$	$j+1$
if (i == n) return -1;	1	1	1
else return i;	1	1	1
}	0	0	0
Total			$j+4$

can be regarded as a single step if its execution time is independent of the problem size. We may also count a statement such as

$x = y;$

as a single step.

To determine the step count of an algorithm, we first determine the number of steps per execution (s/e) of each statement and the total number of times (i.e., frequency) each statement is executed. Combining these two quantities gives us the total contribution of each statement to the total step count. We then add the contributions of all statements to obtain the step count for the entire algorithm.

EXAMPLE 1.4

[Sequential Search] [Tables 1.1](#) and [1.2](#) show the best- and worst-case step-count analyses for `sequentialSearch` ([Figure 1.3](#)).

For the average step-count analysis for a successful search, we assume that the n values in `a` are distinct and that in a successful search, `x` has an equal probability of being any one of these values. Under these assumptions the average step count for a successful search is the sum of the step counts for the n possible successful searches divided by n . To obtain this average, we first obtain the step count for the case $x = a[j]$ where j is in the range $[0, n - 1]$ (see [Table 1.3](#)).

Now we obtain the average step count for a successful search:

$$\frac{1}{n} \sum_{j=0}^{n-1} (j+4) = (n+7)/2$$

This value is a little more than half the step count for an unsuccessful search.

Now suppose that successful searches occur only 80% of the time and that each `a[i]` still has the same probability of being searched for. The average step count for `sequentialSearch` is

$$\begin{aligned} & 0.8 * (\text{average count for successful searches}) + 0.2 * (\text{count for an unsuccessful search}) \\ & = 0.8(n+7)/2 + 0.2(n+3) \\ & = 0.6n + 3.4 \end{aligned}$$

1.4 Counting Cache Misses

1.4.1 A Simple Computer Model

Traditionally, the focus of algorithm analysis has been on counting operations and steps. Such a focus was justified when computers took more time to perform an operation than they took to fetch the data needed for that operation. Today, however, the cost of performing an operation is significantly lower than the cost of fetching data from memory. Consequently, the run time of many algorithms is dominated by the number of memory references (equivalently, number of cache misses) rather than by the number of operations. Hence, algorithm designers focus on reducing not only the number of operations but also the number of memory accesses. Algorithm designers focus also on designing algorithms that hide memory latency.

Consider a simple computer model in which the computer's memory consists of an L1 (level 1) cache, an L2 cache, and main memory. Arithmetic and logical operations are performed by the arithmetic and logic unit (ALU) on data resident in registers (R). [Figure 1.5](#) gives a block diagram for our simple computer model.

Typically, the size of main memory is tens or hundreds of megabytes; L2 cache sizes are typically a fraction of a megabyte; L1 cache is usually in the tens of kilobytes; and the number of registers is between 8 and 32. When you start your program, all your data are in main memory.

To perform an arithmetic operation such as an add, in our computer model, the data to be added are first loaded from memory into registers, the data in the registers are added, and the result is written to memory.

Let one cycle be the length of time it takes to add data that are already in registers. The time needed to load data from L1 cache to a register is two cycles in our model. If the required data are not in L1 cache but are in L2 cache, we get an L1 cache miss and the required data are copied from L2 cache to L1 cache and the register in 10 cycles. When the required data are not in L2 cache either, we have an L2 cache miss and the required data are copied from main memory into L2 cache, L1 cache, and the register in 100 cycles. The write operation is counted as one cycle even when the data are written to main memory because we do not wait for the write to complete before proceeding to the next operation. For more details on cache organization, see [\[5\]](#).

1.4.2 Effect of Cache Misses on Run Time

For our simple model, the statement `a = b + c` is compiled into the computer instructions

```
load a; load b; add; store c;
```

where the `load` operations load data into registers and the `store` operation writes the result of the `add` to memory. The `add` and the `store` together take two cycles. The two `loads` may take anywhere from 4 cycles to 200 cycles depending on whether we get no cache miss, L1 misses, or L2 misses. So the total time for the statement `a = b + c` varies from 6 cycles to 202 cycles. In practice, the variation in time is not as extreme because we can overlap the time spent on successive cache misses.

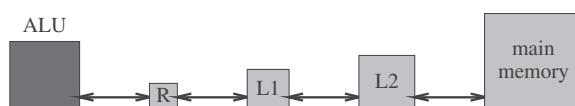

FIGURE 1.5 A simple computer model.

Suppose that we have two algorithms that perform the same task. The first algorithm does 2000 adds that require 4000 load, 2000 add, and 2000 store operations and the second algorithm does 1000 adds. The data access pattern for the first algorithm is such that 25% of the loads result in an L1 miss and another 25% result in an L2 miss. For our simplistic computer model, the time required by the first algorithm is $2000 * 2$ (for the 50% loads that cause no cache miss) + $1000 * 10$ (for the 25% loads that cause an L1 miss) + $1000 * 100$ (for the 25% loads that cause an L2 miss) + $2000 * 1$ (for the adds) + $2000 * 1$ (for the stores) = 118,000 cycles. If the second algorithm has 100% L2 misses, it will take $2000 * 100$ (L2 misses) + $1000 * 1$ (adds) + $1000 * 1$ (stores) = 202,000 cycles. So the second algorithm, which does half the work done by the first, actually takes 76% more time than is taken by the first algorithm.

Computers use a number of strategies (such as preloading data that will be needed in the near future into cache, and when a cache miss occurs, the needed data as well as data in some number of adjacent bytes are loaded into cache) to reduce the number of cache misses and hence reduce the run time of a program. These strategies are most effective when successive computer operations use adjacent bytes of main memory.

Although our discussion has focused on how cache is used for data, computers also use cache to reduce the time needed to access instructions.

1.4.3 Matrix Multiplication

The algorithm of [Figure 1.6](#) multiplies two square matrices that are represented as two-dimensional arrays. It performs the following computation:

$$c[i][j] = \sum_{k=1}^n a[i][k] * b[k][j], \quad 1 \leq i \leq n, 1 \leq j \leq n \quad (1.1)$$

[Figure 1.7](#) is an alternative algorithm that produces the same two-dimensional array c as is produced by [Figure 1.6](#). We observe that [Figure 1.7](#) has two nested `for` loops that are not present in [Figure 1.6](#) and does more work than is done by [Figure 1.6](#) with respect to indexing into the array c . The remainder of the work is the same.

You will notice that if you permute the order of the three nested `for` loops in [Figure 1.7](#), you do not affect the result array c . We refer to the loop order in [Figure 1.7](#) as ijk order. When we swap the second and third `for` loops, we get ikj order. In all, there are $3! = 6$ ways in which we can order the three nested `for` loops. All six orderings result in methods that perform exactly

```
void squareMultiply(int [][] a, int [][] b, int [][] c, int n)
{
    for (int i = 0; i < n; i++)
        for (int j = 0; j < n; j++)
    {
        int sum = 0;
        for (int k = 0; k < n; k++)
            sum += a[i][k] * b[k][j];
        c[i][j] = sum;
    }
}
```

FIGURE 1.6 Multiply two $n \times n$ matrices.

```
void fastSquareMultiply(int [][] a, int [][] b, int [][] c, int n)
{
    for (int i = 0; i < n; i++)
        for (int j = 0; j < n; j++)
            c[i][j] = 0;

    for (int i = 0; i < n; i++)
        for (int j = 0; j < n; j++)
            for (int k = 0; k < n; k++)
                c[i][j] += a[i][k] * b[k][j];
}
```

FIGURE 1.7 Alternative algorithm to multiply square matrices.

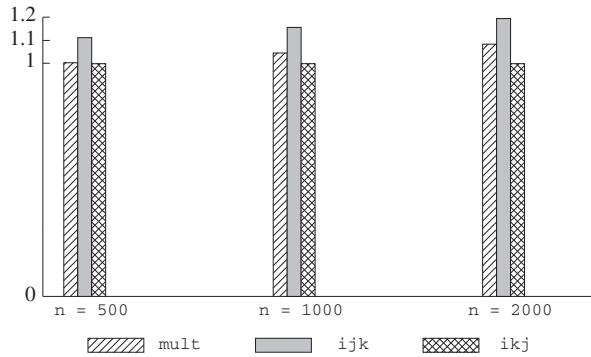

FIGURE 1.8 Normalized run times for matrix multiplication.

the same number of operations of each type. So you might think all six take the same time. Not so. By changing the order of the loops, we change the data access pattern and so change the number of cache misses. This in turn affects the run time.

In `ijk` order, we access the elements of `a` and `c` by rows; the elements of `b` are accessed by column. Since elements in the same row are in adjacent memory and elements in the same column are far apart in memory, the accesses of `b` are likely to result in many L2 cache misses when the matrix size is too large for the three arrays to fit into L2 cache. In `ikj` order, the elements of `a`, `b`, and `c` are accessed by rows. Therefore, `ikj` order is likely to result in fewer L2 cache misses and so has the potential to take much less time than taken by `ijk` order.

For a crude analysis of the number of cache misses, assume we are interested only in L2 misses; that an L2 cache-line can hold w matrix elements; when an L2 cache-miss occurs, a block of w matrix elements is brought into an L2 cache line; and that L2 cache is small compared to the size of a matrix. Under these assumptions, the accesses to the elements of `a`, `b` and `c` in `ijk` order, respectively, result in n^3/w , n^3 , and n^2/w L2 misses. Therefore, the total number of L2 misses in `ijk` order is $n^3(1 + w + 1/n)/w$. In `ikj` order, the number of L2 misses for our three matrices is n^2/w , n^3/w , and n^3/w , respectively. So, in `ikj` order, the total number of L2 misses is $n^3(2 + 1/n)/w$. When n is large, the ratio of `ijk` misses to `ikj` misses is approximately $(1 + w)/2$, which is 2.5 when $w = 4$ (e.g., when we have a 32-byte cache line and the data is double precision) and 4.5 when $w = 8$ (e.g., when we have a 64-byte cache line and double-precision data). For a 64-byte cache line and single-precision (i.e., 4 byte) data, $w = 16$ and the ratio is approximately 8.5.

Figure 1.8 shows the normalized run times of a Java version of our matrix multiplication algorithms. In this figure, `mult` refers to the multiplication algorithm of Figure 1.6. The normalized run time of a method is the time taken by the method divided by the time taken by `ikj` order.

Matrix multiplication using `ikj` order takes 10% less time than does `ijk` order when the matrix size is $n = 500$ and 16% less time when the matrix size is 2000. Equally surprising is that `ikj` order runs faster than the algorithm of Figure 1.6 (by about 5% when $n = 2000$). This despite the fact that `ikj` order does more work than is done by the algorithm of Figure 1.6.

1.5 Asymptotic Complexity

1.5.1 Big Oh Notation (O)

Let $p(n)$ and $q(n)$ be two nonnegative functions. $p(n)$ is *asymptotically bigger* ($p(n)$ asymptotically dominates $q(n)$) than the function $q(n)$ iff

$$\lim_{n \rightarrow \infty} \frac{q(n)}{p(n)} = 0 \quad (1.2)$$

$q(n)$ is *asymptotically smaller* than $p(n)$ iff $p(n)$ is asymptotically bigger than $q(n)$. $p(n)$ and $q(n)$ are *asymptotically equal* iff neither is asymptotically bigger than the other.

In the following discussion the function $f(n)$ denotes the time or space complexity of an algorithm as a function of the problem size n . Since the time or space requirements of a program are nonnegative quantities, we assume that the function f has a nonnegative value for all values of n . Further, since n denotes an instance characteristic, we assume that $n \geq 0$. The function $f(n)$ will, in general, be a sum of terms. For example, the terms of $f(n) = 9n^2 + 3n + 12$ are $9n^2$, $3n$, and 12 . We may compare pairs of terms to determine which is bigger. The biggest term in the example $f(n)$ is $9n^2$.

EXAMPLE 1.5

Since

$$\lim_{n \rightarrow \infty} \frac{10n + 7}{3n^2 + 2n + 6} = \frac{10/n + 7/n^2}{3 + 2/n + 6/n^2} = 0/3 = 0$$

$3n^2 + 2n + 6$ is asymptotically bigger than $10n + 7$ and $10n + 7$ is asymptotically smaller than $3n^2 + 2n + 6$. A similar derivation shows that $8n^4 + 9n^2$ is asymptotically bigger than $100n^3 - 3$, and that $2n^2 + 3n$ is asymptotically bigger than $83n$. $12n + 6$ is asymptotically equal to $6n + 2$.

[Figure 1.9](#) gives the terms that occur frequently in a step-count analysis. Although all the terms in [Figure 1.9](#) have a coefficient of 1, in an actual analysis, the coefficients of these terms may have a different value.

We do not associate a logarithmic base with the functions in [Figure 1.9](#) that include $\log n$ because for any constants a and b greater than 1, $\log_a n = \log_b n / \log_b a$. So $\log_a n$ and $\log_b n$ are asymptotically equal.

The definition of asymptotically smaller implies the following ordering for the terms of [Figure 1.9](#) ($<$ is to be read as “is asymptotically smaller than”):

$$1 < \log n < n < n \log n < n^2 < n^3 < 2^n < n!$$

Asymptotic notation describes the behavior of the time or space complexity for large instance characteristics. Although we will develop asymptotic notation with reference to step counts alone, our development also applies to space complexity and operation counts.

The notation $f(n) = O(g(n))$ (read as “ $f(n)$ is big oh of $g(n)$ ”) means that $f(n)$ is asymptotically smaller than or equal to $g(n)$. Therefore, in an asymptotic sense $g(n)$ is an upper bound for $f(n)$.

EXAMPLE 1.6

From Example 1.5, it follows that $10n + 7 = O(3n^2 + 2n + 6)$; $100n^3 - 3 = O(8n^4 + 9n^2)$. We see also that $12n + 6 = O(6n + 2)$; $3n^2 + 2n + 6 \neq O(10n + 7)$; and $8n^4 + 9n^2 \neq O(100n^3 - 3)$.

Although Example 1.6 uses the big oh notation in a correct way, it is customary to use $g(n)$ functions that are *unit terms* (i.e., $g(n)$ is a single term whose coefficient is 1) except when $f(n) = 0$. In addition, it is customary to use, for $g(n)$, the smallest unit term for which the statement $f(n) = O(g(n))$ is true. When $f(n) = 0$, it is customary to use $g(n) = 0$.

EXAMPLE 1.7

The customary way to describe the asymptotic behavior of the functions used in Example 1.6 is $10n + 7 = O(n)$; $100n^3 - 3 = O(n^3)$; $12n + 6 = O(n)$; $3n^2 + 2n + 6 \neq O(n)$; and $8n^4 + 9n^2 \neq O(n^3)$.

In asymptotic complexity analysis, we determine the biggest term in the complexity; the coefficient of this biggest term is set to 1. The unit terms of a step-count function are step-count terms with their coefficients changed to 1. For example, the unit

Term	Name
1	constant
$\log n$	logarithmic
n	linear
$n \log n$	$n \log n$
n^2	quadratic
n^3	cubic
2^n	exponential
$n!$	factorial

FIGURE 1.9 Commonly occurring terms.

terms of $3n^2 + 6n \log n + 7n + 5$ are n^2 , $n \log n$, n , and 1; the biggest unit term is n^2 . So when the step count of a program is $3n^2 + 6n \log n + 7n + 5$, we say that its asymptotic complexity is $O(n^2)$.

Notice that $f(n) = O(g(n))$ is not the same as $O(g(n)) = f(n)$. In fact, saying that $O(g(n)) = f(n)$ is meaningless. The use of the symbol $=$ is unfortunate, as this symbol commonly denotes the equals relation. We can avoid some of the confusion that results from the use of this symbol (which is standard terminology) by reading the symbol $=$ as “is” and not as “equals.”

1.5.2 Omega (Ω) and Theta (Θ) Notations

Although the big oh notation is the most frequently used asymptotic notation, the omega and theta notations are sometimes used to describe the asymptotic complexity of a program.

The notation $f(n) = \Omega(g(n))$ (read as “ $f(n)$ is omega of $g(n)$ ”) means that $f(n)$ is asymptotically bigger than or equal to $g(n)$. Therefore, in an asymptotic sense, $g(n)$ is a lower bound for $f(n)$. The notation $f(n) = \Theta(g(n))$ (read as “ $f(n)$ is theta of $g(n)$ ”) means that $f(n)$ is asymptotically equal to $g(n)$.

EXAMPLE 1.8

$10n + 7 = \Omega(n)$ because $10n + 7$ is asymptotically equal to n ; $100n^3 - 3 = \Omega(n^3)$; $12n + 6 = \Omega(n)$; $3n^3 + 2n + 6 = \Omega(n)$; $8n^4 + 9n^2 = \Omega(n^3)$; $3n^3 + 2n + 6 \neq \Omega(n^5)$; and $8n^4 + 9n^2 \neq \Omega(n^5)$.

$10n + 7 = \Theta(n)$ because $10n + 7$ is asymptotically equal to n ; $100n^3 - 3 = \Theta(n^3)$; $12n + 6 = \Theta(n)$; $3n^3 + 2n + 6 \neq \Theta(n)$; $8n^4 + 9n^2 \neq \Theta(n^3)$; $3n^3 + 2n + 6 \neq \Theta(n^5)$; and $8n^4 + 9n^2 \neq \Theta(n^5)$.

The best-case step count for sequentialSearch (Figure 1.3) is 4 (Table 1.1), the worst-case step count is $n + 3$, and the average step count is $0.6n + 3.4$. So the best-case asymptotic complexity of sequentialSearch is $\Theta(1)$, and the worst-case and average complexities are $\Theta(n)$. It is also correct to say that the complexity of sequentialSearch is $\Omega(1)$ and $O(n)$ because 1 is a lower bound (in an asymptotic sense) and n is an upper bound (in an asymptotic sense) on the step count.

When using the Ω notation, it is customary to use, for $g(n)$, the largest unit term for which the statement $f(n) = \Omega(g(n))$ is true.

At times it is useful to interpret $O(g(n))$, $\Omega(g(n))$, and $\Theta(g(n))$ as being the following sets:

$$\begin{aligned} O(g(n)) &= \{f(n) | f(n) = O(g(n))\} \\ \Omega(g(n)) &= \{f(n) | f(n) = \Omega(g(n))\} \\ \Theta(g(n)) &= \{f(n) | f(n) = \Theta(g(n))\} \end{aligned}$$

Under this interpretation, statements such as $O(g_1(n)) = O(g_2(n))$ and $\Theta(g_1(n)) = \Theta(g_2(n))$ are meaningful. When using this interpretation, it is also convenient to read $f(n) = O(g(n))$ as “ f of n is in (or is a member of) big oh of g of n ” and so on.

1.5.3 Little Oh Notation (o)

The little oh notation describes a strict upper bound on the asymptotic growth rate of the function f . $f(n)$ is little oh of $g(n)$ iff $f(n)$ is asymptotically smaller than $g(n)$. Equivalently, $f(n) = o(g(n))$ (read as “ f of n is little oh of g of n ”) iff $f(n) = O(g(n))$ and $f(n) \neq \Omega(g(n))$.

EXAMPLE 1.9

[LITTLE OH] $3n + 2 = o(n^2)$ as $3n + 2 = O(n^2)$ and $3n + 2 \neq \Omega(n^2)$. However, $3n + 2 \neq o(n)$. Similarly, $10n^2 + 4n + 2 = o(n^3)$, but is not $o(n^2)$.

The little oh notation is often used in step-count analyses. A step count of $3n + o(n)$ would mean that the step count is $3n$ plus terms that are asymptotically smaller than n . When performing such an analysis, one can ignore portions of the program that are known to contribute less than $\Theta(n)$ steps.

1.6 Recurrence Equations

Recurrence equations arise frequently in the analysis of algorithms, particularly in the analysis of recursive as well as divide-and-conquer algorithms.

EXAMPLE 1.10

[BINARY SEARCH] Consider a binary search of the sorted array $a[l:r]$, where $n = r - l + 1 \geq 0$, for the element x . When $n = 0$, the search is unsuccessful and when $n = 1$, we compare x and $a[l]$. When $n > 1$, we compare x with the element $a[m]$ ($m = \lfloor(l+r)/2\rfloor$) in the middle of the array. If the compared elements are equal, the search terminates; if $x < a[m]$, we search $a[l:m-1]$; otherwise, we search $a[m+1:r]$. Let $t(n)$ be the worst-case complexity of binary search. Assuming that $t(0) = t(1)$, we obtain the following recurrence.

$$t(n) = \begin{cases} t(1) & n \leq 1 \\ t(\lfloor n/2 \rfloor) + c & n > 1 \end{cases} \quad (1.3)$$

where c is a constant.

EXAMPLE 1.11

[MERGE SORT] In a merge sort of $a[0:n-1]$, $n \geq 1$, we consider two cases. When $n = 1$, no work is to be done as a one-element array is always in sorted order. When $n > 1$, we divide a into two parts of roughly the same size, sort these two parts using the merge sort method recursively, then finally merge the sorted parts to obtain the desired sorted array. Since the time to do the final merge is $\Theta(n)$ and the dividing into two roughly equal parts takes $O(1)$ time, the complexity, $t(n)$, of merge sort is given by the recurrence:

$$t(n) = \begin{cases} t(1) & n = 1 \\ t(\lfloor n/2 \rfloor) + t(\lceil n/2 \rceil) + cn & n > 1 \end{cases} \quad (1.4)$$

where c is a constant.

Solving recurrence equations such as Equations 1.3 and 1.4 for $t(n)$ is complicated by the presence of the floor and ceiling functions. By making an appropriate assumption on the permissible values of n , these functions may be eliminated to obtain a simplified recurrence. In the case of Equations 1.3 and 1.4 an assumption such as n is a power of 2 results in the simplified recurrences:

$$t(n) = \begin{cases} t(1) & n \leq 1 \\ t(n/2) + c & n > 1 \end{cases} \quad (1.5)$$

and

$$t(n) = \begin{cases} t(1) & n = 1 \\ 2t(n/2) + cn & n > 1 \end{cases} \quad (1.6)$$

Several techniques—substitution, table lookup, induction, characteristic roots, and generating functions—are available to solve recurrence equations. We describe only the substitution and table lookup methods.

1.6.1 Substitution Method

In the substitution method, recurrences such as Equations 1.5 and 1.6 are solved by repeatedly substituting right-side occurrences (occurrences to the right of $=$) of $t(x)$, $x > 1$, with expressions involving $t(y)$, $y < x$. The substitution process terminates when the only occurrences of $t(x)$ that remain on the right side have $x = 1$.

Consider the binary search recurrence of Equation 1.5. Repeatedly substituting for $t()$ on the right side, we get

$$\begin{aligned} t(n) &= t(n/2) + c \\ &= (t(n/4) + c) + c \\ &= t(n/4) + 2c \\ &= t(n/8) + 3c \\ &\vdots \\ &= t(1) + c \log_2 n \\ &= \Theta(\log n) \end{aligned}$$

For the merge sort recurrence of Equation 1.6, we get

$$\begin{aligned} t(n) &= 2t(n/2) + cn \\ &= 2(2t(n/4) + cn/2) + cn \\ &= 4t(n/4) + 2cn \\ &= 4(2t(n/8) + cn/4) + 2cn \\ &= 8t(n/8) + 3cn \\ &\vdots \\ &= nt(1) + cn \log_2 n \\ &= \Theta(n \log n) \end{aligned}$$

1.6.2 Table-Lookup Method

The complexity of many divide-and-conquer algorithms is given by a recurrence of the form

$$t(n) = \begin{cases} t(1) & n = 1 \\ a * t(n/b) + g(n) & n > 1 \end{cases} \quad (1.7)$$

where a and b are known constants. The merge sort recurrence, Equation 1.6, is in this form. Although the recurrence for binary search, Equation 1.5, isn't exactly in this form, the $n \leq 1$ may be changed to $n = 1$ by eliminating the case $n = 0$. To solve Equation 1.7, we assume that $t(1)$ is known and that n is a power of b (i.e., $n = b^k$). Using the substitution method, we can show that

$$t(n) = n^{\log_b a} [t(1) + f(n)] \quad (1.8)$$

where $f(n) = \sum_{j=1}^k h(b^j)$ and $h(n) = g(n)/n^{\log_b a}$.

Table 1.4 tabulates the asymptotic value of $f(n)$ for various values of $h(n)$. This table allows us to easily obtain the asymptotic value of $t(n)$ for many of the recurrences we encounter when analyzing divide-and-conquer algorithms.

Let us solve the binary search and merge sort recurrences using this table. Comparing Equation 1.5 with $n \leq 1$ replaced by $n = 1$ with Equation 1.7, we see that $a = 1$, $b = 2$, and $g(n) = c$. Therefore, $\log_b(a) = 0$, and $h(n) = g(n)/n^{\log_b a} = c = c(\log n)^0 = \Theta((\log n)^0)$. From **Table 1.4**, we obtain $f(n) = \Theta(\log n)$. Therefore, $t(n) = n^{\log_b a}(c + \Theta(\log n)) = \Theta(\log n)$.

For the merge sort recurrence, Equation 1.6, we obtain $a = 2$, $b = 2$, and $g(n) = cn$. So $\log_b a = 1$ and $h(n) = g(n)/n = c = \Theta((\log n)^0)$. Hence $f(n) = \Theta(\log n)$ and $t(n) = n(t(1) + \Theta(\log n)) = \Theta(n \log n)$.

TABLE 1.4 $f(n)$ Values for Various $h(n)$ Values

$h(n)$	$f(n)$
$O(n^r)$, $r < 0$	$O(1)$
$\Theta((\log n)^i)$, $i \geq 0$	$\Theta(((\log n)^{i+1})/(i+1))$
$\Omega(n^r)$, $r > 0$	$\Theta(h(n))$

1.7 Amortized Complexity

1.7.1 What Is Amortized Complexity?

The complexity of an algorithm or of an operation such as an insert, search, or delete, as defined in Section 1.1, is the *actual complexity* of the algorithm or operation. The actual complexity of an operation is determined by the step count for that operation, and the actual complexity of a sequence of operations is determined by the step count for that sequence. The actual complexity of a sequence of operations may be determined by adding together the step counts for the individual operations in the sequence. Typically, determining the step count for each operation in the sequence is quite difficult, and instead, we obtain an upper bound on the step count for the sequence by adding together the worst-case step count for each operation.

When determining the complexity of a sequence of operations, we can, at times, obtain tighter bounds using *amortized complexity* rather than worst-case complexity. Unlike the actual and worst-case complexities of an operation which are closely related to the step count for that operation, the amortized complexity of an operation is an accounting artifact that often bears no direct relationship to the actual complexity of that operation. The amortized complexity of an operation could be anything. *The only requirement is that the sum of the amortized complexities of all operations in the sequence be greater than or equal to the sum of the actual complexities.* That is

$$\sum_{1 \leq i \leq n} \text{amortized}(i) \geq \sum_{1 \leq i \leq n} \text{actual}(i) \quad (1.9)$$

where $\text{amortized}(i)$ and $\text{actual}(i)$, respectively, denote the amortized and actual complexities of the i th operation in a sequence of n operations. Because of this requirement on the sum of the amortized complexities of the operations in any sequence of operations, we may use the sum of the amortized complexities as an upper bound on the complexity of any sequence of operations.

You may view the amortized cost of an operation as being the amount you charge the operation rather than the amount the operation costs. You can charge an operation any amount you wish so long as the amount charged to all operations in the sequence is at least equal to the actual cost of the operation sequence.

Relative to the actual and amortized costs of each operation in a sequence of n operations, we define a *potential function* $P(i)$ as below

$$P(i) = \text{amortized}(i) - \text{actual}(i) + P(i - 1) \quad (1.10)$$

That is, the i th operation causes the potential function to change by the difference between the amortized and actual costs of that operation. If we sum Equation 1.10 for $1 \leq i \leq n$, we get

$$\sum_{1 \leq i \leq n} P(i) = \sum_{1 \leq i \leq n} (\text{amortized}(i) - \text{actual}(i) + P(i - 1))$$

or

$$\sum_{1 \leq i \leq n} (P(i) - P(i - 1)) = \sum_{1 \leq i \leq n} (\text{amortized}(i) - \text{actual}(i))$$

or

$$P(n) - P(0) = \sum_{1 \leq i \leq n} (\text{amortized}(i) - \text{actual}(i))$$

From Equation 1.9, it follows that

$$P(n) - P(0) \geq 0 \quad (1.11)$$

When $P(0) = 0$, the potential $P(i)$ is the amount by which the first i operations have been overcharged (i.e., they have been charged more than their actual cost).

Generally, when we analyze the complexity of a sequence of n operations, n can be any nonnegative integer. Therefore, Equation 1.11 must hold for all nonnegative integers.

The preceding discussion leads us to the following three methods to arrive at amortized costs for operations:

1. Aggregate Method

In the aggregate method, we determine an upper bound for the sum of the actual costs of the n operations. The amortized cost of each operation is set equal to this upper bound divided by n . You may verify that this assignment of amortized costs satisfies Equation 1.9 and is, therefore, valid.

2. Accounting Method

In this method, we assign amortized costs to the operations (probably by guessing what assignment will work), compute the $P(i)$ s using Equation 1.10, and show that $P(n) - P(0) \geq 0$.

3. Potential Method

Here, we start with a potential function (probably obtained using good guess work) that satisfies Equation 1.11 and compute the amortized complexities using Equation 1.10.

1.7.2 Maintenance Contract

1.7.2.1 Problem Definition

In January, you buy a new car from a dealer who offers you the following maintenance contract: \$50 each month other than March, June, September and December (this covers an oil change and general inspection), \$100 every March, June, and September (this covers an oil change, a minor tune-up, and a general inspection), and \$200 every December (this covers an oil change, a major tune-up, and a general inspection). We are to obtain an upper bound on the cost of this maintenance contract as a function of the number of months.

1.7.2.2 Worst-Case Method

We can bound the contract cost for the first n months by taking the product of n and the maximum cost incurred in any month (i.e., \$200). This would be analogous to the traditional way to estimate the complexity—take the product of the number of operations and the worst-case complexity of an operation. Using this approach, we get $$200n$ as an upper bound on the contract cost. The upper bound is correct because the actual cost for n months does not exceed $$200n$.

1.7.2.3 Aggregate Method

To use the aggregate method for amortized complexity, we first determine an upper bound on the sum of the costs for the first n months. As tight a bound as is possible is desired. The sum of the actual monthly costs of the contract for the first n months is

$$\begin{aligned} & 200 * \lfloor n/12 \rfloor + 100 * (\lfloor n/3 \rfloor - \lfloor n/12 \rfloor) + 50 * (n - \lfloor n/3 \rfloor) \\ &= 100 * \lfloor n/12 \rfloor + 50 * \lfloor n/3 \rfloor + 50 * n \\ &\leq 100 * n/12 + 50 * n/3 + 50 * n \\ &= 50n(1/6 + 1/3 + 1) \\ &= 50n(3/2) \\ &= 75n \end{aligned}$$

The amortized cost for each month is set to \$75. [Table 1.5](#) shows the actual costs, the amortized costs, and the potential function value (assuming $P(0) = 0$) for the first 16 months of the contract.

Notice that some months are charged more than their actual costs and others are charged less than their actual cost. The cumulative difference between what the operations are charged and their actual costs is given by the potential function. The potential function satisfies Equation 1.11 for all values of n . When we use the amortized cost of \$75 per month, we get $$75n$ as an upper bound on the contract cost for n months. This bound is tighter than the bound of $$200n$ obtained using the worst-case monthly cost.

1.7.2.4 Accounting Method

When we use the accounting method, we must first assign an amortized cost for each month and then show that this assignment satisfies Equation 1.11. We have the option to assign a different amortized cost to each month. In our maintenance contract example, we know the actual cost by month and could use this actual cost as the amortized cost. It is, however, easier to work with an equal cost assignment for each month. Later, we shall see examples of operation sequences that consist of two or more types of operations (e.g., when dealing with lists of elements, the operation sequence may be made up of search, insert, and remove operations). When dealing with such sequences we often assign a different amortized cost to operations of different types (however, operations of the same type have the same amortized cost).

TABLE 1.5 Maintenance Contract

Month	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
Actual cost	50	50	100	50	50	100	50	50	100	50	50	200	50	50	100	50
Amortized cost	75	75	75	75	75	75	75	75	75	75	75	75	75	75	75	75
$P()$	25	50	25	50	75	50	75	100	75	100	125	0	25	50	25	50

To get the best upper bound on the sum of the actual costs, we must set the amortized monthly cost to be the smallest number for which Equation 1.11 is satisfied for all n . From the above table, we see that using any cost less than \$75 will result in $P(n) - P(0) < 0$ for some values of n . Therefore, the smallest assignable amortized cost consistent with Equation 1.11 is \$75.

Generally, when the accounting method is used, we have not computed the aggregate cost. Therefore, we would not know that \$75 is the least assignable amortized cost. So we start by assigning an amortized cost (obtained by making an educated guess) to each of the different operation types and then proceed to show that this assignment of amortized costs satisfies Equation 1.11. Once we have shown this, we can obtain an upper bound on the cost of any operation sequence by computing

$$\sum_{1 \leq i \leq k} f(i) * \text{amortized}(i)$$

where k is the number of different operation types and $f(i)$ is the frequency of operation type i (i.e., the number of times operations of this type occur in the operation sequence).

For our maintenance contract example, we might try an amortized cost of \$70. When we use this amortized cost, we discover that Equation 1.11 is not satisfied for $n = 12$ (e.g.) and so \$70 is an invalid amortized cost assignment. We might next try \$80. By constructing a table such as the one above, we will observe that Equation 1.11 is satisfied for all months in the first 12 month cycle, and then conclude that the equation is satisfied for all n . Now, we can use $\$80n$ as an upper bound on the contract cost for n months.

1.7.2.5 Potential Method

We first define a potential function for the analysis. The only guideline you have in defining this function is that the potential function represents the cumulative difference between the amortized and actual costs. So, if you have an amortized cost in mind, you may be able to use this knowledge to develop a potential function that satisfies Equation 1.11, and then use the potential function and the actual operation costs (or an upper bound on these actual costs) to verify the amortized costs.

If we are extremely experienced, we might start with the potential function

$$t(n) = \begin{cases} 0 & n \bmod 12 = 0 \\ 25 & n \bmod 12 = 1 \text{ or } 3 \\ 50 & n \bmod 12 = 2, 4, \text{ or } 6 \\ 75 & n \bmod 12 = 5, 7, \text{ or } 9 \\ 100 & n \bmod 12 = 8 \text{ or } 10 \\ 125 & n \bmod 12 = 11 \end{cases}$$

Without the aid of the table (Table 1.5) constructed for the aggregate method, it would take quite some ingenuity to come up with this potential function. Having formulated a potential function and verified that this potential function satisfies Equation 1.11 for all n , we proceed to use Equation 1.10 to determine the amortized costs.

From Equation 1.10, we obtain $\text{amortized}(i) = \text{actual}(i) + P(i) - P(i - 1)$. Therefore,

$$\begin{aligned} \text{amortized}(1) &= \text{actual}(1) + P(1) - P(0) = 50 + 25 - 0 = 75 \\ \text{amortized}(2) &= \text{actual}(2) + P(2) - P(1) = 50 + 50 - 25 = 75 \\ \text{amortized}(3) &= \text{actual}(3) + P(3) - P(2) = 100 + 25 - 50 = 75 \end{aligned}$$

and so on. Therefore, the amortized cost for each month is \$75. So, the actual cost for n months is at most $\$75n$.

1.7.3 The McWidget Company

1.7.3.1 Problem Definition

The famous McWidget company manufactures widgets. At its headquarters, the company has a large display that shows how many widgets have been manufactured so far. Each time a widget is manufactured, a maintenance person updates this display. The cost for this update is $\$c + dm$, where c is a fixed trip charge, d is a charge per display digit that is to be changed, and m is the number of digits that are to be changed. For example, when the display is changed from 1399 to 1400, the cost to the company is $\$c + 3d$ because 3 digits must be changed. The McWidget company wishes to amortize the cost of maintaining the display over the widgets that are manufactured, charging the same amount to each widget. More precisely, we are looking for an amount $\$e = \text{amortized}(i)$ that should be levied against each widget so that the sum of these charges equals or exceeds the actual cost of maintaining/updating the display ($\$e * n \geq \text{actual total cost incurred for first } n \text{ widgets for all } n \geq 1$). To keep the overall selling price of a widget low, we wish to find as small an e as possible. Clearly, $e > c + d$ because each time a widget is made, at least one digit (the least significant one) has to be changed.

TABLE 1.6 Data for Widgets

Widget	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Actual cost	1	1	1	1	1	1	1	1	1	2	1	1	1	1
Amortized cost—	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12
P()	0.12	0.24	0.36	0.48	0.60	0.72	0.84	0.96	1.08	0.20	0.32	0.44	0.56	0.68
Widget	15	16	17	18	19	20	21	22	23	24	25	26	27	28
Actual cost	1	1	1	1	1	2	1	1	1	1	1	1	1	1
Amortized cost—	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12	1.12
P()	0.80	0.92	1.04	1.16	1.28	0.40	0.52	0.64	0.76	0.88	1.00	1.12	1.24	1.36

1.7.3.2 Worst-Case Method

This method does not work well in this application because there is no finite worst-case cost for a single display update. As more and more widgets are manufactured, the number of digits that need to be changed increases. For example, when the 1000th widget is made, 4 digits are to be changed incurring a cost of $c + 4d$, and when the 1,000,000th widget is made, 7 digits are to be changed incurring a cost of $c + 7d$. If we use the worst-case method, the amortized cost to each widget becomes infinity.

1.7.3.3 Aggregate Method

Let n be the number of widgets made so far. As noted earlier, the least significant digit of the display has been changed n times. The digit in the ten's place changes once for every ten widgets made, that in the hundred's place changes once for every hundred widgets made, that in the thousand's place changes once for every thousand widgets made, and so on. Therefore, the aggregate number of digits that have changed is bounded by

$$n(1 + 1/10 + 1/100 + 1/1000 + \dots) = (1.1111\dots)n$$

So, the amortized cost of updating the display is $\$c + d(1.1111\dots)n/n < c + 1.12d$. If the McWidget company adds $\$c + 1.12d$ to the selling price of each widget, it will collect enough money to pay for the cost of maintaining the display. Each widget is charged the cost of changing 1.12 digits regardless of the number of digits that are actually changed. Table 1.6 shows the actual cost, as measured by the number of digits that change, of maintaining the display, the amortized cost (i.e., 1.12 digits per widget), and the potential function. The potential function gives the difference between the sum of the amortized costs and the sum of the actual costs. Notice how the potential function builds up so that when it comes time to pay for changing two digits, the previous potential function value plus the current amortized cost exceeds 2. From our derivation of the amortized cost, it follows that the potential function is always nonnegative.

1.7.3.4 Accounting Method

We begin by assigning an amortized cost to the individual operations, and then we show that these assigned costs satisfy Equation 1.11. Having already done an amortized analysis using the aggregate method, we see that Equation 1.11 is satisfied when we assign an amortized cost of $\$c + 1.12d$ to each display change. Typically, however, the use of the accounting method is not preceded by an application of the aggregate method and we start by guessing an amortized cost and then showing that this guess satisfies Equation 1.11.

Suppose we assign a guessed amortized cost of $\$c + 2d$ for each display change.

$$\begin{aligned} P(n) - P(0) &= \sum_{1 \leq i \leq n} (\text{amortized}(i) - \text{actual}(i)) \\ &= (c + 2d)n - \sum_{1 \leq i \leq n} \text{actual}(i) \\ &= (c + 2d)n - (c + (1 + 1/10 + 1/100 + \dots)d)n \\ &\geq (c + 2d)n - (c + 1.12d)n \\ &\geq 0 \end{aligned}$$

This analysis also shows us that we can reduce the amortized cost of a widget to $\$c + 1.12d$.

An alternative proof method that is useful in some analyses involves distributing the excess charge $P(i) - P(0)$ over various accounting entities, and using these stored excess charges (called *credits*) to establish $P(i+1) - P(0) \geq 0$. For our McWidget example, we use the display digits as the accounting entities. Initially, each digit is 0 and each digit has a credit of 0 dollars.

```

public int [] nextSubset()
{// return next subset; return null if no next subset
    // generate next subset by adding 1 to the binary number x[1:n]
    int i = n;
    while (i > 0 && x[i] == 1)
        {x[i] = 0; i--;}
    if (i == 0) return null;
    else {x[i] = 1; return x;}
}

```

FIGURE 1.10 Subset enumerator.

Suppose we have guessed an amortized cost of $\$c + (1.111\dots)d$. When the first widget is manufactured, $\$c + d$ of the amortized cost is used to pay for the update of the display and the remaining $\$(0.111\dots)d$ of the amortized cost is retained as a credit by the least significant digit of the display. Similarly, when the second through ninth widgets are manufactured, $\$c + d$ of the amortized cost is used to pay for the update of the display and the remaining $\$(0.111\dots)d$ of the amortized cost is retained as a credit by the least significant digit of the display. Following the manufacture of the ninth widget, the least significant digit of the display has a credit of $\$(0.999\dots)d$ and the remaining digits have no credit. When the tenth widget is manufactured, $\$c + d$ of the amortized cost are used to pay for the trip charge and the cost of changing the least significant digit. The least significant digit now has a credit of $\$(1.111\dots)d$. Of this credit, $\$d$ are used to pay for the change of the next least significant digit (i.e., the digit in the ten's place), and the remaining $\$(0.111\dots)d$ are transferred to the ten's digit as a credit. Continuing in this way, we see that when the display shows 99, the credit on the ten's digit is $\$(0.999\dots)d$ and that on the one's digit (i.e., the least significant digit) is also $\$(0.999\dots)d$. When the 100th widget is manufactured, $\$c+d$ of the amortized cost are used to pay for the trip charge and the cost of changing the least significant digit, and the credit on the least significant digit becomes $\$(1.111\dots)d$. Of this credit, $\$d$ are used to pay for the change of the ten's digit from 9 to 0, the remaining $\$(0.111\dots)d$ credit on the one's digit is transferred to the ten's digit. The credit on the ten's digit now becomes $\$(1.111\dots)d$. Of this credit, $\$d$ are used to pay for the change of the hundred's digit from 0 to 1, the remaining $\$(0.111\dots)d$ credit on the ten's digit is transferred to the hundred's digit.

The above accounting scheme ensures that the credit on each digit of the display always equals $\$(0.111\dots)dv$, where v is the value of the digit (e.g., when the display is 206 the credit on the one's digit is $\$(0.666\dots)d$, the credit on the ten's digit is $\$0$, and that on the hundred's digit is $\$(0.222\dots)d$).

From the preceding discussion, it follows that $P(n) - P(0)$ equals the sum of the digit credits and this sum is always nonnegative. Therefore, Equation 1.11 holds for all n .

1.7.3.5 Potential Method

We first postulate a potential function that satisfies Equation 1.11, and then use this function to obtain the amortized costs. From the alternative proof used above for the accounting method, we can see that we should use the potential function $P(n) = (0.111\dots)d\sum_i v_i$, where v_i is the value of the i th digit of the display. For example, when the display shows 206 (at this time $n = 206$), the potential function value is $(0.888\dots)d$. This potential function satisfies Equation 1.11.

Let q be the number of 9's at the right end of j (i.e., when $j = 12903999$, $q = 3$). When the display changes from j to $j+1$, the potential change is $(0.111\dots)d(1 - 9q)$ and the actual cost of updating the display is $\$c + (q+1)d$. From Equation 1.10, it follows that the amortized cost for the display change is

$$\text{actual cost} + \text{potential change} = c + (q+1)d + (0.111\dots)d(1 - 9q) = c + (1.111\dots)d$$

1.7.4 Subset Generation

1.7.4.1 Problem Definition

The subsets of a set of n elements are defined by the 2^n vectors $x[1:n]$, where each $x[i]$ is either 0 or 1. $x[i] = 1$ iff the i th element of the set is a member of the subset. The subsets of a set of three elements are given by the eight vectors 000, 001, 010, 011, 100, 101, 110, and 111, for example. Starting with an array $x[1:n]$ has been initialized to zeroes (this represents the empty subset), each invocation of algorithm `nextSubset` (Figure 1.10) returns the next subset. When all subsets have been generated, this algorithm returns `null`.

We wish to determine how much time it takes to generate the first m , $1 \leq m \leq 2^n$ subsets. This is the time for the first m invocations of `nextSubset`.

1.7.4.2 Worst-Case Method

The complexity of `nextSubset` is $\Theta(c)$, where c is the number of $x[i]$ s that change. Since all n of the $x[i]$ s could change in a single invocation of `nextSubset`, the worst-case complexity of `nextSubset` is $\Theta(n)$. Using the worst-case method, the time required to generate the first m subsets is $O(mn)$.

1.7.4.3 Aggregate Method

The complexity of `nextSubset` equals the number of $x[i]$ s that change. When `nextSubset` is invoked m times, $x[n]$ changes m times; $x[n-1]$ changes $\lfloor m/2 \rfloor$ times; $x[n-2]$ changes $\lfloor m/4 \rfloor$ times; $x[n-3]$ changes $\lfloor m/8 \rfloor$ times; and so on. Therefore, the sum of the actual costs of the first m invocations is $\sum_{0 \leq i \leq \lfloor \log_2 m \rfloor} (m/2^i) < 2m$. So, the complexity of generating the first m subsets is actually $O(m)$, a tighter bound than obtained using the worst-case method.

The amortized complexity of `nextSubset` is $(\text{sum of actual costs})/m < 2m/m = O(1)$.

1.7.4.4 Accounting Method

We first guess the amortized complexity of `nextSubset`, and then show that this amortized complexity satisfies Equation 1.11. Suppose we guess that the amortized complexity is 2. To verify this guess, we must show that $P(m) - P(0) \geq 0$ for all m .

We shall use the alternative proof method used in the McWidget example. In this method, we distribute the excess charge $P(i) - P(0)$ over various accounting entities, and use these stored excess charges to establish $P(i+1) - P(0) \geq 0$. We use the $x[j]$ s as the accounting entities. Initially, each $x[j]$ is 0 and has a credit of 0. When the first subset is generated, 1 unit of the amortized cost is used to pay for the single $x[j]$ that changes and the remaining 1 unit of the amortized cost is retained as a credit by $x[n]$, which is the $x[j]$ that has changed to 1. When the second subset is generated, the credit on $x[n]$ is used to pay for changing $x[n]$ to 0 in the while loop, 1 unit of the amortized cost is used to pay for changing $x[n-1]$ to 1, and the remaining 1 unit of the amortized cost is retained as a credit by $x[n-1]$, which is the $x[j]$ that has changed to 1. When the third subset is generated, 1 unit of the amortized cost is used to pay for changing $x[n]$ to 1, and the remaining 1 unit of the amortized cost is retained as a credit by $x[n]$, which is the $x[j]$ that has changed to 1. When the fourth subset is generated, the credit on $x[n]$ is used to pay for changing $x[n]$ to 0 in the while loop, the credit on $x[n-1]$ is used to pay for changing $x[n-1]$ to 0 in the while loop, 1 unit of the amortized cost is used to pay for changing $x[n-2]$ to 1, and the remaining 1 unit of the amortized cost is retained as a credit by $x[n-2]$, which is the $x[j]$ that has changed to 1. Continuing in this way, we see that each $x[j]$ that is 1 has a credit of 1 unit on it. This credit is used to pay the actual cost of changing this $x[j]$ from 1 to 0 in the while loop. One unit of the amortized cost of `nextSubset` is used to pay for the actual cost of changing an $x[j]$ to 1 in the else clause, and the remaining one unit of the amortized cost is retained as a credit by this $x[j]$.

The above accounting scheme ensures that the credit on each $x[j]$ that is 1 is exactly 1, and the credit on each $x[j]$ that is 0 is 0.

From the preceding discussion, it follows that $P(m) - P(0)$ equals the number of $x[j]$ s that are 1. Since this number is always nonnegative, Equation 1.11 holds for all m .

Having established that the amortized complexity of `nextSubset` is $2 = O(1)$, we conclude that the complexity of generating the first m subsets equals $m * \text{amortized complexity} = O(m)$.

1.7.4.5 Potential Method

We first postulate a potential function that satisfies Equation 1.11, and then use this function to obtain the amortized costs. Let $P(j)$ be the potential just after the j th subset is generated. From the proof used above for the accounting method, we can see that we should define $P(j)$ to be equal to the number of $x[i]$ s in the j th subset that are equal to 1.

By definition, the 0th subset has all $x[i]$ equal to 0. Since $P(0) = 0$ and $P(j) \geq 0$ for all j , this potential function P satisfies Equation 1.11. Consider any subset $x[1:n]$. Let q be the number of 1s at the right end of $x[]$ (i.e., $x[n], x[n-1], \dots, x[n-q+1]$, are all 1s). Assume that there is a next subset. When the next subset is generated, the potential change is $1 - q$ because q 1s are replaced by 0 in the while loop and a 0 is replaced by a 1 in the else clause. The actual cost of generating the next subset is $q + 1$. From Equation 1.10, it follows that, when there is a next subset, the amortized cost for `nextSubset` is

$$\text{actual cost} + \text{potential change} = q + 1 + 1 - q = 2$$

When there is no next subset, the potential change is $-q$ and the actual cost of `nextSubset` is q . From Equation 1.10, it follows that, when there is no next subset, the amortized cost for `nextSubset` is

$$\text{actual cost} + \text{potential change} = q - q = 0$$

Therefore, we can use 2 as the amortized complexity of `nextSubset`. Consequently, the actual cost of generating the first m subsets is $O(m)$.

1.8 Practical Complexities

We have seen that the time complexity of a program is generally some function of the problem size. This function is very useful in determining how the time requirements vary as the problem size changes. For example, the run time of an algorithm whose complexity is $\Theta(n^2)$ is expected to increase by a factor of 4 when the problem size doubles and by a factor of 9 when the problem size triples.

The complexity function also may be used to compare two algorithms P and Q that perform the same task. Assume that algorithm P has complexity $\Theta(n)$ and that algorithm Q has complexity $\Theta(n^2)$. We can assert that algorithm P is faster than algorithm Q for “sufficiently large” n . To see the validity of this assertion, observe that the actual computing time of P is bounded from above by cn for some constant c and for all $n, n \geq n_1$, while that of Q is bounded from below by dn^2 for some constant d and all $n, n \geq n_2$. Since $cn \leq dn^2$ for $n \geq c/d$, algorithm P is faster than algorithm Q whenever $n \geq \max\{n_1, n_2, c/d\}$.

One should always be cautiously aware of the presence of the phrase *sufficiently large* in the assertion of the preceding discussion. When deciding which of the two algorithms to use, we must know whether the n we are dealing with is, in fact, sufficiently large. If algorithm P actually runs in 10^6n milliseconds while algorithm Q runs in n^2 milliseconds and if we always have $n \leq 10^6$, then algorithm Q is the one to use.

To get a feel for how the various functions grow with n , you should study Figures 1.11 and 1.12 very closely. These figures show that 2^n grows very rapidly with n . In fact, if a algorithm needs 2^n steps for execution, then when $n = 40$, the number of steps

$\log n$	n	$n \log n$	n^2	n^3	2^n
0	1	0	1	1	2
1	2	2	4	8	4
2	4	8	16	64	16
3	8	24	64	512	256
4	16	64	256	4096	65,536
5	32	160	1024	32,768	4,294,967,296

10^6	1 ms	19.92 ms	16.67 m	31.71 y	$3.17 * 10^7$ y	$3.17 * 10^{43}$ y	

μ s = microsecond = 10^{-6} seconds; ms = milliseconds = 10^{-3} seconds

s = seconds; m = minutes; h = hours; d = days; y = years

FIGURE 1.13 Run times on a 1,000,000,000 instructions per second computer.

needed is approximately $1.1 * 10^{12}$. On a computer performing 1,000,000,000 steps per second, this algorithm would require about 18.3 minutes. If $n = 50$, the same algorithm would run for about 13 days on this computer. When $n = 60$, about 310.56 years will be required to execute the algorithm, and when $n = 100$, about $4 * 10^{13}$ years will be needed. We can conclude that the utility of algorithms with exponential complexity is limited to small n (typically $n \leq 40$).

Algorithms that have a complexity that is a high-degree polynomial are also of limited utility. For example, if an algorithm needs n^{10} steps, then our 1,000,000,000 steps per second computer needs 10 seconds when $n = 10$; 3171 years when $n = 100$; and $3.17 * 10^{13}$ years when $n = 1000$. If the algorithm's complexity had been n^3 steps instead, then the computer would need 1 second when $n = 1000$, 110.67 minutes when $n = 10,000$, and 11.57 days when $n = 100,000$.

Figure 1.13 gives the time that a 1,000,000,000 instructions per second computer needs to execute an algorithm of complexity $f(n)$ instructions. One should note that currently only the fastest computers can execute about 1,000,000,000 instructions per second. From a practical standpoint, it is evident that for reasonably large n (say $n > 100$) only algorithms of small complexity (such as n , $n \log_2 n$, n^2 , and n^3) are feasible. Further, this is the case even if we could build a computer capable of executing 10^{12} instructions per second. In this case the computing times of Figure 1.13 would decrease by a factor of 1000. Now when $n = 100$, it would take 3.17 years to execute n^{10} instructions and $4 * 10^{10}$ years to execute 2^n instructions.

2.1 Introduction

In this chapter, we review several basic structures that are usually taught in a first class on data structures. There are several text books that cover this material, some of which are listed here [1–4]. However, we believe that it is valuable to review this material for the following reasons:

1. In practice, these structures are used more often than all of the other data structures discussed in this handbook combined.
2. These structures are used as basic building blocks on which other more complicated structures are based.

Our goal is to provide a crisp and brief review of these structures. For a more detailed explanation, the reader is referred to the text books listed at the end of this chapter. In the following, we assume that the reader is familiar with arrays and pointers.

2.2 Arrays

An array is conceptually defined as a collection of `<index,value>` pairs. The implementation of the array in modern programming languages such as C++ and Java uses indices starting at 0. Languages such as Pascal permitted one to define an array on an arbitrary range of integer indices. In most applications, the array is the most convenient method to store a collection of objects. In these cases, the index associated with a value is unimportant. For example, if an array `city` is being used to store a list of cities in no particular order, it doesn't really matter whether `city[0]` is "Denver" or "Mumbai". If, on the other hand, an array name is being used to store a list of student names in alphabetical order, then, although the absolute index values don't matter, the ordering of names associated with the ordering of the index does matter: that is, `name[i]` must precede `name[j]` in alphabetical order, if $i < j$. Thus, one may distinguish between sorted arrays and unsorted arrays. Sometimes arrays are used so that the index *does* matter. For example, suppose we are trying to represent a histogram: we want to maintain a count of the number of students that got a certain score on an exam from a scale of 0 to 10. If `score[5] = 7`, this means that 7 students received a score of 5. In this situation, it is possible that the desired indices are not supported by the language. For example, C++ does not directly support using indices such as "blue", "green", and "red". This may be rectified by using enumerated types to assign integer values to the indices. In cases when the objects in the array are large and unwieldy and have to be moved around from one array location to another, it may be advantageous to store *pointers* or *references* to objects in the array rather than the objects themselves.

Programming languages provide a mechanism to retrieve the value associated with a supplied index or to associate a value with an index. Programming languages like C++ do not explicitly maintain the size of the array. Rather, it is the programmer's responsibility to be aware of the array size. Further, C++ does not provide automatic range-checking. Again, it is the

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

programmer's responsibility to ensure that the index being supplied is valid. Arrays are usually allocated contiguous storage in the memory. An array may be allocated statically (i.e., during compile-time) or dynamically (i.e., during program execution). For example, in C++, a static array is defined as:

```
int list[20];
while a dynamic one is defined as:
```

```
int* list;
.
.
list = new int[25];
```

An important difference between static and dynamic arrays is that the size of a static array cannot be changed during run time, while that of a dynamic array can (as we will see in Section 2.2.3).

2.2.1 Operations on an Array

1. Retrieval of an element: Given an array index, retrieve the corresponding value. This can be accomplished in $O(1)$ time. This is an important advantage of the array relative to other structures. If the array is sorted, this enables one to compute the minimum, maximum, median (or in general, the i th smallest element) essentially for free in $O(1)$ time.
2. Search: Given an element value, determine whether it is present in the array. If the array is unsorted, there is no good alternative to a sequential search that iterates through all of the elements in the array and stops when the desired element is found:

```
int SequentialSearch(int* array, int n, int x)
// search for x in array[n]
{
    for (int i = 0; i < n; i++)
        if (array[i] == x) return i; // search succeeded
    return -1; // search failed
}
```

In the worst case, this requires $O(n)$ time. If, however, the array is sorted, binary search can be used.

```
int BinarySearch(int* array, int n, int x)
{
    int first = 0, mid, last = n-1;
    while (first < last) {
        mid = (first + last)/2;
        if (array[mid] == x) return mid; // search succeeded
        if (x < array[mid]) last = mid-1;
        else first = mid+1;
    }
    return -1; // search failed
}
```

Binary search only requires $O(\log n)$ time.

3. Insertion and Deletion: These operations can be the array's Achilles heel. First, consider a sorted array. It is usually assumed that the array that results from an insertion or deletion is to be sorted. The worst case scenario presents itself when an element that is smaller than all of the elements currently in the array is to be inserted. This element will be placed in the leftmost location. However, to make room for it, all of the existing elements in the array will have to be shifted one place to the right. This requires $O(n)$ time. Similarly, a deletion from the leftmost element leaves a "vacant" location. Actually, this location can never be vacant because it refers to a word in memory which must contain some value. Thus, if the program accesses a "vacant" location, it doesn't have any way to know that the location is vacant. It may be possible to establish some sort of code based on our knowledge of the values contained in the array. For example, if it is known that an array contains only positive integers, then one could use a zero to denote a vacant location. Because of these and other complications, it is best to eliminate vacant locations that are interspersed among occupied locations by shifting elements to the left so that all vacant locations are placed to the right. In this case, we know which locations are vacant by maintaining an integer variable which contains the number of locations starting at the left that are currently in use. As before, this shifting requires $O(n)$ time. In an unsorted array, the efficiency of insertion and deletion depends on where elements are to be added or removed.

If it is known for example that insertion and deletion will only be performed at the right end of the array, then these operations take $O(1)$ time as we will see later when we discuss stacks.

2.2.2 Sorted Arrays

We have already seen that there are several benefits to using sorted arrays, namely: searching is faster, computing order statistics (the i th smallest element) is $O(1)$, etc. This is the first illustration of a key concept in data structures that will be seen several times in this handbook: *the concept of preprocessing data to make subsequent queries efficient*. The idea is that we are often willing to invest some time at the beginning in setting up a data structure so that subsequent operations on it become faster. Some sorting algorithms such as heap sort and merge sort require $O(n \log n)$ time in the worst case, whereas other simpler sorting algorithms such as insertion sort, bubble sort and selection sort require $O(n^2)$ time in the worst case. Others such as quick sort have a worst case time of $O(n^2)$, but require $O(n \log n)$ on the average. Radix sort requires $\Theta(n)$ time for certain kinds of data. We refer the reader to [5] for a detailed discussion.

However, as we have seen earlier, insertion into and deletion from a sorted array can take $\Theta(n)$ time, which is large. It is possible to merge two sorted arrays into a single sorted array in time linear in the sum of their sizes. However, the usual implementation needs additional $\Theta(n)$ space. See [6] for an $O(1)$ -space merge algorithm.

2.2.3 Array Doubling

To increase the length of a (dynamically allocated) one-dimensional array a that contains elements in positions $a[0..n - 1]$, we first define an array of the new length (say m), then copy the n elements from a to the new array, and finally change the value of a so that it references the new array. It takes $\Theta(m)$ time to create an array of length m because all elements of the newly created array are initialized to a default value. It then takes an additional $\Theta(n)$ time to copy elements from the source array to the destination array. Thus, the total time required for this operation is $\Theta(m + n)$. This operation is used in practice to increase the array size when it becomes full. The new array is usually twice the length of the original; that is, $m = 2n$. The resulting complexity ($\Theta(n)$) would normally be considered to be expensive. However, when this cost is amortized over the subsequent n insertions, it in fact only adds $\Theta(1)$ time per insertion. Since the cost of an insertion is $\Omega(1)$, this does not result in an asymptotic increase in insertion time. In general, increasing array size by a constant factor every time its size is to be increased does not adversely affect the asymptotic complexity. A similar approach can be used to reduce the array size. Here, the array size would be reduced by a constant factor every time.

2.2.4 Multiple Lists in a Single Array

The array is wasteful of space when it is used to represent a list of objects that changes over time. In this scenario, we usually allocate a size greater than the number of objects that have to be stored, for example by using the array doubling idea discussed above. Consider a completely-filled array of length 8192 into which we are inserting an additional element. This insertion causes the array-doubling algorithm to create a new array of length 16,384 into which the 8192 elements are copied (and the new element inserted) before releasing the original array. This results in a space requirement during the operation which is almost three times the number of elements actually present. When several lists are to be stored, it is more efficient to store them all in a single array rather than allocating one array for each list.

Although this representation of multiple lists is more space-efficient, insertions can be more expensive because it may be necessary to move elements belonging to other lists in addition to elements in one's own list. This representation is also harder to implement (Figure 2.1).

2.2.5 Heterogeneous Arrays

The definition of an array in modern programming languages requires all of its elements to be of the same type. How do we then address the scenario where we wish to use the array to store elements of different types? In earlier languages like C, one could use the union facility to artificially coalesce the different types into one type. We could then define an array on this new type.

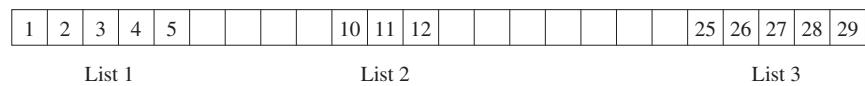

FIGURE 2.1 Multiple lists in a single array.

The kind of object that an array element actually contains is determined by a tag. The following defines a structure that contains one of three types of data.

```
struct Animal{
    int id;
    union {
        Cat c;
        Dog d;
        Fox f;
    }
}
```

The programmer would have to establish a convention on how the `id` tag is to be used: for example, that `id = 0` means that the animal represented by the struct is actually a cat, etc. The union allocates memory for the largest type among `Cat`, `Dog`, and `Fox`. This is wasteful of memory if there is a great disparity among the sizes of the objects. With the advent of object-oriented languages, it is now possible to define the base type `Animal`. `Cat`, `Dog`, and `Fox` may be implemented using inheritance as derived types of `Animal`. An array of pointers to `Animal` can now be defined. These pointers can be used to refer to any of `Cat`, `Dog`, and `Fox`.

2.2.6 Multidimensional Arrays

2.2.6.1 Row- or Column Major Representation

Earlier representations of multidimensional arrays mapped the location of each element of the multidimensional array into a location of a one-dimensional array. Consider a two-dimensional array with r rows and c columns. The number of elements in the array $n = rc$. The element in location $[i][j]$, $0 \leq i < r$ and $0 \leq j < c$, will be mapped onto an integer in the range $[0, n - 1]$. If this is done in row-major order—the elements of row 0 are listed in order from left to right followed by the elements of row 1, then row 2, etc.—the mapping function is $ic + j$. If elements are listed in column-major order, the mapping function is $jr + i$. Observe that we are required to perform a multiplication and an addition to compute the location of an element in an array.

2.2.6.2 Array of Arrays Representation

In Java, a two-dimensional array is represented as a one-dimensional array in which each element is, itself, a one-dimensional array. The array

```
int [][] x = new int[4][5];
```

is actually a one-dimensional array whose length is 4. Each element of x is a one-dimensional array whose length is 5. [Figure 2.2](#) shows an example. This representation can also be used in C++ by defining an array of pointers. Each pointer can then be used to point to a dynamically-created one-dimensional array. The element $x[i][j]$ is found by first retrieving the pointer $x[i]$. This gives the address in memory of $x[i][0]$. Then $x[i][j]$ refers to the element j in row i . Observe that this only requires the addition operator to locate an element in a one-dimensional array.

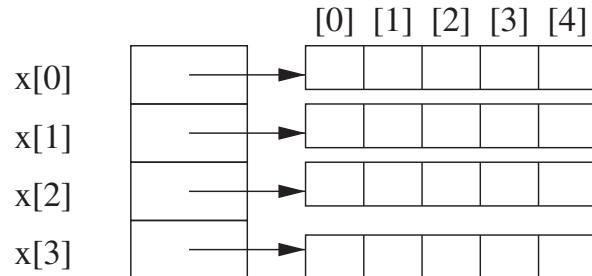

FIGURE 2.2 The array of arrays representation.

2.2.6.3 Irregular Arrays

A two-dimensional array is regular in that every row has the same number of elements. When two or more rows of an array have different number of elements, we call the array irregular. Irregular arrays may also be created and used using the array of arrays representation.

2.2.7 Sparse Matrices

A matrix is sparse if a large number of its elements are 0. Rather than store such a matrix as a two-dimensional array with lots of zeroes, a common strategy is to save space by explicitly storing only the non-zero elements. This topic is of interest to the scientific computing community because of the large sizes of some of the sparse matrices it has to deal with. The specific approach used to store matrices depends on the nature of sparsity of the matrix. Some matrices, such as the tridiagonal matrix have a well-defined sparsity pattern. The tridiagonal matrix is one where all of the nonzero elements lie on one of three diagonals: the main diagonal and the diagonals above and below it. See Figure 2.3a.

There are several ways to represent this matrix as a one-dimensional array. We could order elements by rows giving [2,1,1,3,4,1,1,2,4,7,4,3,5] or by diagonals giving [1,1,4,3,2,3,1,7,5,1,4,2,4]. Figure 2.3 shows other special matrices: the upper and lower triangular matrices which can also be represented using a one-dimensional representation.

Other sparse matrices may have an irregular or unstructured pattern. Consider the matrix in Figure 2.4a. We show two representations. Figure 2.4b shows a one-dimensional array of triples, where each triple represents a nonzero element and consists of the row, column, and value. Figure 2.4c shows an irregular array representation. Each row is represented by a one-dimensional array of pairs, where each pair contains the column number and the corresponding nonzero value.

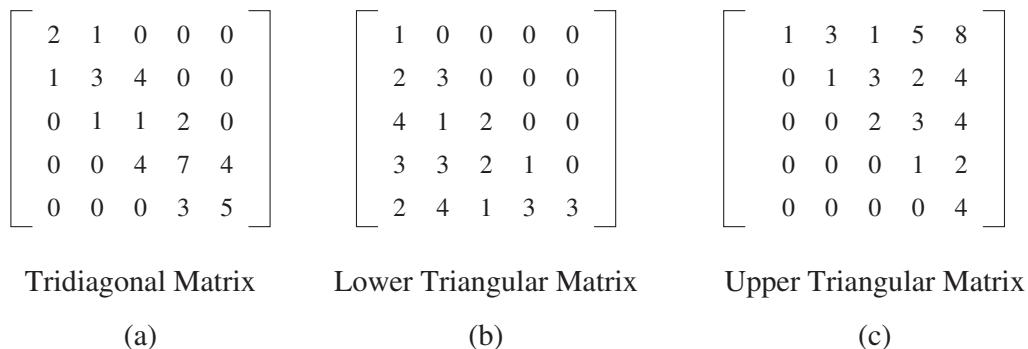

FIGURE 2.3 Matrices with regular structures. (a) Tridiagonal Matrix, (b) Lower Triangular Matrix, (c) Upper Triangular Matrix.

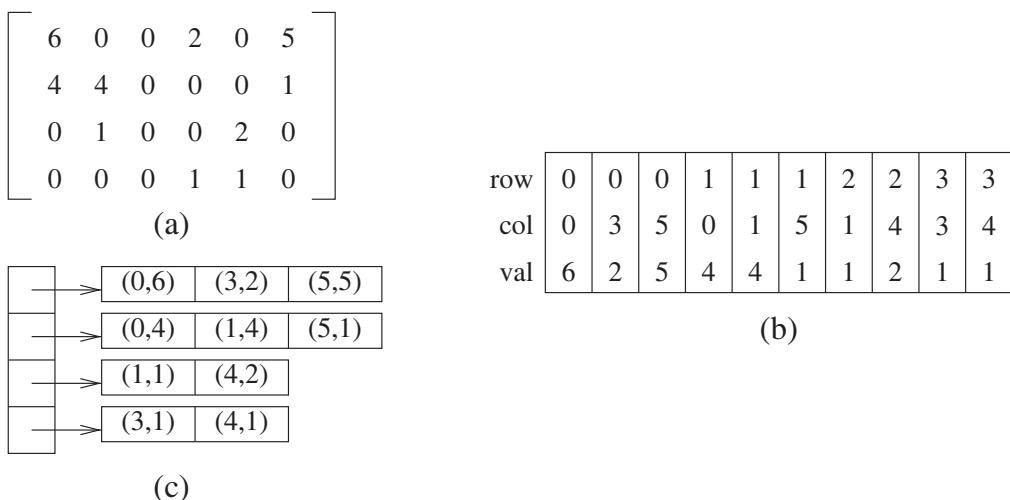

FIGURE 2.4 Unstructured matrices.

2.3 Linked Lists

The linked list is an alternative to the array when a collection of objects is to be stored. The linked list is implemented using pointers. Thus, an element (or node) of a linked list contains the actual data to be stored and a pointer to the next node. Recall that a pointer is simply the address in memory of the next node. Thus, a key difference from arrays is that a linked list does not have to be stored contiguously in memory.

The code fragment below defines a linked list data structure, which is also illustrated in [Figure 2.5](#):

```
class ListNode {
friend class List;
private:
    int data;
    ListNode *link;
}

class List {
public:
    // List manipulation operations go here
    ...
private:
    ListNode *first;
}
```

A chain is a linked list where each node contains a pointer to the next node in the list. The last node in the list contains a null (or zero) pointer. A circular list is identical to a chain *except* that the last node contains a pointer to the first node. A doubly linked circular list differs from the chain and the circular list in that each node contains *two* pointers. One points to the next node (as before), while the other points to the *previous* node.

2.3.1 Chains

The following code searches for a key k in a chain and returns true if the key is found and false, otherwise.

```
bool List::Search(int k) {
    for (ListNode *current = first; current; current = current->next)
        if (current->data == k) return true;
    return false;
}
```

In the worst case, Search takes $\Theta(n)$ time. In order to insert a node `newnode` in a chain immediately after node `current`, we simply set `newnode`'s pointer to the node following `current` (if any) and `current`'s pointer to `newnode` as shown in the [Figure 2.6](#).

To delete a node `current`, it is *necessary* to have a pointer to the node preceding `current`. This node's pointer is then set to `current->next` and node `current` is freed. Both insertion and deletion can be accomplished in $O(1)$ time *provided* that the required pointers are initially available. Whether this is true or not depends on the context in which these operations are called. For example, if you are required to delete the node with key 50, if it exists, from a linked list, you would first have to search for 50. Your search algorithm would maintain a trailing pointer so that when 50 is found, a pointer to the previous node is available. Even though, deletion takes $\Theta(1)$ time, deletion in this context would require $\Theta(n)$ time in the worst case because of the search. In some cases, the context depends on how the list is organized. For example, if the list is to be sorted, then node insertions should be made so as to maintain the sorted property (which could take $\Theta(n)$ time). On the other hand, if the list is unsorted, then a node insertion can take place anywhere in the list. In particular, the node could be inserted at the front of the list in $\Theta(1)$ time.

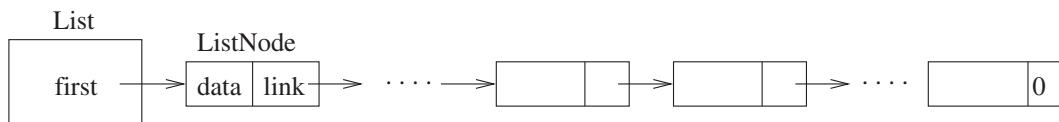

FIGURE 2.5 The structure of a linked list.

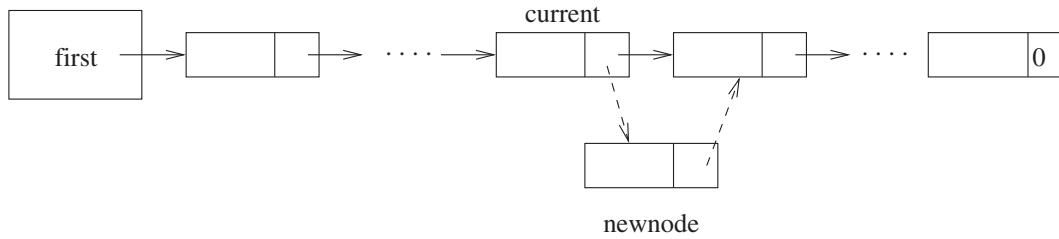

FIGURE 2.6 Insertion into a chain. The dashed links show the pointers after *newnode* has been inserted.

Interestingly, the author has often seen student code in which the insertion algorithm traverses the entire linked list and inserts the new element at the end of the list!

As with arrays, chains can be sorted or unsorted. Unfortunately, however, many of the benefits of a sorted array do not extend to sorted linked lists because arbitrary elements of a linked list cannot be accessed quickly. In particular, it is not possible to carry out binary search in $O(\log n)$ time. Nor is it possible to locate the i th smallest element in $O(1)$ time. On the other hand, merging two sorted lists into one sorted list is more convenient than merging two sorted arrays into one sorted array because the traditional implementation requires space to be allocated for the target array. A code fragment illustrating the merging of two sorted lists is shown below. This is a key operation in mergesort:

```
void Merge(List listOne, List listTwo, List& merged) {
    ListNode* one = listOne.first;
    ListNode* two = listTwo.first;
    ListNode* last = 0;

    if (one == 0) {merged.first = two; return;}
    if (two == 0) {merged.first = one; return;}

    if (one->data < two->data) last = merged.first = one;
    else last = merged.first = two;
    while (one && two)
        if (one->data < two->data) {
            last->next = one; last= one; one = one->next;
        }
        else {
            last->next = two; last = two; two = two->next;
        }
    if (one) last->next = one;
    else last->next = two;
}
```

The merge operation is not defined when lists are unsorted. However, one may need to combine two lists into one. This is the concatenation operation. With chains, the best approach is to attach the second list to the end of the first one. In our implementation of the linked list, this would require one to traverse the first list until the last node is encountered and then set its *next* pointer to point to the first element of the second list. This requires time proportional to the size of the first linked list. This can be improved by maintaining a pointer to the last node in the linked list.

It is possible to traverse a singly linked list in both directions (i.e., left to right and a restricted right-to-left traversal) by reversing links during the left-to-right traversal. Figure 2.7 shows a possible configuration for a list under this scheme.

As with the heterogeneous arrays described earlier, heterogeneous lists can be implemented in object-oriented languages by using inheritance.

2.3.2 Circular Lists

In the previous section, we saw that to concatenate two unsorted chains efficiently, one needs to maintain a rear pointer in addition to the first pointer. With circular lists, it is possible to accomplish this with a single pointer as follows: consider the circular list in Figure 2.8. The second node in the list can be accessed through the first in $O(1)$ time. Now, consider the list that begins at this second node and ends at the first node. This may be viewed as a chain with access pointers to the first and last nodes.

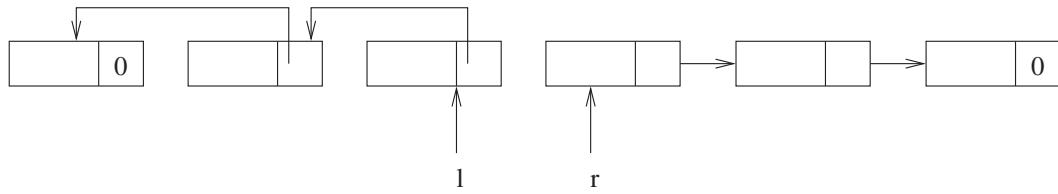

FIGURE 2.7 Illustration of a chain traversed in both directions.

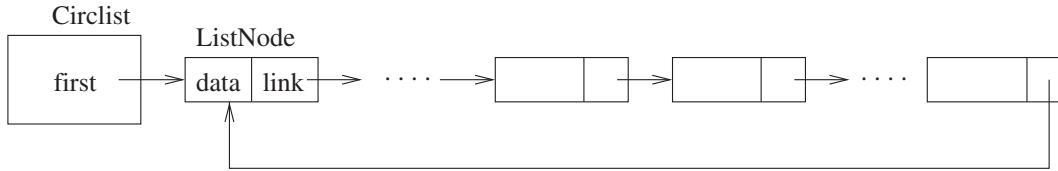

FIGURE 2.8 A circular list.

Concatenation can now be achieved in $O(1)$ time by linking the last node of one chain to the first node of the second chain and vice versa.

2.3.3 Doubly Linked Circular Lists

A node in a doubly linked list differs from that in a chain or a singly linked list in that it has two pointers. One points to the next node as before, while the other points to the previous node. This makes it possible to traverse the list in both directions. We observe that this is possible in a chain as we saw in [Figure 2.7](#). The difference is that with a doubly linked list, one can initiate the traversal from any arbitrary node in the list. Consider the following problem: we are provided a pointer x to a node in a list and are required to delete it as shown in [Figure 2.9](#). To accomplish this, one needs to have a pointer to the previous node. In a chain or a circular list, an expensive list traversal is required to gain access to this previous node. However, this can be done in $O(1)$ time in a doubly linked circular list. The code fragment that accomplishes this is as below:

```
void DblList::Delete(DblListNode* x)
{
    x->prev->next = x->next;
    x->next->prev = x->prev;
    delete x;
}
```

An application of doubly linked lists is to store a list of siblings in a Fibonacci heap ([Chapter 7](#)).

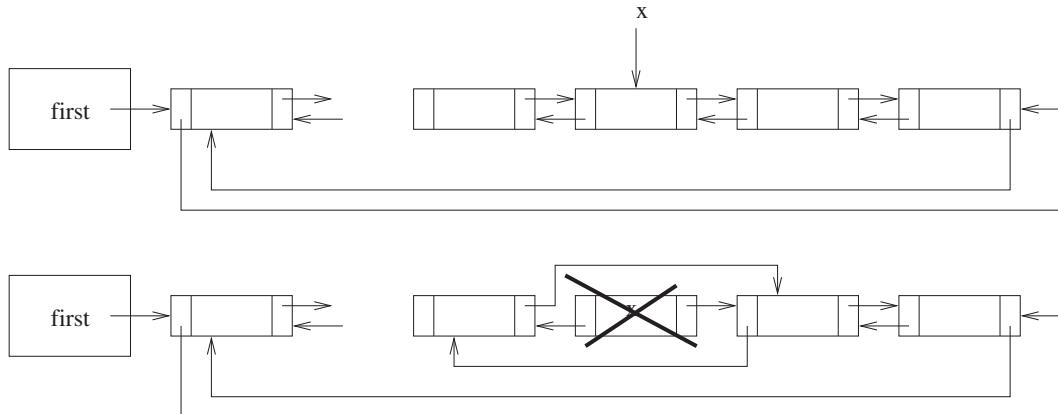

FIGURE 2.9 Deletion from a doubly linked list.

2.3.4 Generalized Lists

A generalized list A is a finite sequence of $n \geq 0$ elements, e_0, e_1, \dots, e_{n-1} , where e_i is either an atom or a generalized list. The elements e_i that are not atoms are said to be sublists of A . Consider the generalized list $A = ((a, b, c), ((d, e), f), g)$. This list contains three elements: the sublist (a, b, c) , the sublist $((d, e), f)$ and the atom g . The generalized list may be implemented by employing a GenListNode type as follows:

```
private:
    GenListNode* next;
    bool tag;
    union {
        char data;
        GenListNode* down;
    };
};
```

If `tag` is `true`, the element represented by the node is a sublist and `down` points to the first node in the sublist. If `tag` is false, the element is an atom whose value is contained in `data`. In both cases, `next` simply points to the next element in the list. [Figure 2.10](#) illustrates the representation.

2.4 Stacks and Queues

The stack and the queue are data types that support insertion and deletion operations with well-defined semantics. Stack deletion deletes the element in the stack that was inserted the last, while a queue deletion deletes the element in the queue that was inserted the earliest. For this reason, the stack is often referred to as a LIFO (Last In First Out) data type and the queue as an FIFO (First In First out) data type. A deque (double ended queue) combines the stack and the queue by supporting both types of deletions.

Stacks and queues find a lot of applications in Computer Science. For example, a system stack is used to manage function calls in a program. When a function f is called, the system creates an activation record and places it on top of the system stack. If function f calls function g , the local variables of f are added to its activation record and an activation record is created for g . When g terminates, its activation record is removed and f continues executing with the local variables that were stored in its activation record. A queue is used to schedule jobs at a resource when a first-in first-out policy is to be implemented. Examples could include a queue of print-jobs that are waiting to be printed or a queue of packets waiting to be transmitted over a wire. Stacks and queues are also used routinely to implement higher-level algorithms. For example, a queue is used to implement a breadth-first traversal of a graph. A stack may be used by a compiler to process an expression such as $(a + b) \times (c + d)$.

2.4.1 Stack Implementation

Stacks and queues can be implemented using either arrays or linked lists. Although the burden of a correct stack or queue implementation appears to rest on deletion rather than insertion, it is convenient in actual implementations of these data types to place restrictions on the insertion operation as well. For example, in an array implementation of a stack, elements are inserted in a left-to-right order. A stack deletion simply deletes the rightmost element.

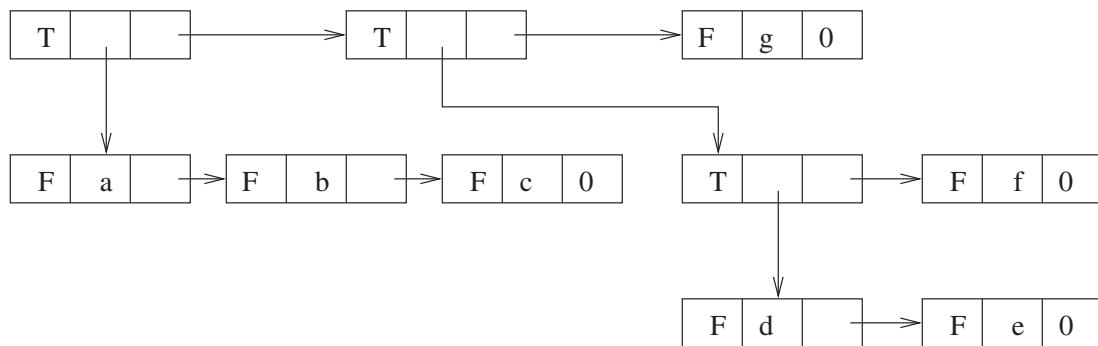

FIGURE 2.10 Generalized list for $((a,b,c), ((d,e),f),g)$.

A simple array implementation of a stack class is shown below:

```
class Stack {
public:
    Stack(int maxSize = 100); // 100 is default size
    void Insert(int);
    int* Delete(int&);

private:
    int *stack;
    int size;
    int top; // highest position in array that contains an element
};
```

The stack operations are implemented as follows:

```
Stack::Stack(int maxSize): size(maxSize)
{
    stack = new int[size];
    top = -1;
}

void Stack::Insert(int x)
{
    if (top == size-1) cerr << "Stack Full" << endl;
    else stack[++top] = x;
}

int* Stack::Delete(int& x)
{
    if (top == -1) return 0; // stack empty
    else {
        x = stack[top--];
        return &x;
    }
}
```

The operation of the following code fragment is illustrated in [Figure 2.11](#).

```
Stack s;
int x;
s.Insert(10);
s.Insert(20);
s.Insert(30);
s.Delete(x);
s.Insert(40);
s.Delete(x);
```

It is easy to see that both stack operations take $O(1)$ time. The stack data type can also be implemented using linked lists by requiring all insertions and deletions to be made at the front of the linked list.

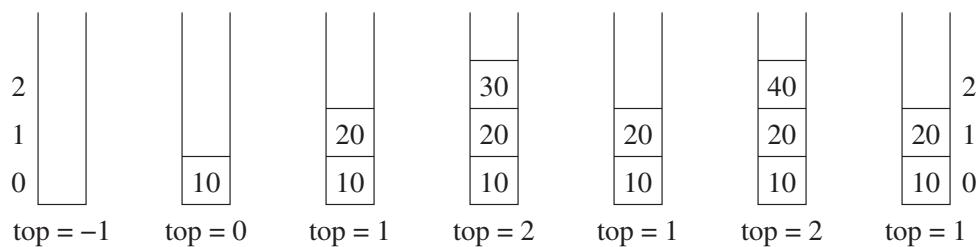

FIGURE 2.11 Stack operations.

2.4.2 Queue Implementation

An array implementation of a queue is a bit trickier than that of a stack. Insertions can be made in a left-to-right fashion as with a stack. However, deletions must now be made from the left. Consider a simple example of an array of size 5 into which the integers 10, 20, 30, 40, and 50 are inserted as shown in [Figure 2.12a](#). Suppose three elements are subsequently deleted ([Figure 2.12b](#)).

What if we are now required to insert the integer 60. On one hand, it appears that we are out of room as there is no more place to the right of 50. On the other hand, there are three locations available to the left of 40. This suggests that we use a circular array implementation of a queue, which is described below.

```
class Queue {
public:
    Queue(int maxSize = 100); // 100 is default size
    void Insert(int);
    int* Delete(int&);

private:
    int *queue;
    int size;
    int front, rear;
};
```

The queue operations are implemented below:

```
Queue::Queue(int maxSize): size(maxSize)
{
    queue= new int[size];
    front = rear = 0;
}

void Queue::Insert(int x)
{
    int k = (rear + 1);
    if (front == k) cerr << "Queue Full!" <, endl;
    else queue[rear] = x;
}

int* Queue::Delete(int& x)
{
    if (front == rear) return 0; // queue is empty
    x = queue[++front];
    return &x;
}
```

[Figure 2.13](#) illustrates the operation of this code on an example. The first figure shows an empty queue with $\text{first} = \text{rear} = 0$. The second figure shows the queue after the integer 10 is inserted. The third figure shows the queue when 20, 30, 40, 50, and 60 have been inserted. The fourth figure shows the queue after 70 is inserted. Notice that, although one slot remains empty, the queue is now full because `Queue::Insert` will not permit another element to be inserted. If it did permit an insertion at this stage, `front` and `rear` would be the same. This is the condition that `Queue::Delete` checks to determine whether the queue is empty! This would make it impossible to distinguish between the queue being full and being empty. The fifth figure shows the queue after two integers (10 and 20) are deleted. The last figure shows a full queue after the insertion of integers 80 and 90.

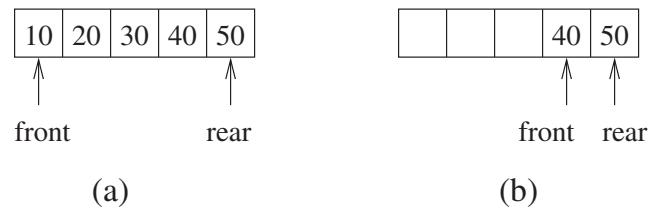

FIGURE 2.12 Pitfalls of a simple array implementation of a queue.

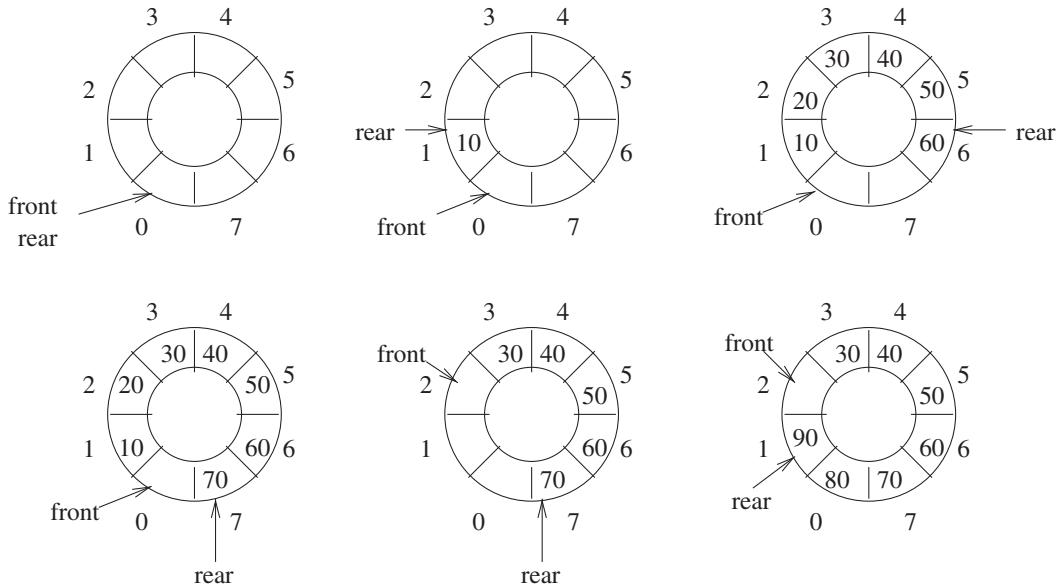

FIGURE 2.13 Implementation of a queue in a circular array.

It is easy to see that both queue operations take $O(1)$ time. The queue data type can also be implemented using linked lists by requiring all insertions and deletions to be made at the front of the linked list.

3.1 Introduction

The tree is a natural representation for *hierarchical* information. Thus, trees are used to represent genealogical information (e.g., family trees and evolutionary trees), organizational charts in large companies, the directory structure of a file system on a computer, parse trees in compilers and the structure of a knock-out sports tournament. The Dewey decimal notation, which is used to classify books in a library, is also a tree structure. In addition to these and other applications, the tree is used to design fast algorithms in computer science because of its *efficiency* relative to the simpler data structures discussed in [Chapter 2](#). Operations that take linear time on these structures often take logarithmic time on an appropriately organized tree structure. For example, the average time complexity for a search on a key is linear on a linked list and *logarithmic* on a binary search tree. Many of the data structures discussed in succeeding chapters of this handbook are tree structures.

Several kinds of trees have been defined in the literature:

1. *Free or unrooted tree*: this is defined as a graph (a set of vertices and a set of edges that join pairs of vertices) such that there exists a unique path between any two vertices in the graph. The minimum spanning tree of a graph is a well-known example of a free tree. Graphs are discussed in [Chapter 4](#).
2. *Rooted tree*: a finite set of one or more nodes such that
 - a. There is a special node called the *root*.
 - b. The remaining nodes are partitioned into $n \geq 0$ disjoint sets T_1, \dots, T_n , where each of these sets is a tree. T_1, \dots, T_n are called the subtrees of the root.If the order in which the subtrees are arranged is not important, then the tree is a rooted, unordered (or *oriented*) tree. If the order of the subtrees is important, the tree is rooted and ordered. [Figure 3.1](#) depicts the relationship between the three types of trees. We will henceforth refer to the rooted, ordered tree simply as “tree.”
3. *k-ary tree*: a finite set of nodes that is either empty or consists of a root and the elements of k disjoint k -ary trees called the 1st, 2nd, \dots , k th subtrees of the root. The *binary tree* is a k -ary tree with $k = 2$. Here, the first and second subtrees are respectively called the left and right subtrees of the root. Note that binary trees are not trees. One difference is that a binary

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

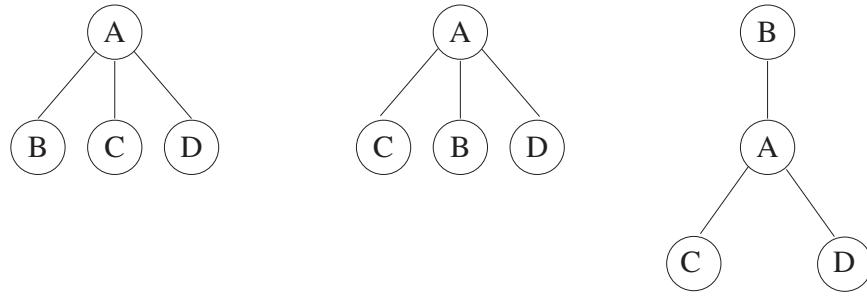

FIGURE 3.1 The three trees shown are distinct if they are viewed as rooted, ordered trees. The first two are identical if viewed as oriented trees. All three are identical if viewed as free trees.

FIGURE 3.2 Different binary trees.

tree can be empty, whereas a tree cannot. Second, the two trees shown in Figure 3.2 are different binary trees but would be different drawings of the same tree.

Figure 3.3 shows a tree with 11 nodes. The number of subtrees of a node is its *degree*. Nodes with degree 0 are called *leaf* nodes. Thus, node *A* has degree 3, nodes *B*, *D*, and *I* have degree 2, node *E* has degree 1, and nodes *C*, *F*, *G*, *H*, *J*, and *K* have degree 0 (and are leaves of the tree). The degree of a tree is the maximum of the degree of the nodes in the tree. The roots of the subtrees of a node *X* are its *children*. *X* is the parent of its children. Children of the same parent are *siblings*. In the example, *B*, *C*, and *D* are each other's siblings and are all children of *A*. The *ancestors* of a node are all the nodes excluding itself along the path from the root to that node. The *level* of a node is defined by letting the root be at level zero. If a node is at level *l*, then its children are at level *l* + 1. The *height* of a tree is the maximum level of any node in the tree. The tree in the example has height 4. These terms are defined in the same way for binary trees. See [1–6] for more information on trees.

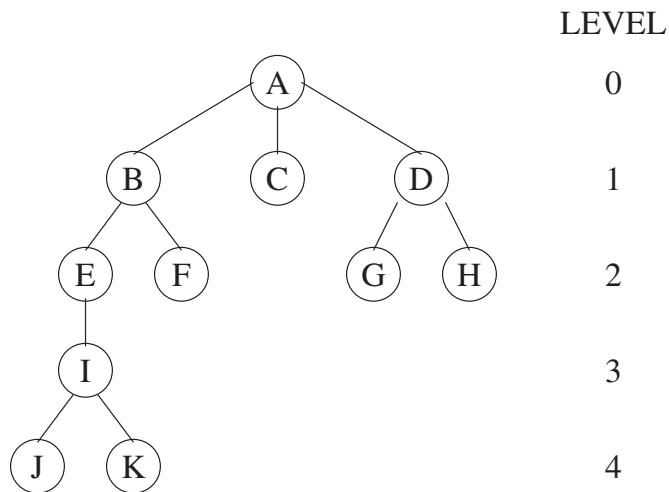

FIGURE 3.3 An example tree.

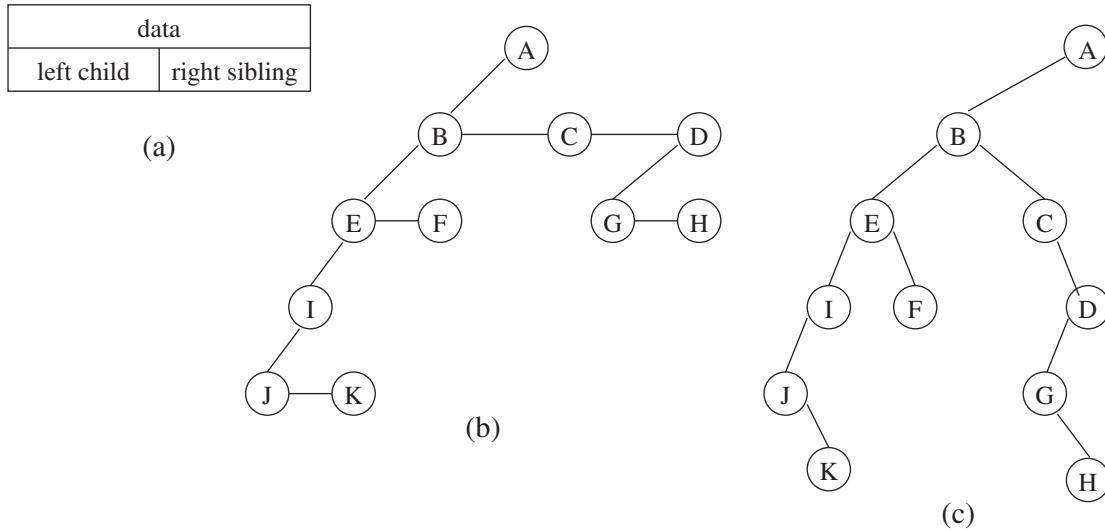

FIGURE 3.4 Tree representations.

3.2 Tree Representation

3.2.1 List Representation

The tree of Figure 3.3 can be written as the generalized list $(A \ (B \ (E \ (I \ (J, K)), F), C, D(G, H)))$. The information in the root node comes first followed by a list of subtrees of the root. This enables us to represent a tree in memory using generalized lists as discussed in Chapter 2.

3.2.2 Left Child-Right Sibling Representation

Figure 3.4a shows the node structure used in this representation. Each node has a pointer to its leftmost child (if any) and to the sibling on its immediate right (if any). The tree in Figure 3.3 is represented by the tree in Figure 3.4b.

3.2.3 Binary Tree Representation

Observe that the left child-right sibling representation of a tree (Figure 3.4b) may be viewed as a binary tree by rotating it clockwise by 45 degrees. This gives the binary tree representation shown in Figure 3.4c. This representation can be extended to represent a *forest*, which is defined as an ordered set of trees. Here, the roots of the trees are viewed as siblings. Thus, a root's right pointer points to the next tree root in the set. We have

Lemma 3.1

There is a one-to-one correspondence between the set of forests and the set of binary trees.

3.3 Binary Trees and Properties

Binary trees were defined in Section 3.1. For convenience, a binary tree is sometimes extended by adding *external* nodes. External nodes are imaginary nodes that are added wherever an empty subtree was present in the original tree. The original tree nodes are known as *internal* nodes. Figure 3.5a shows a binary tree and (b) the corresponding extended tree. Observe that in an extended binary tree, all internal nodes have degree 2 while all external nodes have degree 0. (Some authors use the term *full* binary tree to denote a binary tree whose nodes have 0 or two children.) The *external path length* of a tree is the sum of the lengths of all root-to-external node paths in the tree. In the example, this is $2 + 2 + 3 + 3 + 2 = 12$. The *internal path length* is similarly defined by adding lengths of all root-to-internal node paths. In the example, this quantity is $0 + 1 + 1 + 2 = 4$.

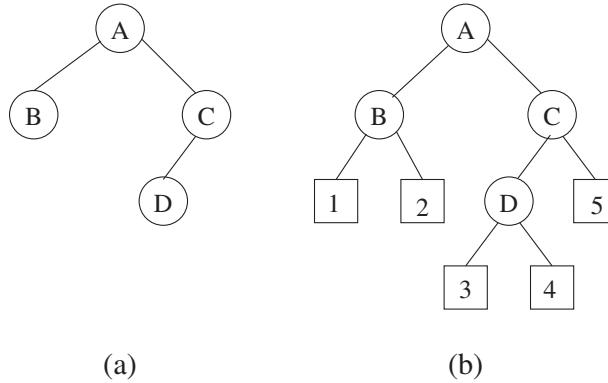

FIGURE 3.5 (b) shows the extended binary tree corresponding to the binary tree of (a). External nodes are depicted by squares.

3.3.1 Properties

Lemma 3.2

A binary tree with n internal nodes has $n + 1$ external nodes.

Proof. Each internal node in the extended tree has branches leading to two children. Thus, the total number of branches is $2n$. Only $n - 1$ internal nodes have a single incoming branch from a parent (the root does not have a parent). Thus, each of the remaining $n + 1$ branches points to an external node. ■

Lemma 3.3

For any non-empty binary tree with n_0 leaf nodes and n_2 nodes of degree 2, $n_0 = n_2 + 1$.

Proof. Let n_1 be the number of nodes of degree 1 and $n = n_0 + n_1 + n_2$ (Equation 1) be the total number of nodes. The number of branches in a binary tree is $n - 1$ since each non-root node has a branch leading into it. But, all branches stem from nodes of degree 1 and 2. Thus, the number of branches is $n_1 + 2n_2$. Equating the two expressions for number of branches, we get $n = n_1 + 2n_2 + 1$ (Equation 2). From Equations 1 and 2, we get $n_0 = n_2 + 1$. ■

Lemma 3.4

The external path length of any binary tree with n internal nodes is $2n$ greater than its internal path length.

Proof. The proof is by induction. The lemma clearly holds for $n = 0$ when the internal and external path lengths are both zero. Consider an extended binary tree T with n internal nodes. Let E_T and I_T denote the external and internal path lengths of T . Consider the extended binary tree S that is obtained by deleting an internal node whose children are both external nodes (i.e., a leaf) and replacing it with an external node. Let the deleted internal node be at level l . Thus, the internal path length decreases by l while the external path length decreases by $2(l+1) - l = l + 2$. From the induction hypothesis, $E_S = I_S + 2(n-1)$. But, $E_T = E_S + l + 2$ and $I_T = I_S + l$. Thus, $E_T - I_T = 2n$. ■

Lemma 3.5

The maximum number of nodes on level i of a binary tree is 2^i , $i \geq 0$.

Proof. This is easily proved by induction on i .

Lemma 3.6

The maximum number of nodes in a binary tree of height k is $2^{k+1} - 1$.

Proof. Each level i , $0 \leq i \leq k$, has 2^i nodes. Summing over all i results in $\sum_{i=0}^k 2^i = 2^{k+1} - 1$.

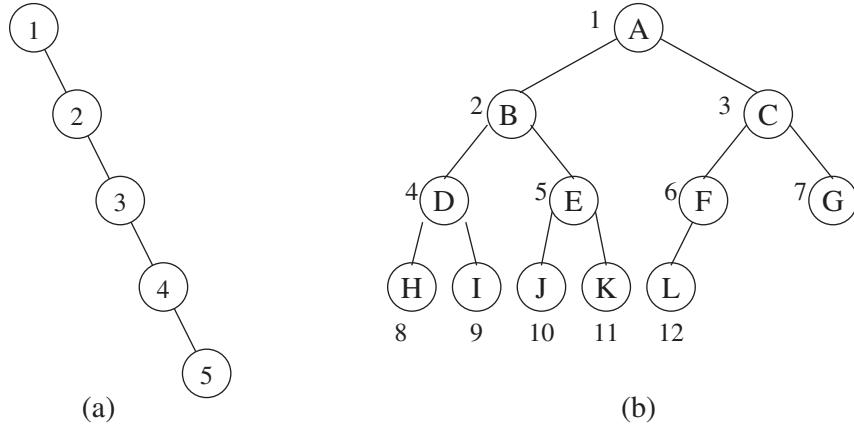

FIGURE 3.6 (a) Skewed and (b) complete binary trees.

Lemma 3.7

The height of a binary tree with n internal nodes is at least $\lceil \log_2(n+1) \rceil$ and at most $n-1$.

Proof. The worst case is a skewed tree (Figure 3.6a) and the best case is a tree with 2^i nodes at every level i except possibly the bottom level (Figure 3.6b). If the height is h , then $n+1 \leq 2^h$, where $n+1$ is the number of external nodes. ■

Lemma 3.8

The number of distinct binary trees with n nodes is $\frac{1}{n+1} \binom{2n}{n}$.

Proof. For a detailed proof, we refer the reader to [7]. However, we note that $C_n = \frac{1}{n+1} \binom{2n}{n}$ are known as the Catalan numbers, which occur frequently in combinatorial problems. The Catalan number C_n also describes the number of trees with $n+1$ nodes and the number of binary trees with $2n+1$ nodes all of which have 0 or 2 children. ■

3.3.2 Binary Tree Representation

Binary trees are usually represented using nodes and pointers. A `TreeNode` class may be defined as:

```
class TreeNode {
    TreeNode* LeftChild;
    TreeNode* RightChild;
    KeyType data;
};
```

In some cases, a node might also contain a `parent` pointer which facilitates a “bottom-up” traversal of the tree. The tree is accessed by a pointer `root` of type `TreeNode*` to its root. When the binary tree is *complete* (i.e., there are 2^i nodes at every level i , except possibly the last level which has nodes filled in from left to right), it is convenient to use an array representation. The complete binary tree in Figure 3.6b can be represented by the array

```
1 2 3 4 5 6 7 8 9 10 11 12
[ A B C D E F G H I J K L ]
```

Observe that the children (if any) of a node located at position i of the array can be found at positions $2i$ and $2i+1$ and its parent at $\lfloor i/2 \rfloor$.

3.4 Binary Tree Traversals

Several operations on trees require one to traverse the entire tree: that is, given a pointer to the root of a tree, process every node in the tree systematically. Printing a tree is an example of an operation that requires a tree traversal. Starting at a node, we can

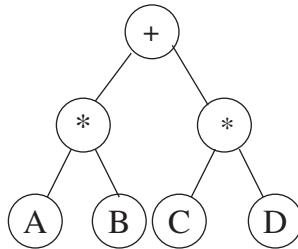

FIGURE 3.7 An expression tree.

do one of three things: visit the node (V), traverse the left subtree recursively (L), and traverse the right subtree recursively (R). If we adopt the convention that the left subtree will be visited before the right subtree, we have three types of traversals $LV R$, $V LR$, and LRV which are called *inorder*, *preorder*, and *postorder*, respectively, because of the position of V with respect to L and R . In the following, we will use the expression tree in Figure 3.7 to illustrate the three traversals, which result in infix, prefix, and postfix forms of the expression. A fourth traversal, the level order traversal, is also studied.

3.4.1 Inorder Traversal

The following is a recursive algorithm for an inorder traversal that prints the contents of each node when it is visited. The recursive function is invoked by the call `inorder(root)`. When run on the example expression tree, it returns `A*B+C*D`.

```

inorder(TreeNode* currentNode)
{
    if (currentNode) {
        inorder(currentNode->LeftChild);
        cout << currentNode->data;
        inorder(currentNode->RightChild);
    }
}
  
```

3.4.2 Preorder Traversal

The following is a recursive algorithm for a preorder traversal that prints the contents of each node when it is visited. The recursive function is invoked by the call `preorder(root)`. When run on the example expression tree, it returns `+*AB*CD`.

```

preorder(TreeNode* currentNode)
{
    if (currentNode) {
        cout << currentNode->data;
        preorder(currentNode->LeftChild);
        preorder(currentNode->RightChild);
    }
}
  
```

3.4.3 Postorder Traversal

The following is a recursive algorithm for a postorder traversal that prints the contents of each node when it is visited. The recursive function is invoked by the call `postorder(root)`. When run on the example expression tree, it prints `AB*CD*+`.

```

postorder(TreeNode* currentNode)
{
    if (currentNode) {
        postorder(currentNode->LeftChild);
        postorder(currentNode->RightChild);
        cout << currentNode->data;
    }
}
  
```

The complexity of each of the three algorithms is linear in the number of tree nodes. Non-recursive versions of these algorithms may be found in Reference 6. Both versions require (implicitly or explicitly) a stack.

3.4.4 Level Order Traversal

The level order traversal uses a queue. This traversal visits the nodes in the order suggested in Figure 3.6b. It starts at the root and then visits all nodes in increasing order of their level. Within a level, the nodes are visited in left-to-right order.

```
LevelOrder(TreeNode* root)
{
    Queue q<TreeNode*>;
    TreeNode* currentNode = root;
    while (currentNode) {
        cout << currentNode->data;
        if (currentNode->LeftChild) q.Add(currentNode->LeftChild);
        if (currentNode->RightChild) q.Add(currentNode->RightChild);
        currentNode = q.Delete(); //q.Delete returns a node pointer
    }
}
```

3.5 Threaded Binary Trees

3.5.1 Threads

Lemma 3.2 implies that a binary tree with n nodes has $n + 1$ null links. These null links can be replaced by pointers to nodes called threads. Threads are constructed using the following rules:

1. A null right child pointer in a node is replaced by a pointer to the inorder successor of p (i.e., the node that would be visited after p when traversing the tree inorder).
2. A null left child pointer in a node is replaced by a pointer to the inorder predecessor of p .

Figure 3.8 shows the binary tree of Figure 3.7 with threads drawn as broken lines. In order to distinguish between threads and normal pointers, two boolean fields `LeftThread` and `RightThread` are added to the node structure. If $p\rightarrow\text{LeftThread}$ is 1, then $p\rightarrow\text{LeftChild}$ contains a thread; otherwise it contains a pointer to the left child. Additionally, we assume that the tree contains a head node such that the original tree is the left subtree of the head node. The `LeftChild` pointer of node A and the `RightChild` pointer of node D point to the head node.

3.5.2 Inorder Traversal of a Threaded Binary Tree

Threads make it possible to perform an inorder traversal without using a stack. For any node p , if p 's right thread is 1, then its inorder successor is $p\rightarrow\text{RightChild}$. Otherwise the inorder successor is obtained by following a path of left-child links from the right child of p until a node with left thread 1 is reached. Function `Next` below returns the inorder successor of `currentNode` (assuming that `currentNode` is not 0). It can be called repeatedly to traverse the entire tree in inorder in $O(n)$ time. The code below assumes that the last node in the inorder traversal has a threaded right pointer to a dummy head node.

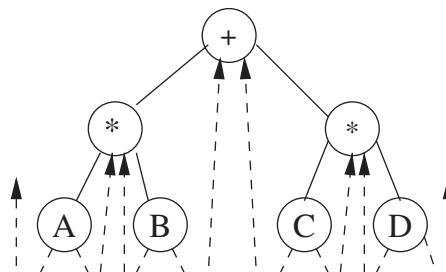

FIGURE 3.8 A threaded binary tree.

```

TreeNode* Next(TreeNode* currentNode)
{
    TreeNode* temp = currentNode->RightChild;
    if (currentNode->RightThread == 0)
        while (temp->LeftThread == 0)
            temp = temp->LeftChild;
    currentNode = temp;
    if (currentNode == headNode)
        return 0;
    else
        return currentNode;
}

```

Threads simplify the algorithms for preorder and postorder traversal. It is also possible to insert a node into a threaded tree in $O(1)$ time [6].

3.6 Binary Search Trees

3.6.1 Definition

A *binary search tree* (BST) is a binary tree that has a key associated with each of its nodes. The keys in the left subtree of a node are smaller than or equal to the key in the node and the keys in the right subtree of a node are greater than or equal to the key in the node. To simplify the discussion, we will assume that the keys in the binary search tree are distinct. Figure 3.9 shows some binary trees to illustrate the definition.

3.6.2 Search

We describe a recursive algorithm to search for a key k in a tree T : first, if T is empty, the search fails. Second, if k is equal to the key in T 's root, the search is successful. Otherwise, we search T 's left or right subtree recursively for k depending on whether it is less or greater than the key in the root.

```

bool Search(TreeNode* b, KeyType k)
{
    if (b == 0) return 0;
    if (k == b->data) return 1;
    if (k < b->data) return Search(b->LeftChild,k);
    if (k > b->data) return Search(b->RightChild,k);
}

```

3.6.3 Insert

To insert a key k , we first carry out a search for k . If the search fails, we insert a new node with k at the null branch where the search terminated. Thus, inserting the key 17 into the binary search tree in Figure 3.9b creates a new node which is the left child of 18. The resulting tree is shown in Figure 3.10a.

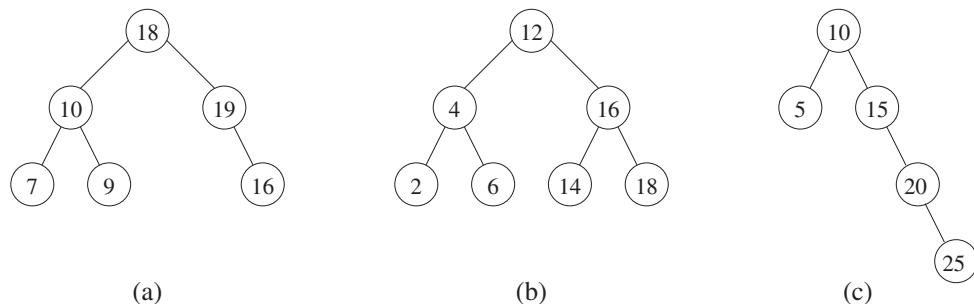

FIGURE 3.9 Binary trees with distinct keys: (a) is not a BST. (b) and (c) are BSTs.

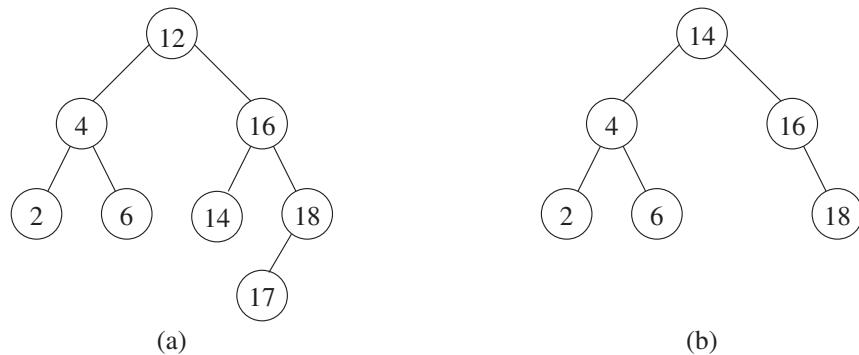

FIGURE 3.10 Tree of Figure 3.9b with (a) 18 inserted and (b) 12 deleted.

```

typedef TreeNode* TreeNodePtr;

Node* Insert(TreeNodePtr& b, KeyType k)
{
    if (b == 0) {b = new TreeNode; b->data= k; return b;}
    if (k == b->data) return 0; // don't permit duplicates
    if (k < b->data) Insert(b->LeftChild, k);
    if (k > b->data) Insert(b->RightChild, k);
}

```

3.6.4 Delete

The procedure for deleting a node x from a binary search tree depends on its degree. If x is a leaf, we simply set the appropriate child pointer of x 's parent to 0 and delete x . If x has one child, we set the appropriate pointer of x 's parent to point directly to x 's child and then delete x . In Figure 3.9c, node 20 is deleted by setting the right child of 15 to 25. If x has two children, we replace its key with the key in its inorder successor y and then delete node y . The inorder successor contains the smallest key greater than x 's key. This key is chosen because it can be placed in node x without violating the binary search tree property. Since y is obtained by first following a `RightChild` pointer and then following `LeftChild` pointers until a node with a null `LeftChild` pointer is encountered, it follows that y has degree 0 or 1. Thus, it is easy to delete y using the procedure described above. Consider the deletion of 12 from Figure 3.9b. This is achieved by replacing 12 with 14 in the root and then deleting the leaf node containing 14. The resulting tree is shown in Figure 3.10b.

3.6.5 Miscellaneous

Although Search, Insert, and Delete are the three main operations on a binary search tree, there are others that can be defined which we briefly describe below.

- *Minimum and Maximum* that respectively find the minimum and maximum elements in the binary search tree. The minimum element is found by starting at the root and following `LeftChild` pointers until a node with a `0 LeftChild` pointer is encountered. That node contains the minimum element in the tree.
 - Another operation is to find the k th smallest element in the binary search tree. For this, each node must contain a field with the number of nodes in its left subtree. Suppose that the root has m nodes in its left subtree. If $k \leq m$, we recursively search for the k th smallest element in the left subtree. If $k = m + 1$, then the root contains the k th smallest element. If $k > m + 1$, then we recursively search the right subtree for the $k - m - 1$ st smallest element.
 - The *Join* operation takes two binary search trees A and B as input such that all the elements in A are smaller than all the elements of B . The objective is to obtain a binary search tree C which contains all the elements originally in A and B . This is accomplished by deleting the node with the largest key in A . This node becomes the root of the new tree C . Its `LeftChild` pointer is set to A and its `RightChild` pointer is set to B .
 - The *Split* operation takes a binary search tree C and a key value k as input. The binary search tree is to be split into two binary search trees A and B such that all keys in A are less than or equal to k and all keys in B are greater than k . This is achieved by searching for k in the binary search tree. The trees A and B are created as the search proceeds down the tree as shown in [Figure 3.11](#).

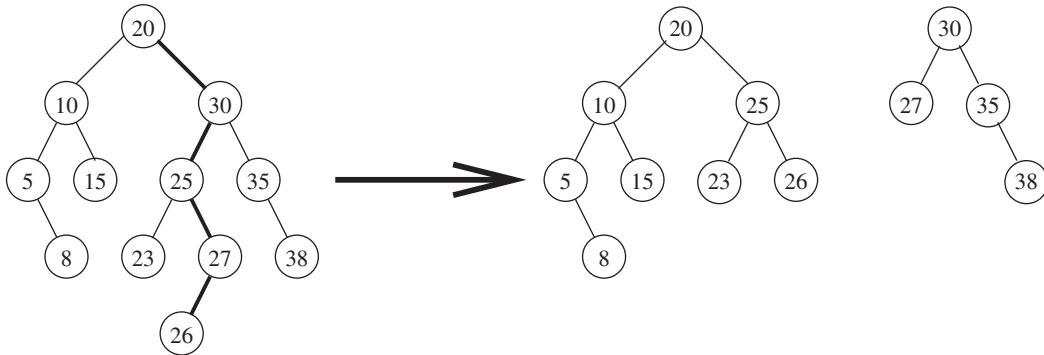

FIGURE 3.11 Splitting a binary search tree with $k = 26$.

- An inorder traversal of a binary search tree produces the elements of the binary search tree in sorted order. Similarly, the inorder successor of a node with key k in the binary search tree yields the smallest key larger than k in the tree. (Note that we used this property in the Delete operation described in the previous section.)

All of the operations described above take $O(h)$ time, where h is the height of the binary search tree. The bounds on the height of a binary tree are derived in Lemma 3.7. It has been shown that when insertions and deletions are made at random, the height of the binary search tree is $O(\log n)$ on the average.

3.7 Heaps

3.7.1 Priority Queues

Heaps are used to implement priority queues. In a priority queue, the element with highest (or lowest) priority is deleted from the queue, while elements with arbitrary priority are inserted. A data structure that supports these operations is called a max(min) priority queue. Henceforth, in this chapter, we restrict our discussion to a max priority queue. A priority queue can be implemented by a simple, unordered linked list. Insertions can be performed in $O(1)$ time. However, a deletion requires a search for the element with the largest priority followed by its removal. The search requires time linear in the length of the linked list. When a max heap is used, both of these operations can be performed in $O(\log n)$ time.

3.7.2 Definition of a Max-Heap

A max heap is a complete binary tree such that for each node, the key value in the node is greater than or equal to the value in its children. Observe that this implies that the root contains the largest value in the tree. Figure 3.12 shows some examples of max heaps.

We define a class Heap with the following data members.

```
private:
    Element *heap;
    int n; // current size of max heap
    int MaxSize; // Maximum allowable size of the heap
```

The heap is represented using an array (a consequence of the complete binary tree property) which is dynamically allocated.

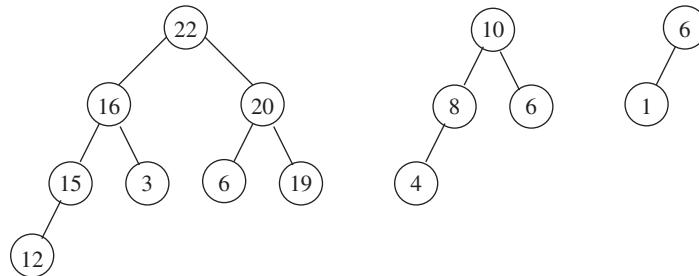

FIGURE 3.12 Max heaps.

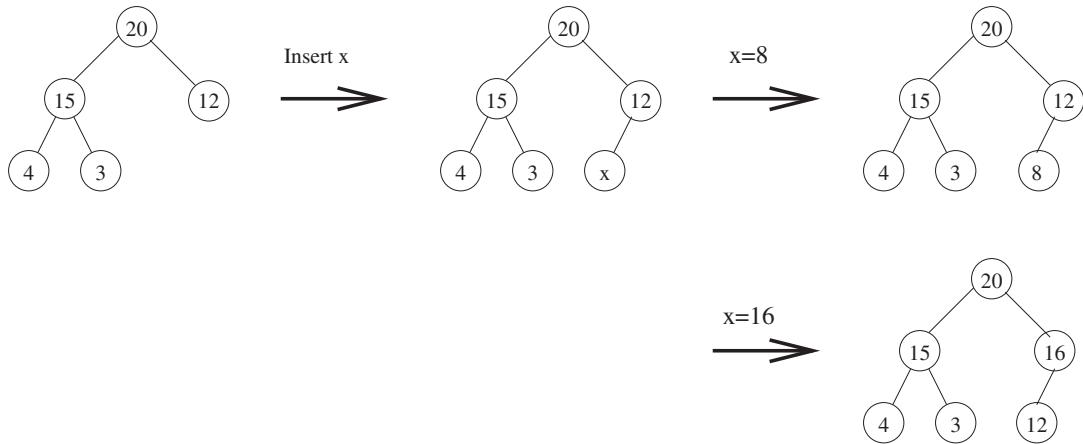

FIGURE 3.13 Insertion into max heaps.

3.7.3 Insertion

Suppose that the max heap initially has n elements. After insertion, it will have $n + 1$ elements. Thus, we need to add a node so that the resulting tree is a complete binary tree with $n + 1$ nodes. The key to be inserted is initially placed in this new node. However, the key may be larger than its parent resulting in a violation of the *max* property with its parent. In this case, we swap keys between the two nodes and then repeat the process at the next level. Figure 3.13 demonstrates two cases of an insertion into a max heap.

The algorithm is described below. In the worst case, the insertion algorithm moves up the heap from leaf to root spending $O(1)$ time at each level. For a heap with n elements, this takes $O(\log n)$ time.

```
void MaxHeap::Insert(Element x)
{
    if (n == MaxSize) {HeapFull(); return;}
    n++;
    for (int i = n; i > 1; i = i/2) {
        if (x.key <= heap[i/2].key) break;
        heap[i] = heap[i/2];
    }
    heap[i] = x;
}
```

3.7.4 Deletion

The element to be deleted (i.e., the maximum element in the heap) is removed from the root node. Since the binary tree must be restructured to become a complete binary tree on $n - 1$ elements, the node in position n is deleted. The element in the deleted node is placed in the root. If this element is less than either of the root's (at most) two children, there is a violation of the max property. This is fixed by swapping the value in the root with its larger child. The process is repeated at the other levels until there is no violation. Figure 3.14 illustrates deletion from a max heap.

The deletion algorithm is described below. In the worst case, the deletion algorithm moves down the heap from root to leaf spending $O(1)$ time at each level. For a heap with n elements, this takes $O(\log n)$ time.

```
Element* MaxHeap::DeleteMax(Element& x)
{
    if (n == 0) {HeapEmpty(); return 0;}
    x = heap[1];
    Element last = heap[n];
    n--;
    for (int i = 1, j = 2; j <= n; i = j, j *= 2) {
        if (j < n)
            if (heap[j].key < heap[j+1].key) j++;
        // j points to the larger child
    }
}
```

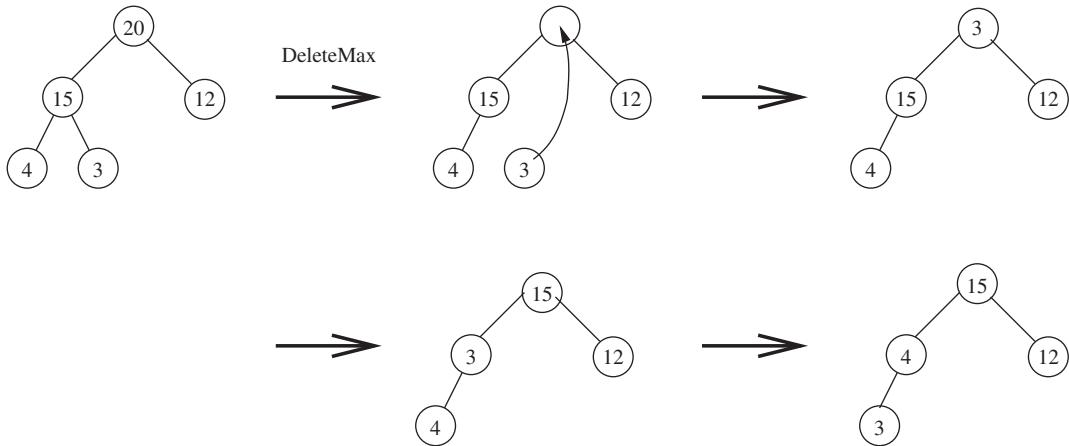

FIGURE 3.14 Deletion from max heaps.

```

    if (last.key >= heap[j].key) break;
    heap[i] = heap[j]; // move child up
}
heap[i] = last;
return &x;
}

```

3.8 Tournament Trees

Consider the following problem: suppose we have k sequences, each of which is sorted in nondecreasing order, that are to be merged into one sequence in nondecreasing order. This can be achieved by repeatedly transferring the element with the smallest key to an output array. The smallest key has to be found from the leading elements in the k sequences. Ordinarily, this would require $k - 1$ comparisons for each element transferred. However, with a tournament tree, this can be reduced to $\log_2 k$ comparisons per element.

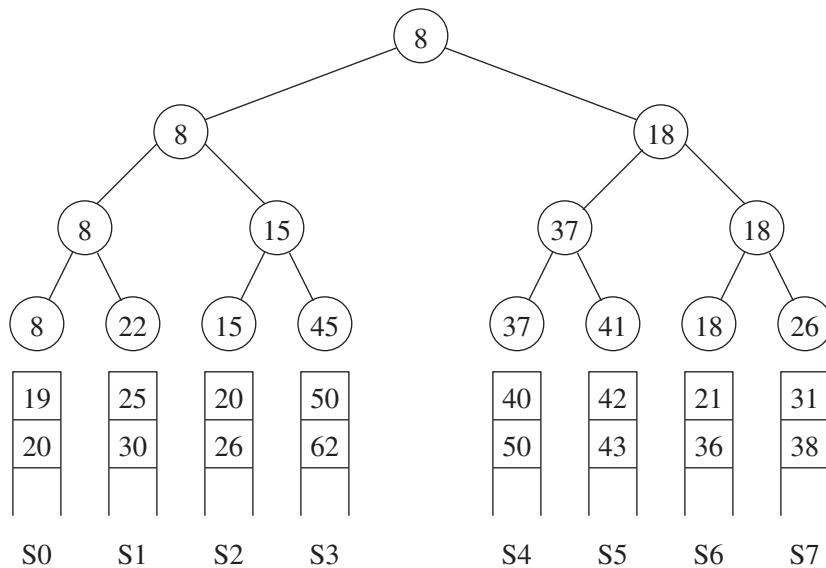

FIGURE 3.15 A winner tree for $k = 8$. Three keys in each of the eight sequences are shown. For example, sequence 2 consists of 15, 20, and 26.

3.8.1 Winner Trees

A winner tree is a complete binary tree in which each node represents the smaller of its two children. The root represents the smallest node in the tree. Figure 3.15 illustrates a winner tree with $k = 8$ sequences. The winner of the tournament is the value 8 from sequence 0. The winner of the tournament is the smallest key from the 8 sequences and is transferred to an output array. The next element from sequence 0 is now brought into play and a tournament is played to determine the next winner. This is illustrated in Figure 3.16. It is easy to see that the tournament winner can be computed in $\Theta(\log n)$ time.

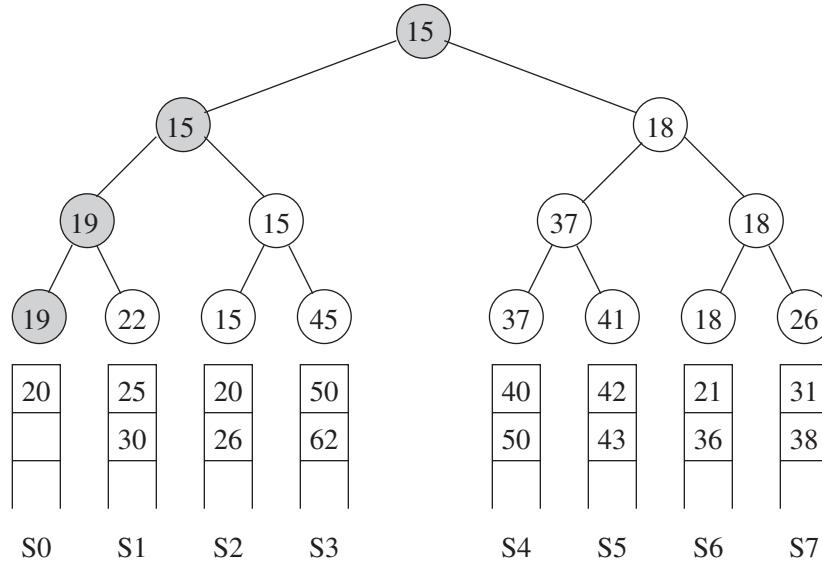

FIGURE 3.16 Winner tree of Figure 3.15 after the next element of sequence 0 plays the tournament. Matches are played at the shaded nodes.

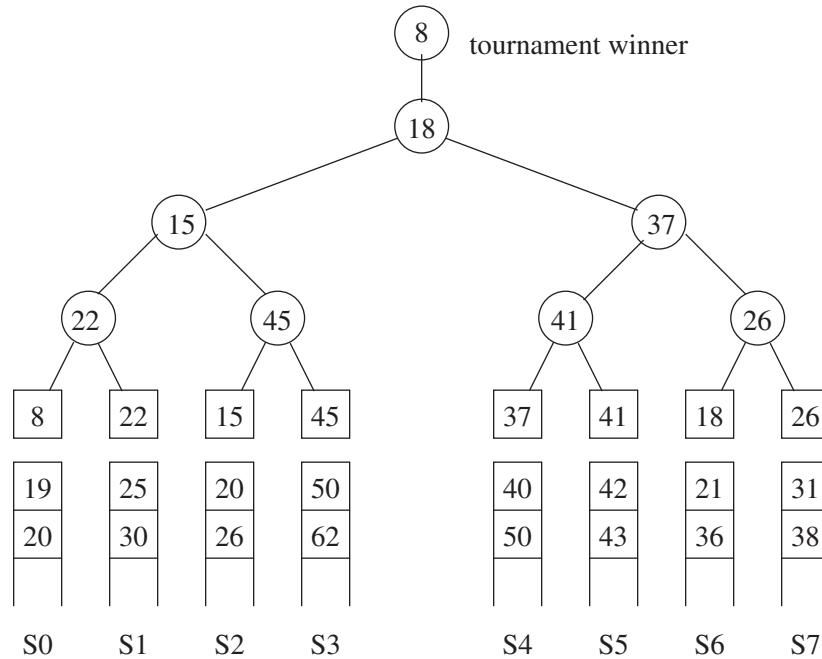

FIGURE 3.17 Loser tree corresponding to the winner tree of Figure 3.15.

3.8.2 Loser Trees

The loser tree is an alternative representation that stores the *loser* of a match at the corresponding node. The loser tree corresponding to [Figure 3.15](#) is shown in [Figure 3.17](#). An advantage of the loser tree is that to restructure the tree after a winner has been output, it is sufficient to examine nodes on the path from the leaf to the root rather than the siblings of nodes on this path.

4.1 Introduction

Trees, as data structures, are somewhat limited because they can only represent relations of a hierarchical nature, such as that of parent and child. A generalization of a tree so that a binary relation is allowed between any pair of elements would constitute a graph—formally defined as follows:

A *graph* $G = (V, E)$ consists of a finite set of *vertices* $V = \{v_1, v_2, \dots, v_n\}$ and a finite set E of *edges* $E = \{e_1, e_2, \dots, e_m\}$ (see [Figure 4.1](#)). To each edge e there corresponds a pair of vertices (u, v) which e is said to be *incident* on. While drawing a graph we represent each vertex by a dot and each edge by a line segment joining its two *end vertices*. A graph is said to be a *directed graph* (or *digraph* for short) (see [Figure 4.2](#)) if the vertex pair (u, v) associated with each edge e (also called *arc*) is an ordered pair. Edge e is then said to be *directed from* vertex u to vertex v , and the direction is shown by an arrowhead on the edge. A graph is *undirected* if the end vertices of all the edges are unordered (i.e., edges have no direction). Throughout this chapter we use the letters n and m to denote the number of vertices $|V|$ and number of edges $|E|$ respectively, in a graph. A vertex is often referred to as a *node* (a term more popular in applied fields).

Two or more edges having the same pair of end vertices are called *parallel edges* or *multi edges*, and a graph with multi edges is sometimes referred to as a *multigraph*. An edge whose two end vertices are the same is called a *self-loop* (or just *loop*). A graph in which neither parallel edges nor self loops are allowed is often called a *simple graph*. If both self-loops and parallel edges are allowed we have a *general graph* (also referred to as *pseudograph*). Graphs in [Figures 4.1](#) and [4.2](#) are both simple but the graph in [Figure 4.3](#) is pseudograph. If the graph is simple we can refer to each edge by its end vertices. The number of edges incident on a vertex v , with self-loops counted twice, is called the *degree*, $\deg(v)$, of vertex v . In directed graphs a vertex has *in-degree* (number of edges going into it) and *out-degree* (number of edges going out of it).

In a digraph if there is a directed edge (x, y) from x to y , vertex y is called a *successor* of x and vertex x is called a *predecessor* of y . In case of an undirected graph two vertices are said to be *adjacent* or *neighbors* if there is an edge between them.

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

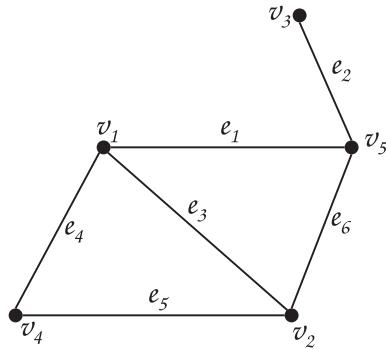

FIGURE 4.1 Undirected graph with 5 vertices and 6 edges.

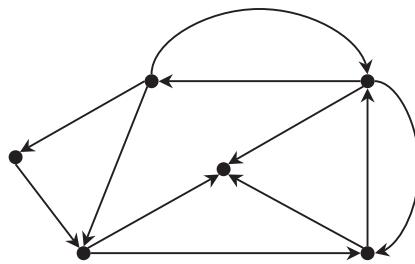

FIGURE 4.2 Digraph with 6 vertices and 11 edges.

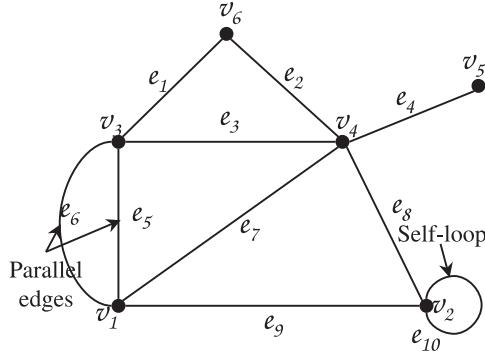

FIGURE 4.3 A pseudograph of 6 vertices and 10 edges.

A *weighted graph* is a (directed or undirected) graph in which a real number is assigned to each edge. This number is referred to as the *weight* of that edge. Weighted directed graphs are often referred to as *networks*. In a practical network this number (weight) may represent the driving distance, the construction cost, the transit time, the reliability, the transition probability, the carrying capacity, or any other such attribute of the edge [1–4].

Graphs are the most general and versatile data structures. Graphs have been used to model and solve a large variety of problems in the discrete domain. In their modeling and problem solving ability graphs are to the discrete world what differential equations are to the world of the continuum.

4.2 Graph Representations

For a given graph a number of different representations are possible. The ease of implementation, as well as the efficiency of a graph algorithm depends on the proper choice of the graph representation. The two most commonly used data structures for representing a graph (directed or undirected) are *adjacency lists* and *adjacency matrix*. In this section we discuss these and other data structures used in representing graphs.

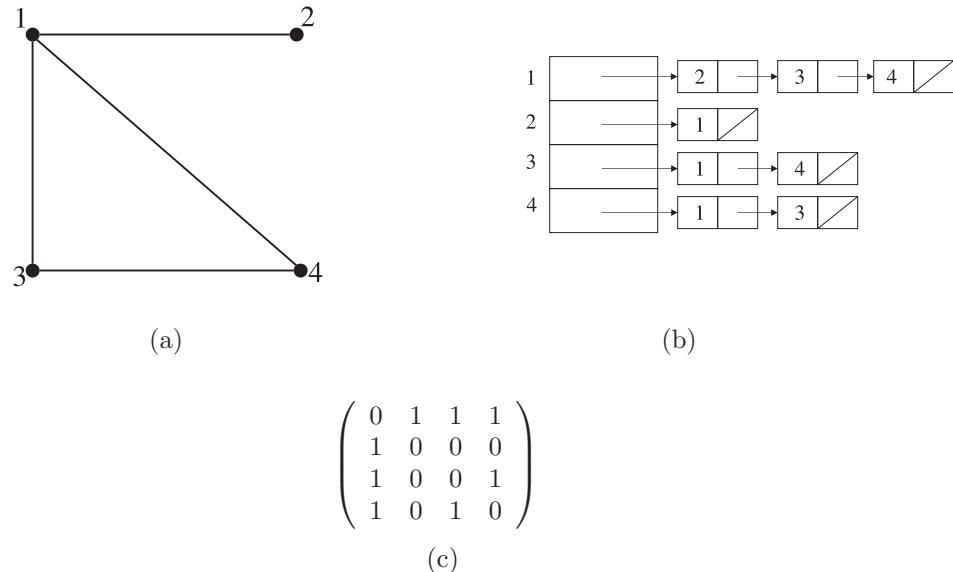

FIGURE 4.4 An undirected graph (a) with four vertices and four edges; (b) its adjacency lists representation, and (c) its adjacency matrix representation.

Adjacency lists: The adjacency lists representation of a graph G consists of an array Adj of n linked lists, one for each vertex in G , such that $Adj[v]$ for vertex v consists of all vertices adjacent to v . This list is often implemented as a linked list. (Sometimes it is also represented as a table, in which case it is called the *star representation* [3].)

Adjacency Matrix: The adjacency matrix of a graph $G = (V, E)$ is an $n \times n$ matrix $A = [a_{ij}]$ in which $a_{ij} = 1$ if there is an edge from vertex i to vertex j in G ; otherwise $a_{ij} = 0$. Note that in an adjacency matrix a self-loop can be represented by making the corresponding diagonal entry 1. Parallel edges could be represented by allowing an entry to be greater than 1, but doing so is uncommon, since it is usually convenient to represent each element in the matrix by a single bit. The adjacency lists and adjacency matrix of an undirected graph are shown in Figure 4.4, and the corresponding two representations for a digraph are shown in Figure 4.5.

Clearly the memory required to store a graph of n vertices in the form of adjacency matrix is $O(n^2)$, whereas for storing it in the form of its adjacency lists is $O(m + n)$. In general if the graph is sparse, adjacency lists are used but if the graph is dense, adjacency matrix is preferred. The nature of graph processing is an important factor in selecting the data structure.

There are other less frequently used data structures for representing graphs, such as *forward* or *backward star*, the *edge-list*, and *vertex-edge incidence matrix* [1–5].

4.2.1 Weighted Graph Representation

Both adjacency lists and adjacency matrix can be adapted to take into account the weights associated with each edge in the graph. In the former case an additional field is added in the linked list to include the weight of the edge; and in the latter case the graph is represented by a *weight matrix* in which the (i,j) th entry is the weight of edge (i,j) in the weighted graph. These two representations for a weighted graph are shown in Figure 4.6. The boxed numbers next to the edges in Figure 4.6a are the weights of the corresponding edges.

It should be noted that in a weight matrix, W , of a weighted graph, G , if there is no edge (i, j) in G , the corresponding element w_{ij} is usually set to ∞ (in practice, some very large number). The diagonal entries are usually set to ∞ (or to some other value depending on the application and algorithm). It is easy to see that the weight matrix of an undirected graph (like the adjacency matrix) is symmetric.

4.3 Connectivity, Distance, and Spanning Trees

Just as two vertices x and y in a graph are said to be adjacent if there is an edge joining them, two edges are said to be adjacent if they share (i.e., are incident on) a common vertex. A *simple path*, or *path* for short, is a sequence of adjacent edges (v_1, v_2) ,

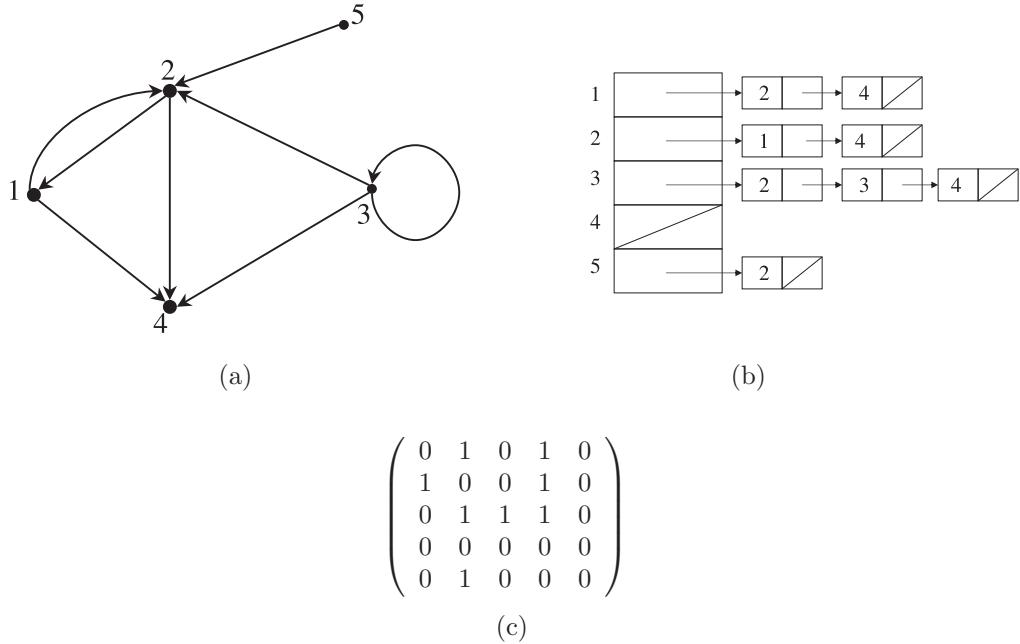

FIGURE 4.5 Two representations: (a) A digraph with five vertices and eight edges; (b) its adjacency lists representation, and (c) its adjacency matrix representation.

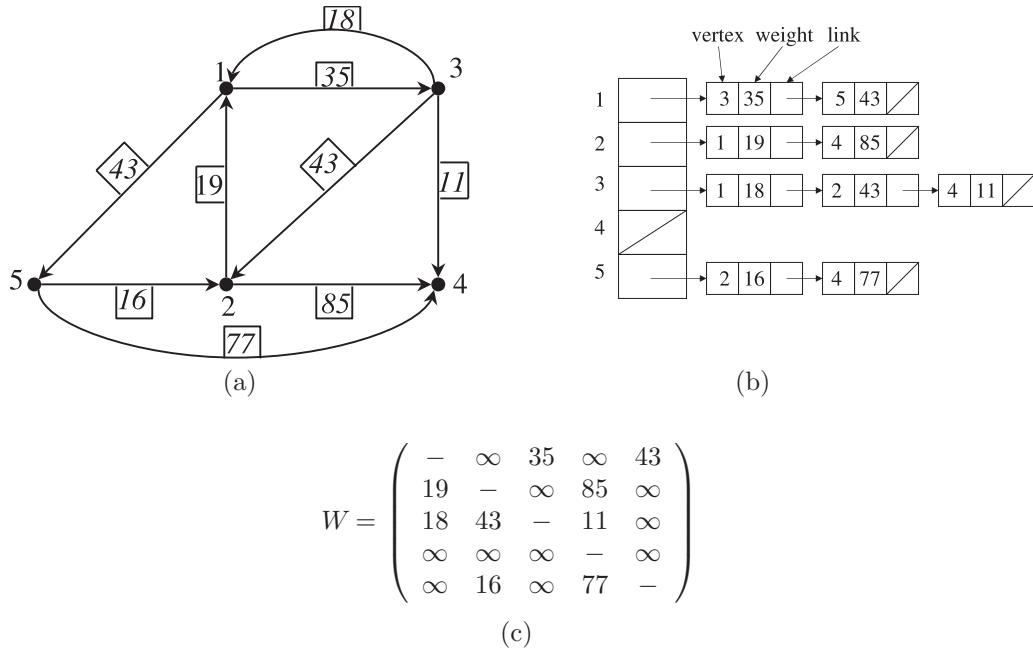

FIGURE 4.6 Two representations: (a) A weighted digraph with five vertices and nine edges; (b) its adjacency lists, and (c) its weight matrix.

$(v_2, v_3), \dots, (v_{k-2}, v_{k-1}), (v_{k-1}, v_k)$, sometimes written (v_1, v_2, \dots, v_k) , in which all the vertices v_1, v_2, \dots, v_k are distinct except possibly $v_1 = v_k$. In a digraph this path is said to be *directed from* v_1 to v_k ; in an undirected graph this path is said to be *between* v_1 and v_k . The number of edges in a path, in this case, $k - 1$, is called the *length* of the path. In Figure 4.3 sequence $(v_6, v_4), (v_4, v_1), (v_1, v_2) = (v_6, v_4, v_1, v_2)$ is a path of length 3 between v_6 and v_2 . In the digraph in Figure 4.6 sequence $(3, 1), (1, 5), (5, 2), (2, 4) = (3, 1, 5, 2, 4)$ is a directed path of length 4 from vertex 3 to vertex 4. A *cycle* or *circuit* is a path in which the

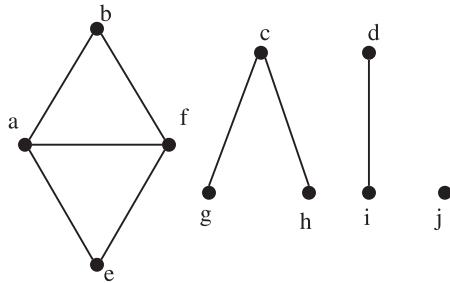

FIGURE 4.7 A disconnected graph of 10 vertices, 8 edges, and 4 components.

first and the last vertices are the same. In [Figure 4.3](#) $(v_3, v_6, v_4, v_1, v_3)$ is a cycle of length 4. In [Figure 4.6](#) $(3, 2, 1, 3)$ is a cycle of length 3. A graph that contains no cycle is called *acyclic*.

A *subgraph* of a graph $G = (V, E)$ is a graph whose vertices and edges are in G . A subgraph g of G is said to be *induced* by a subset of vertices $S \subseteq V$ if g results when the vertices in $V - S$ and all the edges incident on them are removed from G . For example, in [Figure 4.3](#), the subgraph induced by $\{v_1, v_3, v_4\}$ would consist of these three vertices and four edges $\{e_3, e_5, e_6, e_7\}$.

An undirected graph G is said to be *connected* if there is at least one path between every pair of vertices v_i and v_j in G . Graph G is said to be *disconnected* if it has at least one pair of distinct vertices u and v such that there is no path between u and v . Two vertices x and y in an undirected graph $G = (V, E)$ are said to be *connected* if there exists a path between x and y . This relation of being connected is an equivalence relation on the vertex set V , and therefore it partitions the vertices of G into equivalence classes. Each equivalence class of vertices induces a subgraph of G . These subgraphs are called *connected components* of G . In other words, a connected component is a maximal connected subgraph of G . A connected graph consists of just one component, whereas a disconnected graph consists of several (connected) components. Each of the graphs in [Figures 4.1, 4.3](#), and [4.4](#) is connected. But the graph given in [Figure 4.7](#) is disconnected, consisting of four components.

Notice that a component may consist of just one vertex such as j in [Figure 4.7](#) with no edges. Such a component (subgraph or graph) is called an *isolated vertex*. Equivalently, a vertex with zero degree is called an isolated vertex. Likewise, a graph (subgraph or component) may consist of just one edge, such as edge (i, d) in [Figure 4.7](#).

One of the simplest and often the most important and useful questions about a given graph G is: Is G connected? And if G is not connected what are its connected components? This question will be taken up in the next section, and an algorithm for determining the connected components will be provided; but first a few more concepts and definitions.

Connectivity in a directed graph G is more involved. A digraph is said to be connected if the undirected graph obtained by ignoring the edge directions in G is connected. A directed graph is said to be *strongly connected* if for every pair of vertices v_i and v_j there exists at least one directed path from v_i to v_j and at least one from v_j to v_i . A digraph which is connected but not strongly connected is called *weakly connected*. A disconnected digraph (like a disconnected undirected graph) consists of connected components; and a weakly-connected digraph consists of strongly-connected components. For example, the connected digraph in [Figure 4.5](#) consists of four strongly-connected components—induced by each of the following subsets of vertices $\{1, 2\}, \{3\}, \{4\}$, and $\{5\}$.

Another important question is that of distance from one vertex to another. The *distance* from vertex a to b is the length of the shortest path (i.e., a path of the smallest length) from a to b , if such a path exists. If no path from a to b exists, the distance is undefined and is often set to ∞ . Thus, the distance from a vertex to itself is 0; and the distance from a vertex to an adjacent vertex is 1. In an undirected graph distance from a to b equals the distance from b to a , that is, it is symmetric. It is also not difficult to see that the distances in a connected undirected graph (or a strongly connected digraph) satisfy the triangle inequality. In a connected, undirected (unweighted) graph G , the maximum distance between any pair of vertices is called the *diameter* of G .

4.3.1 Spanning Trees

A connected, undirected, acyclic (without cycles) graph is called a *tree*, and a set of trees is called a *forest*. We have already seen *rooted trees* and *forests of rooted trees* in the preceding chapter, but the unrooted trees and forests discussed in this chapter are graphs of a very special kind that play an important role in many applications.

In a connected undirected graph G there is at least one path between every pair of vertices and the absence of a cycle implies that there is at most one such path between any pair of vertices in G . Thus if G is a tree, there is exactly one path between every pair of vertices in G . The argument is easily reversed, and so an undirected graph G is a tree if and only if there is exactly one path between every pair of vertices in G . A tree with n vertices has exactly $(n - 1)$ edges. Since $(n - 1)$ edges are the fewest possible to

connect n points, trees can be thought of as graphs that are *minimally connected*. That is, removing any edge from a tree would disconnect it by destroying the only path between at least one pair of vertices.

A *spanning tree* for a connected graph G is a subgraph of G which is a tree containing every vertex of G . If G is not connected, a set consisting of one spanning tree for each component is called a *spanning forest* of G . To construct a spanning tree (forest) of a given undirected graph G , we examine the edges of G one at a time and retain only those that do not form a cycle with the edges already selected. Systematic ways of examining the edges of a graph will be discussed in the next section.

4.4 Searching a Graph

It is evident that for answering almost any nontrivial question about a given graph G we must examine every edge (and in the process every vertex) of G at least once. For example, before declaring a graph G to be disconnected we must have looked at every edge in G ; for otherwise, it might happen that the one edge we had decided to ignore could have made the graph connected. The same can be said for questions of *separability*, *planarity*, and other properties [5,6].

There are two natural ways of scanning or searching the edges of a graph as we move from vertex to vertex: (i) once at a vertex v we scan all edges incident on v and then move to an adjacent vertex w , then from w we scan all edges incident on w . This process is continued till all the edges *reachable* from v are scanned. This method of fanning out from a given vertex v and visiting all vertices reachable from v in order of their distances from v (i.e., first visit all vertices at a distance one from v , then all vertices at distances two from v , and so on) is referred to as the *breadth-first search* (BFS) of the graph. (ii) An opposite approach would be, instead of scanning every edge incident on vertex v , we move to an adjacent vertex w (a vertex not visited before) as soon as possible, leaving v with possibly unexplored edges for the time being. In other words, we trace a path through the graph going on to a new vertex whenever possible. This method of traversing the graph is called the *depth-first search* (DFS). Breadth-first and depth-first searches are fundamental methods of graph traversal that form the basis of many graph algorithms [5–8]. The details of these two methods follow.

4.4.1 Depth-First Search

Depth-first search on an undirected graph $G = (V, E)$ explores the graph as follows. When we are “visiting” a vertex $v \in V$, we follow one of the edges (v, w) incident on v . If the vertex w has been previously visited, we return to v and choose another edge. If the vertex w (at the other end of edge (v, w) from v) has not been previously visited, we visit it and apply the process recursively to w . If all the edges incident on v have been thus traversed, we go back along the edge (u, v) that had first led to the current vertex v and continue exploring the edges incident on u . We are finished when we try to back up from the vertex at which the exploration began.

[Figure 4.8](#) illustrates how depth-first search examines an undirected graph G represented as an adjacency lists. We start with a vertex a . From a we traverse the first edge that we encounter, which is (a, b) . Since b is a vertex never visited before, we stay at b and traverse the first untraversed edge encountered at b , which is (b, c) . Now at vertex c , the first untraversed edge that we find is (c, a) . We traverse (c, a) and find that a has been previously visited. So we return to c , marking the edge (c, a) in some way (as a dashed line in [Figure 4.8c](#)) to distinguish it from edges like (b, c) , which lead to new vertices and shown as the thick lines. Back at vertex c , we look for another untraversed edge and traverse the first one that we encounter, which is (c, d) . Once again, since d is a new vertex, we stay at d and look for an untraversed edge. And so on. The numbers next to the vertices in [Figure 4.8c](#) show the order in which they were visited; and the numbers next to the edges show the order in which they were traversed.

Depth-first search performed on a connected undirected graph $G = (V, E)$, partitions the edge set into two types: (i) Those that led to new vertices during the search constitute the branches of a spanning tree of G and (ii) the remaining edges in E are called *back edges* because their traversal led to an already visited vertex from which we backed down to the current vertex.

A recursive depth-first search algorithm is given in [Figure 4.9](#). Initially, every vertex x is marked *unvisited* by setting $num[x] = 0$. Note that in the algorithm shown in [Figure 4.9](#), only the tree edges are kept track of. The time complexity of the depth-first search algorithm is $O(m + n)$, provided the input is in the form of an adjacency matrix.

4.4.2 Breadth-First Search

In breadth-first search we start exploring from a specified vertex s and mark it “visited.” All other vertices of the given undirected graph G are marked as “unvisited” by setting $num[] = 0$. Then we visit all vertices adjacent to s (i.e., in the adjacency list of s). Next, we visit all unvisited vertices adjacent to the first vertex in the adjacency list of s . Unlike the depth-first search, in breadth-first search we explore (fan out) from vertices in order in which they themselves were visited. To implement this method of search, we maintain a queue (Q) of visited vertices. As we visit a new vertex for the first time, we place it in (i.e., at the back of) the queue. We take a vertex v from front of the queue and traverse all untraversed edges incident at v —adding to the list of tree edges those

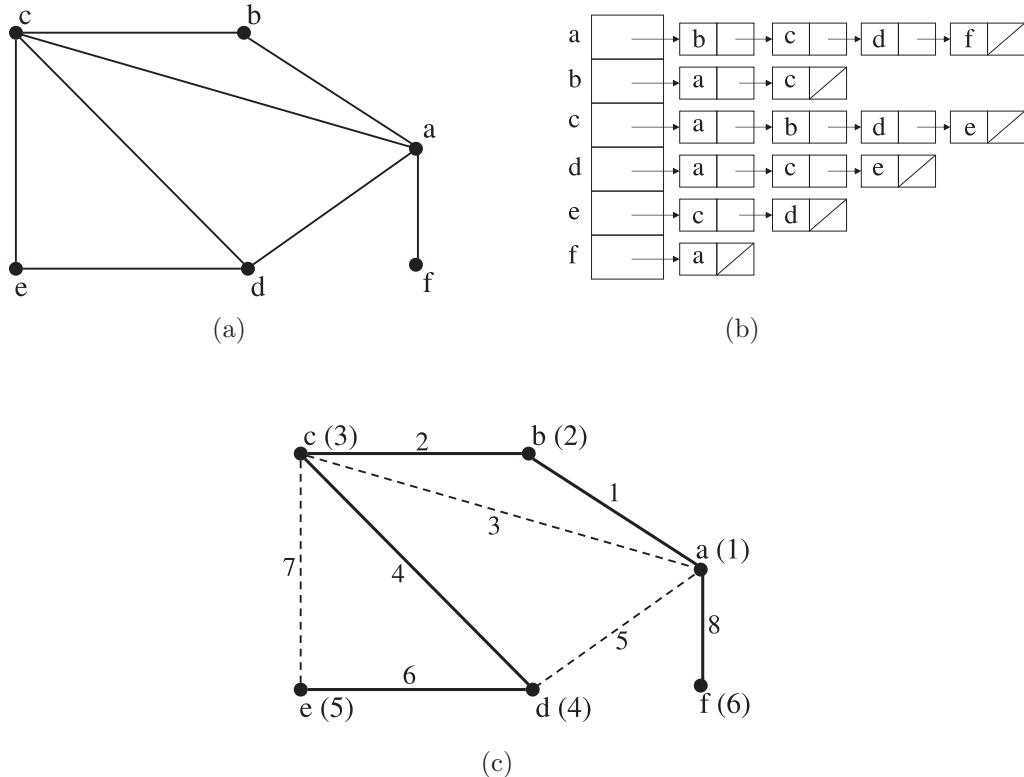

FIGURE 4.8 A graph (a); its adjacency lists (b); and its depth-first traversal (c). The numbers are the order in which vertices were visited and edges traversed. Edges whose traversal led to new vertices are shown with thick lines, and edges that led to vertices that were already visited are shown with dashed lines.

```

DepthFirstSearch( $G$ )
for each vertex  $x \in V$  do
     $num[x] \leftarrow 0$ 
end for
 $TreeEdges \leftarrow 0$ 
 $i \leftarrow 0$ 
for each vertex  $x \in V$  do
    if  $num[x] = 0$  then
        DFS-Visit( $x$ )
    end if
end for

DFS-Visit( $v$ )
 $i \leftarrow i + 1$ 
 $num[v] \leftarrow i$ 
for each vertex  $w \in Adj[v]$  do
    if  $num[w] = 0$  then // w is new vertex //
         $TreeEdges \leftarrow TreeEdges \cup (v, w)$  // (v, w) is a tree edge //
        DFS-Visit( $w$ )
    end if
end for

```

```

BreadthFirstSearch( $G, s$ )
  for each vertex  $x \in V - \{s\}$  do
     $visited[x] \leftarrow 0$  {// all vertices unvisited except  $s$  //}
  end for
   $TreeEdges \leftarrow null$ 
   $Q \leftarrow \phi$  {// queue of vertices is initially empty //}
   $visited[s] \leftarrow 1$  {// mark  $s$  as visited //}
  enqueue( $Q, s$ ) {// place  $s$  in the queue //}
  while  $Q \neq \phi$  do {// queue is not empty //}
     $v \leftarrow \text{dequeue}(Q)$ 
    for each  $w \in Adj[v]$  do
      if  $visited[w] = 0$  then {//  $w$  is a new vertex //}
         $visited[w] \leftarrow 1$ 
         $TreeEdges \leftarrow TreeEdges \cup \{(v, w)\}$ 
        enqueue( $Q, w$ )
      end if
    end for
  end while

```

FIGURE 4.10 Algorithm for breadth-first search on an undirected graph G from vertex s .

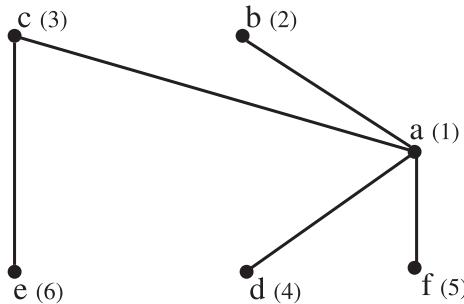

FIGURE 4.11 Spanning tree produced by breadth-first search on graph in Figure 4.8 starting from vertex a . The numbers show the order in which vertices were visited.

edges that lead to unvisited vertices from v ignoring the rest. Once a vertex v has been taken out of the queue, all the neighbors of v have been visited and v is completely explored.

Thus, during the execution of a breadth-first search we have three types of vertices: (i) unvisited, those that have never been in the queue; (ii) completely explored, those that have been in the queue but are not now in the queue; and (iii) visited but not completely explored, that is, those that are currently in the queue.

Since every vertex (reachable from the start vertex s) enters and exits the queue exactly once and every edge in the adjacency list of a vertex is traversed exactly once, the time complexity of the breadth-first search is $O(n + m)$.

An algorithm for performing a breadth-first search on an undirected connected graph G from a specified vertex s is given in Figure 4.10. It produces a breadth-first tree in G rooted at vertex s . For example, the spanning tree produced by BFS conducted on the graph in Figure 4.8 starting at vertex a , is shown in Figure 4.11. The numbers next to the vertices show the order in which the vertices were visited during the BFS.

4.5 Simple Applications of DFS and BFS

In the preceding section we discussed two basic but powerful and efficient techniques for systematically searching a graph such that every edge is traversed exactly once and every vertex is visited once. With proper modifications and embellishments these search techniques can be used to solve a variety of graph problems. Some of the simple ones are discussed in this section.

```

for each vertex  $v \in V$  do
     $compnum[v] \leftarrow 0$ 
end for
for each vertex  $v \in V$  do
    if  $compnum[v] = 0$  then
         $c \leftarrow c + 1$ 
        COMP( $v$ )
    end if
end for

COMP( $x$ )
 $compnum[x] \leftarrow c$ 
for each  $w \in Adj[x]$  do
    if  $compnum[w] = 0$  then
        COMP( $w$ )
    end if
end for

```

FIGURE 4.12 Depth-first search algorithm for finding connected components of a graph.

Cycle Detection: The existence of a back edge (i.e., a nontree edge) during a depth-first search indicates the existence of cycle. To test this condition we just add an *else* clause to the **if** $num[w] = 0$ statement in **DFS-Visit(v)** procedure in [Figure 4.9](#). That is, if, $num[w] \neq 0$, (v, w) is a back edge, which forms a cycle with tree edges in the path from w to v .

Spanning Tree: If the input graph G for the depth-first (or breadth-first) algorithm is connected, the set **TreeEdges** at the termination of the algorithm in [Figure 4.9](#) (or in [Figure 4.10](#), for breadth-first) produces a spanning tree of G .

Connected Components: If, on the other hand, the input graph $G = (V, E)$ is disconnected we can use depth-first search to identify each of its connected components by assigning a unique component number $compnum[v]$ to every vertex belonging to one component. The pseudocode of such an algorithm is given below ([Figure 4.12](#)).

4.5.1 Depth-First Search on a Digraph

Searching a digraph is somewhat more involved because the direction of the edges is an additional feature that must be taken into account. In fact, a depth-first search on a digraph produces four kinds of edges (rather than just two types for undirected graphs): (i) Tree edges—lead to an unvisited vertex (ii) Back edges—lead to an (visited) ancestor vertex in the tree (iii) Down-edges (also called forward edges) lead to a (visited) descendant vertex in the tree, and (iv) Cross edges, lead to a visited vertex, which is neither ancestor nor descendant in the tree [[3,5,6,8,9](#)].

4.5.2 Topological Sorting

The simplest use of the depth-first search technique on digraphs is to determine a labeling of the vertices of an acyclic digraph $G = (V, E)$ with integers $1, 2, \dots, |V|$, such that if there is a directed edge from vertex i to vertex j , then $i < j$; such a labeling is called *topological sort* of the vertices of G . For example, the vertices of the digraph in [Figure 4.13a](#) are topologically sorted but those of [Figure 4.13b](#) are not. Topological sorting can be viewed as the process of finding a linear order in which a given partial order can be embedded. It is not difficult to show that it is possible to topologically sort the vertices of a digraph if and only if it is acyclic. Topological sorting is useful in the analysis of activity networks where a large, complex project is represented as a digraph in which the vertices correspond to the goals in the project and the edges correspond to the activities. The topological sort gives an order in which the goals can be achieved [[1,3,10](#)].

Topological sorting begins by finding a vertex of $G = (V, E)$ with no outgoing edge (such a vertex must exist if G is acyclic) and assigning this vertex the highest number—namely, $|V|$. This vertex is then deleted from G , along with all its incoming edges. Since the remaining digraph is also acyclic, we can repeat the process and assign the next highest number, namely $|V| - 1$, to a vertex with no outgoing edges, and so on. To keep the algorithm $O(|V| + |E|)$, we must avoid searching the modified digraph for a vertex with no outgoing edges.

We do so by performing a single depth-first search on the given acyclic digraph G . In addition to the usual array num , we will need another array, $label$, of size $|V|$ for recording the topologically sorted vertex labels. That is, if there is an edge (u, v) in G ,

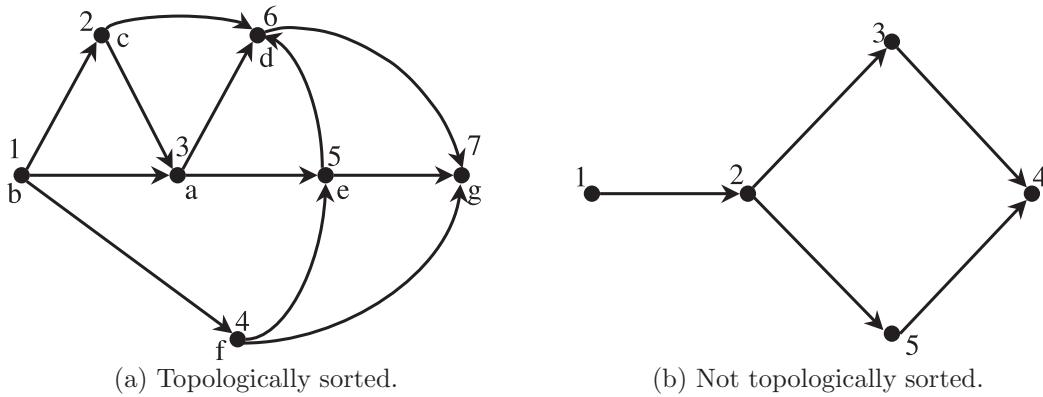

FIGURE 4.13 Acyclic digraphs.

```

Topological-Sort( $G$ )
for each vertex  $x \in V$  do
     $num[x] \leftarrow 0$ 
     $label[x] \leftarrow 0$ 
end for
 $j \leftarrow n + 1$ 
 $i \leftarrow 0$ 
for each vertex  $x \in V$  do
    if  $num[x] = 0$  then {//  $x$  has no labeled ancestor //}
        TOPSORT( $x$ )
    end if
end for

TOPSORT( $v$ )
 $i \leftarrow i + 1$ 
 $num[v] \leftarrow i$ 
for each  $w \in Adj[v]$  do {// examine all descendants of  $w$  //}
    if  $num[w] = 0$  then
        TOPSORT( $w$ )
    else if  $label[w] = 0$  then
        Error {// cycle detected //}
    end if
     $j \leftarrow j - 1$ 
     $label[v] \leftarrow j$ 
end for

```

FIGURE 4.14 Algorithm for topological sorting.

then $label[u] < label[v]$. The complete search and labeling procedure **TOPSORT** is given in Figure 4.14. Use the acyclic digraph in Figure 4.13a with vertex set $V = \{a, b, c, d, e, f, g\}$ as the input to the topological sort algorithm in Figure 4.14; and verify that the vertices get relabeled 1 to 7, as shown next to the original names—in a correct topological order.

4.6 Minimum Spanning Tree

How to connect a given set of points with lowest cost is a frequently-encountered problem, which can be modeled as the problem of finding a minimum-weight spanning tree T in a weighted, connected, undirected graph $G = (V, E)$. Methods for finding such a spanning tree, called a *minimum spanning tree* (MST), have been investigated in numerous studies and have a long history [11]. In this section we will discuss the bare essentials of the two commonly used MST algorithms—Kruskal's and Prim's—and briefly mention a third one.

4.6.1 Kruskal's MST Algorithm

An algorithm due to J. B. Kruskal, which employs the smallest-edge-first strategy, works as follows: First we sort all the edges in the given network by weight, in nondecreasing order. Then one by one the edges are examined in order, smallest to the largest. If an edge e_i , upon examination, is found to form a cycle (when added to edges already selected) it is discarded. Otherwise, e_i is selected to be included in the minimum spanning tree T . The construction stops when the required $n - 1$ edges have been selected or when all m edges have been examined. If the given network is disconnected, we would get a *minimum spanning forest* (instead of tree). More formally, Kruskal's method may be stated as follows:

```

 $T \leftarrow \emptyset$ 
while  $|T| < (n - 1)$  and  $E \neq \emptyset$  do
     $e \leftarrow$  smallest edge in  $E$ 
     $E \leftarrow E - \{e\}$ 
    if  $T \cup \{e\}$  has no cycle then
         $T \leftarrow T \cup \{e\}$ 
    end if
end while
if  $|T| < (n - 1)$  then
    write 'network disconnected'
end if
```

Although the algorithm just outlined is simple enough, we do need to work out some implementation details and select an appropriate data structure for achieving an efficient execution.

There are two crucial implementations details that we must consider in this algorithm. If we initially sort all m edges in the given network, we may be doing a lot of unnecessary work. All we really need is to be able to determine the next smallest edge in the network at each iteration. Therefore, in practice, the edges are only partially sorted and kept as a heap with smallest edge at the root of a min heap. In a graph with m edges, the initial construction of the heap would require $O(m)$ computational steps; and the next smallest edge from a heap can be obtained in $O(\log m)$ steps. With this improvement, the sorting cost is $O(m + p \log m)$, where p is the number of edges examined before an MST is constructed. Typically, p is much smaller than m .

The second crucial detail is how to maintain the edges selected (to be included in the MST) so far, such that the next edge to be examined can be efficiently tested for a cycle formation.

As edges are examined and included in T , a forest of disconnected trees (i.e., subtrees of the final spanning tree) is produced. The edge e being examined will form a cycle if and only if both its end vertices belong to the same subtree in T . Thus to ensure that the edge currently being examined does not form a cycle, it is sufficient to check if it connects two different subtrees in T . An efficient way to accomplish this is to group the n vertices of the given network into disjoint subsets defined by the subtrees (formed by the edges included in T so far). Thus if we maintain the partially constructed MST by means of subsets of vertices, we can add a new edge by forming the UNION of two relevant subsets, and we can check for cycle formation by FINDing if the two end vertices of the edge, being examined, are in the same subset. These subsets can themselves be kept as rooted trees. The root is an element of the subset and is used as a name to identify that subset. The FIND subprocedure is called twice—once for each end vertex of edge e —to determine the sets to which the two end vertices belong. If they are different, the UNION subprocedure will merge the two subsets. (If they are the same subset, edge e will be discarded.)

The subsets, kept as rooted trees, are implemented by keeping an array of *parent* pointers for each of the n elements. Parent of a root, of course, is null. (In fact, it is useful to assign $\text{parent}[root] = -$ number of vertices in the tree.) While taking the UNION of two subsets, we merge the smaller subset into the larger one by pointing the parent pointer in the root of the smaller subset to the root of the larger subset. Some of these details are shown in Figure 4.15. Note that r_1 and r_2 are the roots identifying the sets to which vertices u and v belong.

When algorithm in Figure 4.15 is applied to the weighted graph in Figure 4.16, the order in which edges are included one by one to form the MST are $(3, 5), (4, 6), (4, 5), (4, 2), (6, 7), (3, 1)$. After the first five smallest edges are included in the MST, the 6^{th} and 7^{th} and 8^{th} smallest edges are rejected. Then the 9^{th} smallest edge $(1, 3)$ completes the MST and the last two edges are ignored.

4.6.2 Prim's MST Algorithm

A second algorithm, discovered independently by several people (Jarnik in 1936, Prim in 1957, Dijkstra in 1959) employs the “nearest neighbor” strategy and is commonly referred to as Prim's algorithm. In this method one starts with an arbitrary vertex s and joins it to its nearest neighbor, say y . That is, of all edges incident on vertex s , edge (s, y) , with the smallest weight, is made

INITIALIZATION:

```

set parent array to  $-1$  { $\{/ \} n$  vertices from singleton sets  $\{/ \}$ }
form initial heap of  $m$  edges
 $ecount \leftarrow 0$  { $\{/ \} \text{number of edges examined so far } \{/ \}$ }
 $tcount \leftarrow 0$  { $\{/ \} \text{number of edges in } T \text{ so far } \{/ \}$ }
 $T \leftarrow \phi$ 
```

ITERATION:

```

while  $tcount < (n - 1)$  and  $ecount < m$  do
     $e \leftarrow \text{edge}(u, v)$  from top of heap
     $ecount \leftarrow ecount + 1$ 
    remove  $e$  from heap
    restore heap
     $r1 \leftarrow \text{FIND}(u)$ 
     $r2 \leftarrow \text{FIND}(v)$ 
    if  $r1 \neq r2$  then
         $T \leftarrow T \cup \{e\}$ 
         $tcount \leftarrow tcount + 1$ 
        UNION( $r1, r2$ )
    end if
end while
if  $tcount < (n - 1)$  then
    write ‘network disconnected’
end if
```

FIGURE 4.15 Kruskal’s minimum spanning tree algorithm.

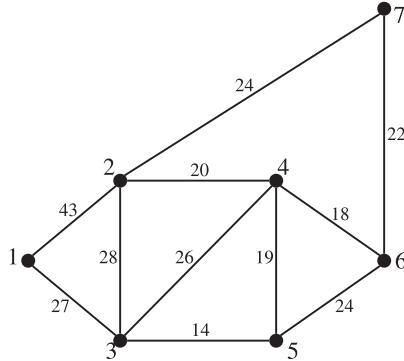

FIGURE 4.16 A connected weighted graph for MST algorithm.

part of the MST. Next, of all the edges incident on s or y we choose one with minimum weight that leads to some third vertex, and make this edge part of the MST. We continue this process of “reaching out” from the partially constructed tree (so far) and bringing in the “nearest neighbor” until all vertices reachable from s have been incorporated into the tree.

As an example, let us use this method to find the minimum spanning tree of the weighted graph given in Figure 4.16. Suppose that we start at vertex 1. The nearest neighbor of vertex 1 is vertex 3. Therefore, edge $(1, 3)$ becomes part of the MST. Next, of all the edges incident on vertices 1 and 3 (and not included in the MST so far) we select the smallest, which is edge $(3, 5)$ with weight 14. Now the partially constructed tree consists of two edges $(1, 3)$ and $(3, 5)$. Among all edges incident at vertices 1, 3, and 5, edge $(5, 4)$ is the smallest, and is therefore included in the MST. The situation at this point is shown in Figure 4.17. Clearly, $(4, 6)$, with weight 18 is the next edge to be included. Finally, edges $(4, 2)$ and $(6, 7)$ will complete the desired MST.

The primary computational task in this algorithm is that of finding the next edge to be included into the MST in each iteration. For each efficient execution of this task we will maintain an array $near[u]$ for each vertex u not yet in the tree (i.e., $u \in V - V_T$).

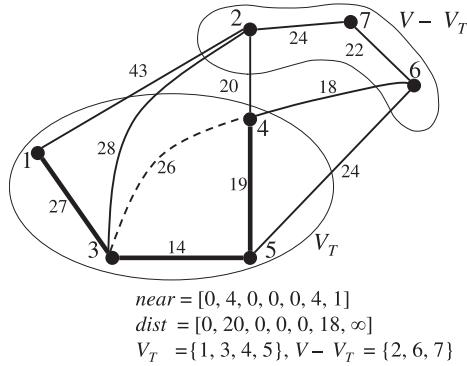

FIGURE 4.17 Partially constructed MST for the network of Figure 4.16.

INITIALIZATION:

```

choose starting vertex  $s$  arbitrarily
for every vertex  $i$  other than  $s$  do
     $\text{near}[i] \leftarrow s$ 
     $\text{dist}[i] \leftarrow w_{si}$ 
end for
 $V_T \leftarrow \{s\}$  { // set of vertices in MST so far //}
 $E_T \leftarrow \emptyset$  { // set of edges in MST so far //}

```

ITERATION:

```

while  $|V_T| < n$  do
     $u \leftarrow$  vertex in  $(V - V_T)$  with smallest value of  $\text{dist}(u)$ 
    if  $\text{dist}[u] \geq \infty$  then
        write 'graph disconnected' and exit
    end if
     $E_T \leftarrow E_T \cup \{(u, \text{near}[u])\}$ 
     $V_T \leftarrow V_T \cup \{u\}$ 
    for  $x \in (V - V_T)$  do
        if  $w_{ux} < \text{dist}[x]$  then
             $\text{dist}[x] \leftarrow w_{ux}$ 
             $\text{near}[x] \leftarrow u$ 
        end if
    end for
end while

```

FIGURE 4.18 Prim's minimum spanning tree algorithm.

$\text{near}[u]$ is that vertex in V_T which is closest to u . (Note that V is the set of all vertices in the network and V_T is the subset of V included in MST thus far.) Initially, we set $\text{near}[s] \leftarrow 0$ to indicate that s is in the tree, and for every other vertex v , $\text{near}[v] \leftarrow s$.

For convenience, we will maintain another array $\text{dist}[u]$ of the actual distance (i.e., edge weight) to that vertex in V_T which is closest to u . In order to determine which vertex is to be added to the set V_T next, we compare all nonzero values in dist array and pick the smallest. Thus $n - i$ comparisons are sufficient to identify the i th vertex to be added. Initially, since s is the only vertex in V_T , $\text{dist}[u]$ is set to w_{su} . As the algorithm proceeds, these two arrays are updated in each iteration (see Figure 4.17 for an illustration).

A formal description of the nearest-neighbor algorithm is given in Figure 4.18. It is assumed that the input is given in the form of an $n \times n$ weight matrix W (in which nonexistent edges have ∞ weights). Set $V = \{1, 2, \dots, n\}$ is the set of vertices of the graph. V_T and E_T are the sets of vertices and edges of the partially formed (minimum spanning) tree. Vertex set V_T is identified by zero entries in array near .

4.6.3 Boruvka's MST Algorithm

There is yet a third method for computing a minimum spanning tree, which was first proposed by O. Boruvka in 1926 (but rediscovered by G. Chouquet in 1938 and G. Sollin in 1961). It works as follows: First, the smallest edge incident on each vertex is found; these edges form part of the minimum spanning tree. There are at least $\lceil n/2 \rceil$ such edges. The connected components formed by these edges are collapsed into “supernodes” (There are no more than $\lfloor n/2 \rfloor$ such vertices at this point.) The process is repeated on “supernodes” and then on the resulting “supersupernodes,” and so on, until only a single vertex remains. This will require at most $\lfloor \log_2 n \rfloor$ steps, because at each step the number of vertices is reduced at least by a factor of 2. Because of its inherent parallelism the nearest-neighbor-from-each-vertex approach is particularly appealing for parallel implementations.

These three “greedy” algorithms and their variations have been implemented with different data structures and their relative performance—both theoretical as well as empirical—have been studied widely. The results of some of these studies can be found in [6,12–14].

4.6.4 Constrained MST

In many applications, the minimum spanning tree is required to satisfy an additional constraint, such as (i) the degree of each vertex in the MST should be equal to or less than a specified value; or (ii) the diameter of the MST should not exceed a specified value; or (iii) the MST must have at least a specified number of leaves (vertices of degree 1 in a tree); and the like. The problem of computing such a *constrained minimum spanning tree* is usually NP-complete. For a discussion of various constrained MST problems and some heuristics solving them see [15].

4.7 Shortest Paths

In the preceding section we dealt with the problem of connecting a set of points with smallest cost. Another commonly encountered and somewhat related problem is that of finding the lowest-cost path (called shortest path) between a given pair of points. There are many types of shortest-path problems. For example, determining the shortest path (i.e., the most economical path or fastest path, or minimum-fuel-consumption path) from one specified vertex to another specified vertex; or shortest paths from a specified vertex to all other vertices; or perhaps shortest path between all pairs of vertices. Sometimes, one wishes to find a shortest path from one given vertex to another given vertex that passes through certain specified intermediate vertices. In some applications, one requires not only the shortest but also the second and third shortest paths. Thus, the shortest-path problems constitute a large class of problems; particularly if we generalize it to include related problems, such as the longest-path problems, the most-reliable-path problems, the largest-capacity-path problems, and various routing problems. Therefore, the number of papers, books, reports, dissertations, and surveys dealing with the subject of shortest paths runs into hundreds [16].

Here we will discuss two very basic and important shortest-path problems: (i) how to determine the shortest distance (and a shortest path) from a specified vertex s to another specified vertex t , and (ii) how to determine shortest distances (and paths) from every vertex to every other vertex in the network. Several other problems can be solved using these two basic algorithms.

4.7.1 Single-Source Shortest Paths, Nonnegative Weights

Let us first consider a classic algorithm due to Dijkstra for finding a shortest path (and its weight) from a specified vertex s (*source* or *origin*) to another specified vertex t (*target* or *sink*) in a network G in which all edge weights are nonnegative. The basic idea behind Dijkstra's algorithm is to fan out from s and proceed toward t (following the directed edges), labeling the vertices with their distances from s obtained so far. The label of a vertex u is made *permanent* once we know that it represents the shortest possible distance from s (to u). All vertices not permanently labeled have *temporary* labels.

We start by giving a permanent label 0 to source vertex s , because zero is the distance of s from itself. All other vertices get labeled ∞ , temporarily, because they have not been reached yet. Then we label each immediate successor v of source s , with temporary labels equal to the weight of the edge (s, v) . Clearly, the vertex, say x , with smallest temporary label (among all its immediate successors) is the vertex closest to s . Since all edges have nonnegative weights, there can be no shorter path from s to x . Therefore, we make the label of x permanent. Next, we find all immediate successors of vertex x , and shorten their temporary labels if the path from s to any of them is shorter by going through x (than it was without going through x). Now, from among all temporarily labeled vertices we pick the one with the smallest label, say vertex y , and make its label permanent. This vertex y is the second closest vertex from s . Thus, at each iteration, we reduce the values of temporary labels whenever possible (by selecting a shorter path through the most recent permanently labeled vertex), then select the vertex with the smallest temporary label

```

INITIALIZATION:
for all  $v \in V$  do
     $dist[v] \leftarrow \infty$ 
     $final[v] \leftarrow \text{false}$ 
     $pred[v] \leftarrow -1$ 
end for
 $dist[s] \leftarrow 0$ 
 $final[s] \leftarrow \text{true}$ 
 $recent \leftarrow s$ 
{ $\text{// vertex } s \text{ is permanently labeled with } 0.$  All other vertices are temporarily labeled with  $\infty$ . Vertex  $s$  is the most recent vertex to be permanently labeled  $\text{//}$ }

ITERATION:
while  $final[t] = \text{false}$  do
    for every immediate successor  $v$  of  $recent$  do
        if not  $final[v]$  then { $\text{// update temporary labels } \text{//}$ }
             $newlabel \leftarrow dist[recent] + w_{recent,v}$ 
            if  $newlabel < dist[v]$  then
                 $dist[v] \leftarrow newlabel$ 
                 $pred[v] \leftarrow recent$  { $\text{// relabel } v \text{ if there is a shorter path via vertex } recent \text{ and make } recent \text{ the predecessor of } v \text{ on the shortest path from } s \text{ //}$ }
            end if
        end if
    end for
    let  $y$  be the vertex with the smallest temporary label, which is  $\neq \infty$ 
     $final[y] \leftarrow \text{true}$ 
     $recent \leftarrow y$  { $\text{// } y, \text{ the next closest vertex to } s \text{ gets permanently labeled } \text{//}$ }
end while

```

FIGURE 4.19 Dijkstra's shortest-path algorithm.

and make it permanent. We continue in this fashion until the target vertex t gets permanently labeled. In order to distinguish the permanently labeled vertices from the temporarily labeled ones, we will keep a boolean array $final$ of order n . When the i th vertex becomes permanently labeled, the i th element of this array changes from $false$ to $true$. Another array, $dist$, of order n will be used to store labels of vertices. A variable $recent$ will be used to keep track of most recent vertex to be permanently labeled.

Assuming that the network is given in the form of a weight matrix $W = [w_{ij}]$, with ∞ weights for nonexistent edges, and vertices s and t are specified, this algorithm (which is called *Dijkstra's shortest-path* or the *label-setting algorithm*) may be described as follows (Figure 4.19).

4.7.2 Single-Source Shortest Paths, Arbitrary Weights

In Dijkstra's shortest-path algorithm (Figure 4.19), it was assumed that all edge weights w_{ij} were nonnegative numbers. If some of the edge weights are negative, Dijkstra's algorithm will not work. (Negative weights in a network may represent costs and positive ones, profit.) The reason for the failure is that once the label of a vertex is made permanent, it cannot be changed in future iterations. In order to handle a network that has both positive and negative weights, we must ensure that no label is considered permanent until the program halts. Such an algorithm (called a *label-correcting method*, in contrast to Dijkstra's *label-setting method*) is described as below.

Like Dijkstra's algorithm, the label of the starting vertex s is set to zero and that of every other vertex is set to ∞ , a very large number. That is, the initialization consists of

```

 $dist(s) \leftarrow 0$ 
for all  $v \neq s$  do
     $dist(v) \leftarrow \infty$ 
end for

```

In the iterative step, $dist(v)$ is always updated to the currently known distance from s to v , and the predecessor $pred(v)$ of v is also updated to be the predecessor vertex of v on the currently known shortest path from s to v . More compactly, the iteration may be expressed as follows:

```
while  $\exists$  an edge  $(u, v)$  such that  $dist(u) + w_{u,v} < dist(v)$  do
     $dist(v) \leftarrow dist(u) + w_{u,v}$ 
     $pred(v) \leftarrow u$ 
end while
```

Several implementations of this basic iterative step have been studied, experimented with, and reported in the literature. One very efficient implementation, works as follows.

We maintain a queue of “vertices to be examined.” Initially, this queue, Q , contains only the starting vertex s . The vertex u from the front of the queue is “examined” (as follows) and deleted. Examining u consists of considering all edges (u, v) going out of u . If the length of the path to vertex v (from s) is reduced by going through u , that is,

```
if  $dist(u) + w_{u,v} < dist(v)$  then
     $dist(v) \leftarrow dist(u) + w_{u,v}$  { $/\!\!/$   $dist(v)$  is reset to the smaller value  $/\!\!/$ }
     $pred(v) \leftarrow u$ 
end if
```

Moreover, this vertex v is added to the queue (if it is not already in the queue) as a vertex to be examined later. Note that v enters the queue only if $dist(v)$ is decremented as above and if v is currently not in the queue. Observe that unlike in Dijkstra’s method (the label-setting method) a vertex may enter (and leave) the queue several times—each time a shorter path is discovered. It is easy to see that the label-correcting algorithm will not terminate if the network has a cycle of negative weight.

4.7.3 All-Pairs Shortest Paths

We will now consider the problem of finding a shortest path between every pair of vertices in the network. Clearly, in an n -vertex directed graph there are $n(n - 1)$ such paths—one for each ordered pair of distinct vertices—and $n(n - 1)/2$ paths in an undirected graph. One could, of course, solve this problem by repeated application of Dijkstra’s algorithm, once for each vertex in the network taken as the source vertex s . We will instead consider a different algorithm for finding shortest paths between all pairs of vertices, which is known as *Warshall-Floyd algorithm*. It requires computation time proportional to n^3 , and allows some of the edges to have negative weights, as long as no cycles of net negative weight exist.

The algorithm works by inserting one or more vertices into paths, whenever it is advantageous to do so. Starting with $n \times n$ weight matrix $W = [w_{ij}]$ of direct distances between the vertices of the given network G , we construct a sequence of n matrices $W^{(1)}, W^{(2)}, \dots, W^{(n)}$. Matrix $W^{(1)}$, $1 \leq l \leq n$, may be thought of as the matrix whose (i, j) th entry $w_{ij}^{(l)}$ gives the length of the shortest path among all paths from i to j with vertices $1, 2, \dots, l$ allowed as intermediate vertices. Matrix $W^{(l)} = w_{ij}^{(l)}$ is constructed as follows:

$$\begin{aligned} w_{ij}^{(0)} &= w_{ij} \\ w_{ij}^{(l)} &= \min \left\{ w_{ij}^{(l-1)}, w_{il}^{(l-1)} + w_{lj}^{(l-1)} \right\} \text{ for } l = 1, 2, \dots, n \end{aligned} \quad (4.1)$$

In other words, in iteration 1, vertex 1 is inserted in the path from vertex i to vertex j if $w_{ij} > w_{i1} + w_{1j}$. In iteration 2, vertex 2 can be inserted, and so on.

For example, in Figure 4.6 the shortest path from vertex 2 to 4 is 2–1–3–4; and the following replacements occur:

$$\text{Iteration 1 : } w_{23}^{(0)} \text{ is replaced by } (w_{21}^{(0)} + w_{13}^{(0)})$$

$$\text{Iteration 2 : } w_{24}^{(2)} \text{ is replaced by } (w_{23}^{(2)} + w_{34}^{(2)})$$

Once the shortest distance is obtained in $w_{23}^{(3)}$, the value of this entry will not be altered in subsequent operations.

We assume as usual that the weight of a nonexistent edge is ∞ , that $x + \infty = \infty$, and that $\min\{x, \infty\} = x$ for all x . It can easily be seen that all distance matrices $W^{(l)}$ calculated from Equation 4.1 can be overwritten on W itself. The algorithm may be stated as follows:

If the network has no negative-weight cycle, the diagonal entries $w_{ii}^{(n)}$ represent the length of shortest cycles passing through vertex i . The off-diagonal entries $w_{ij}^{(n)}$ are the shortest distances. Notice that negative weight of an individual edge has no effect on this algorithm as long as there is no cycle with a net negative weight.

```

for  $l \leftarrow 1$  to  $n$  do
  for  $i \leftarrow 1$  to  $n$  do
    if  $w_{il} \neq \infty$  then
      for  $j \leftarrow 1$  to  $n$  do
         $w_{ij} \leftarrow \min\{w_{ij}, w_{il} + w_{lj}\}$ 
      end for
    end if
  end for
end for

```

FIGURE 4.20 All-pairs shortest distance algorithm.

Note that the algorithm in Figure 4.20 does not actually list the paths, it only produces their costs or weights. Obtaining paths is slightly more involved than it was in algorithm in Figure 4.19 where a predecessor array $pred$ was sufficient. Here the paths can be constructed from a *path matrix* $P = [p_{ij}]$ (also called *optimal policy matrix*), in which p_{ij} is the second to the last vertex along the shortest path from i to j —the last vertex being j . The path matrix P is easily calculated by adding the following steps in Figure 4.20. Initially, we set

$$\begin{aligned} p_{ij} &\leftarrow i, \text{ if } w_{ij} \neq \infty, \text{ and} \\ p_{ij} &\leftarrow 0, \text{ if } w_{ij} = \infty. \end{aligned}$$

In the l th iteration if vertex l is inserted between i and j ; that is, if $w_{il} + w_{lj} < w_{ij}$, then we set $p_{ij} \leftarrow p_{lj}$. At the termination of the execution, the shortest path $(i, v_1, v_2, \dots, v_q, j)$ from i to j can be obtained from matrix P as follows:

$$\begin{aligned} v_q &= p_{ij} \\ v_{q-1} &= p_{i,v_q} \\ v_{q-2} &= p_{i,v_{q-1}} \\ &\vdots \\ i &= p_{i,v_1} \end{aligned}$$

The storage requirement is n^2 , no more than for storing the weight matrix itself. Since all the intermediate matrices as well as the final distance matrix are overwritten on W itself. Another n^2 storage space would be required if we generated the path matrix P also. The computation time for the algorithm in Figure 4.20 is clearly $O(n^3)$, regardless of the number of edges in the network.

4.8 Eulerian and Hamiltonian Graphs

A path when generalized to include visiting a vertex more than once is called a *trail*. In other words, a trail is a sequence of edges $(v_1, v_2), (v_2, v_3), \dots, (v_{k-2}, v_{k-1}), (v_{k-1}, v_k)$ in which all the vertices (v_1, v_2, \dots, v_k) may not be distinct but all the edges are distinct. Sometimes a trail is referred to as a (non-simple) path and path is referred to as a simple path. For example in Figure 4.8a $(b, a), (a, c), (c, d), (d, a), (a, f)$ is a trail (but not a simple path because vertex a is visited twice).

If the first and the last vertex in a trail are the same, it is called a *closed trail*, otherwise an *open trail*. An *Eulerian trail* in a graph $G = (V, E)$ is one that includes every edge in E (exactly once). A graph with a closed Eulerian trail is called a *Eulerian graph*. Equivalently, in an Eulerian graph, G , starting from a vertex one can traverse every edge in G exactly once and return to the starting vertex. According to a theorem proved by Euler in 1736, (considered the beginning of graph theory), a connected graph is Eulerian if and only if the degree of its every vertex is even.

Given a connected graph G it is easy to check if G is Eulerian. Finding an actual Eulerian trail of G is more involved. An efficient algorithm for traversing the edges of G to obtain an Euler trail was given by Fleury. The details can be found in Reference 4.

A cycle in a graph G is said to be *Hamiltonian* if it passes through every vertex of G . Many families of special graphs are known to be Hamiltonian, and a large number of theorems have been proved that give sufficient conditions for a graph to be Hamiltonian. However, the problem of determining if an arbitrary graph is Hamiltonian is NP-complete.

Graph theory, a branch of combinatorial mathematics, has been studied for over two centuries. However, its applications and algorithmic aspects have made enormous advances only in the past fifty years with the growth of computer technology and operations research. Here we have discussed just a few of the better-known problems and algorithms. Additional material is available in

the references provided. In particular, for further exploration the Stanford GraphBase [17], the LEDA [18], and the Graph Boost Library [19] provide valuable and interesting platforms with collection of graph-processing programs and benchmark databases.

5.1 Introduction

A single-ended priority queue (or simply, a priority queue) is a collection of elements in which each element has a priority. There are two varieties of priority queues—max and min. The primary operations supported by a max (min) priority queue are (a) find the element with maximum (minimum) priority, (b) insert an element, and (c) delete the element whose priority is maximum (minimum). However, many authors consider additional operations such as (d) delete an arbitrary element (assuming we have a pointer to the element), (e) change the priority of an arbitrary element (again assuming we have a pointer to this element), (f) meld two max (min) priority queues (i.e., combine two max (min) priority queues into one), and (g) initialize a priority queue with a nonzero number of elements.

Several data structures: for example, heaps ([Chapter 3](#)), leftist trees [[1,2](#)], Fibonacci heaps [[3](#)] ([Chapter 7](#)), binomial heaps [[4](#)] ([Chapter 7](#)), skew heaps [[5](#)] ([Chapter 6](#)), and pairing heaps [[6](#)] ([Chapter 7](#)) have been proposed for the representation of a priority queue. The different data structures that have been proposed for the representation of a priority queue differ in terms of the performance guarantees they provide. Some guarantee good performance on a per operation basis while others do this only in the amortized sense. Max (min) heaps permit one to delete the max (min) element and insert an arbitrary element into an n element priority queue in $O(\log n)$ time per operation; a find max (min) takes $O(1)$ time. Additionally, a heap is an implicit data structure that has no storage overhead associated with it. All other priority queue structures are pointer-based and so require additional storage for the pointers.

Max (min) leftist trees also support the insert and delete max (min) operations in $O(\log n)$ time per operation and the find max (min) operation in $O(1)$ time. Additionally, they permit us to meld pairs of priority queues in logarithmic time.

The remaining structures do not guarantee good complexity on a per operation basis. They do, however, have good amortized complexity. Using Fibonacci heaps, binomial queues, or skew heaps, find max (min), inserts and melds take $O(1)$ time (actual and amortized) and a delete max (min) takes $O(\log n)$ amortized time. When a pairing heap is used, the amortized complexity is $O(1)$ for find max (min) and insert (provided no decrease key operations are performed) and $O(\log n)$ for delete max (min) operations [[7](#)]. Jones [[8](#)] gives an empirical evaluation of many priority queue data structures.

In this chapter, we focus on the leftist tree data structure. Two varieties of leftist trees—height-biased leftist trees [[2](#)] and weight-biased leftist trees [[1](#)] are described. Both varieties of leftist trees are binary trees that are suitable for the representation of a single-ended priority queue. When a max (min) leftist tree is used, the traditional single-ended priority queue operations—find max (min) element, delete/remove max (min) element, and insert an element—take, respectively, $O(1)$, $O(\log n)$ and $O(\log n)$ time each, where n is the number of elements in the priority queue. Additionally, an n -element max (min) leftist tree can be initialized in $O(n)$ time and two max (min) leftist trees that have a total of n elements may be melded into a single max (min) leftist tree in $O(\log n)$ time.

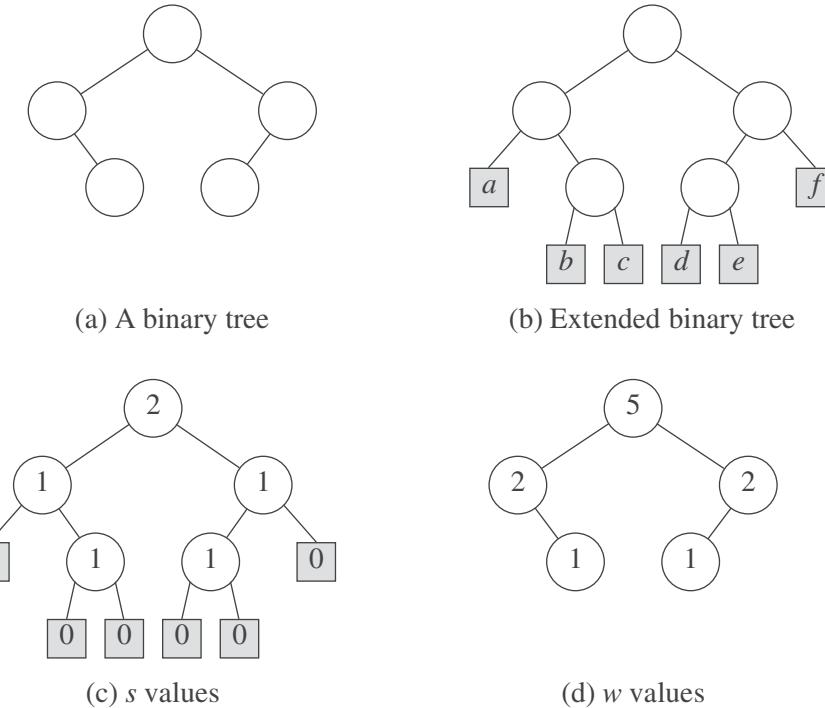

FIGURE 5.1 s and w values. (a) A binary tree. (b) Extended binary tree.

5.2 Height-Biased Leftist Trees

5.2.1 Definition

Consider a binary tree in which a special node called an **external node** replaces each empty subtree. The remaining nodes are called **internal nodes**. A binary tree with external nodes added is called an **extended binary tree**. Figure 5.1a shows a binary tree. Its corresponding extended binary tree is shown in Figure 5.1b. The external nodes appear as shaded boxes. These nodes have been labeled *a* through *f* for convenience.

Let $s(x)$ be the length of a shortest path from node x to an external node in its subtree. From the definition of $s(x)$, it follows that if x is an external node, its s value is 0. Furthermore, if x is an internal node, its s value is

$$\min\{s(L), s(R)\} + 1$$

where L and R are, respectively, the left and right children of x . The s values for the nodes of the extended binary tree of Figure 5.1b appear in Figure 5.1c.

Definition 5.1: (Crane [2]).

A binary tree is a **height-biased leftist tree (HBLT)** iff at every internal node, the s value of the left child is greater than or equal to the s value of the right child.

The binary tree of Figure 5.1a is not an HBLT. To see this, consider the parent of the external node a . The s value of its left child is 0, while that of its right is 1. All other internal nodes satisfy the requirements of the HBLT definition. By swapping the left and right subtrees of the parent of a , the binary tree of Figure 5.1a becomes an HBLT.

Theorem 5.1

Let x be any internal node of an HBLT.

- a. The number of nodes in the subtree with root x is at least $2^{s(x)} - 1$.
 - b. If the subtree with root x has m nodes, $s(x)$ is at most $\log_2(m + 1)$.

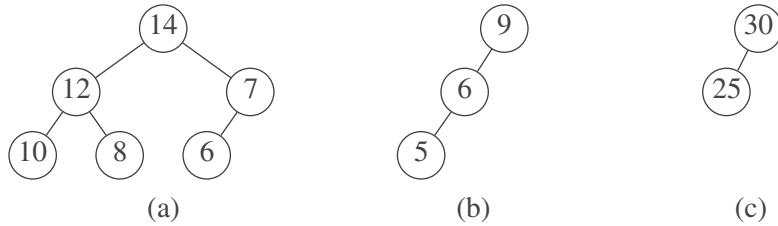

FIGURE 5.2 Some max trees.

- c. The length, $\text{rightmost}(x)$, of the right-most path from x to an external node (i.e., the path obtained by beginning at x and making a sequence of right-child moves) is $s(x)$.

Proof. From the definition of $s(x)$, it follows that there are no external nodes on the $s(x) - 1$ levels immediately below node x (as otherwise the s value of x would be less). The subtree with root x has exactly one node on the level at which x is, two on the next level, four on the next, \dots , and $2^{s(x)-1}$ nodes $s(x) - 1$ levels below x . The subtree may have additional nodes at levels more than $s(x) - 1$ below x . Hence the number of nodes in the subtree x is at least $\sum_{i=0}^{s(x)-1} 2^i = 2^{s(x)} - 1$. Part (b) follows from (a). Part (c) follows from the definition of s and the fact that, in an HBLT, the s value of the left child of a node is always greater than or equal to that of the right child. ■

Definition 5.2

A **max tree** (**min tree**) is a tree in which the value in each node is greater (less) than or equal to those in its children (if any).

Some max trees appear in Figure 5.2, and some min trees appear in Figure 5.3. Although these examples are all binary trees, it is not necessary for a max tree to be binary. Nodes of a max or min tree may have an arbitrary number of children.

Definition 5.3

A **max HBLT** is an HBLT that is also a max tree. A **min HBLT** is an HBLT that is also a min tree.

The max trees of Figure 5.2 as well as the min trees of Figure 5.3 are also HBLTs; therefore, the trees of Figure 5.2 are max HBLTs, and those of Figure 5.3 are min HBLTs. A max priority queue may be represented as a max HBLT, and a min priority queue may be represented as a min HBLT.

5.2.2 Insertion Into a Max HBLT

The insertion operation for max HBLTs may be performed by using the max HBLT meld operation, which combines two max HBLTs into a single max HBLT. Suppose we are to insert an element x into the max HBLT H . If we create a max HBLT with the single element x and then meld this max HBLT and H , the resulting max HBLT will include all elements in H as well as the element x . Hence an insertion may be performed by creating a new max HBLT with just the element that is to be inserted and then melding this max HBLT and the original.

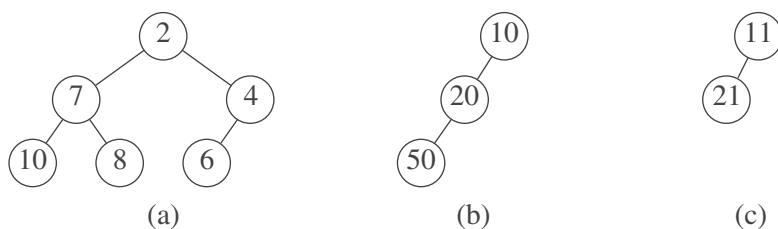

FIGURE 5.3 Some min trees.

5.2.3 Deletion of Max Element from a Max HBLT

The max element is in the root. If the root is deleted, two max HBLTs, the left and right subtrees of the root, remain. By melding together these two max HBLTs, we obtain a max HBLT that contains all elements in the original max HBLT other than the deleted max element. So the delete max operation may be performed by deleting the root and then melding its two subtrees.

5.2.4 Melding Two Max HBLTs

Since the length of the right-most path of an HBLT with n elements is $O(\log n)$, a meld algorithm that traverses only the right-most paths of the HBLTs being melded, spending $O(1)$ time at each node on these two paths, will have complexity logarithmic in the number of elements in the resulting HBLT. With this observation in mind, we develop a meld algorithm that begins at the roots of the two HBLTs and makes right-child moves only.

The meld strategy is best described using recursion. Let A and B be the two max HBLTs that are to be melded. If one is empty, then we may use the other as the result. So assume that neither is empty. To perform the meld, we compare the elements in the two roots. The root with the larger element becomes the root of the melded HBLT. Ties may be broken arbitrarily. Suppose that A has the larger root and that its left subtree is L . Let C be the max HBLT that results from melding the right subtree of A and the max HBLT B . The result of melding A and B is the max HBLT that has A as its root and L and C as its subtrees. If the s value of L is smaller than that of C , then C is the left subtree. Otherwise, L is.

EXAMPLE 5.1

Consider the two max HBLTs of [Figure 5.4a](#). The s value of a node is shown outside the node, while the element value is shown inside. When drawing two max HBLTs that are to be melded, we will always draw the one with larger root value on the left. Ties are broken arbitrarily. Because of this convention, the root of the left HBLT always becomes the root of the final HBLT. Also, we will shade the nodes of the HBLT on the right.

Since the right subtree of 9 is empty, the result of melding this subtree of 9 and the tree with root 7 is just the tree with root 7. We make the tree with root 7 the right subtree of 9 temporarily to get the max tree of [Figure 5.4b](#). Since the s value of the left subtree of 9 is 0 while that of its right subtree is 1, the left and right subtrees are swapped to get the max HBLT of [Figure 5.4c](#).

Next consider melding the two max HBLTs of [Figure 5.4d](#). The root of the left subtree becomes the root of the result. When the right subtree of 10 is melded with the HBLT with root 7, the result is just this latter HBLT. If this HBLT is made the right subtree of 10, we get the max tree of [Figure 5.4e](#). Comparing the s values of the left and right children of 10, we see that a swap is not necessary.

Now consider melding the two max HBLTs of [Figure 5.4f](#). The root of the left subtree is the root of the result. We proceed to meld the right subtree of 18 and the max HBLT with root 10. The two max HBLTs being melded are the same as those melded in [Figure 5.4d](#). The resultant max HBLT ([Figure 5.4e](#)) becomes the right subtree of 18, and the max tree of [Figure 5.4g](#) results. Comparing the s values of the left and right subtrees of 18, we see that these subtrees must be swapped. Swapping results in the max HBLT of [Figure 5.4h](#).

As a final example, consider melding the two max HBLTs of [Figure 5.4i](#). The root of the left max HBLT becomes the root of the result. We proceed to meld the right subtree of 40 and the max HBLT with root 18. These max HBLTs were melded in [Figure 5.4f](#). The resultant max HBLT ([Figure 5.4g](#)) becomes the right subtree of 40. Since the left subtree of 40 has a smaller s value than the right has, the two subtrees are swapped to get the max HBLT of [Figure 5.4k](#). Notice that when melding the max HBLTs of [Figure 5.4i](#), we first move to the right child of 40, then to the right child of 18, and finally to the right child of 10. All moves follow the right-most paths of the initial max HBLTs.

5.2.5 Initialization

It takes $O(n \log n)$ time to initialize a max HBLT with n elements by inserting these elements into an initially empty max HBLT one at a time. To get a linear time initialization algorithm, we begin by creating n max HBLTs with each containing one of the n elements. These n max HBLTs are placed on a FIFO queue. Then max HBLTs are deleted from this queue in pairs, melded, and added to the end of the queue until only one max HBLT remains.

EXAMPLE 5.2

We wish to create a max HBLT with the five elements 7, 1, 9, 11, and 2. Five single-element max HBLTs are created and placed in a FIFO queue. The first two, 7 and 1, are deleted from the queue and melded. The result ([Figure 5.5a](#)) is added to

the queue. Next the max HBLTs 9 and 11 are deleted from the queue and melded. The result appears in [Figure 5.5b](#). This max HBLT is added to the queue. Now the max HBLT 2 and that of [Figure 5.5a](#) are deleted from the queue and melded. The resulting max HBLT ([Figure 5.5c](#)) is added to the queue. The next pair to be deleted from the queue consists of the max HBLTs of Figures [Figure 5.5b](#) and [c](#). These HBLTs are melded to get the max HBLT of [Figure 5.5d](#). This max HBLT is added to the queue. The queue now has just one max HBLT, and we are done with the initialization.

For the complexity analysis of the initialization operation, assume, for simplicity, that n is a power of 2. The first $n/2$ melds involve max HBLTs with one element each, the next $n/4$ melds involve max HBLTs with two elements each; the next $n/8$ melds are with trees that have four elements each; and so on. The time needed to meld two leftist trees with 2^i elements each is $O(i+1)$, and so the total time for the initialization is

$$O(n/2 + 2 * (n/4) + 3 * (n/8) + \dots) = O\left(n \sum \frac{i}{2^i}\right) = O(n)$$

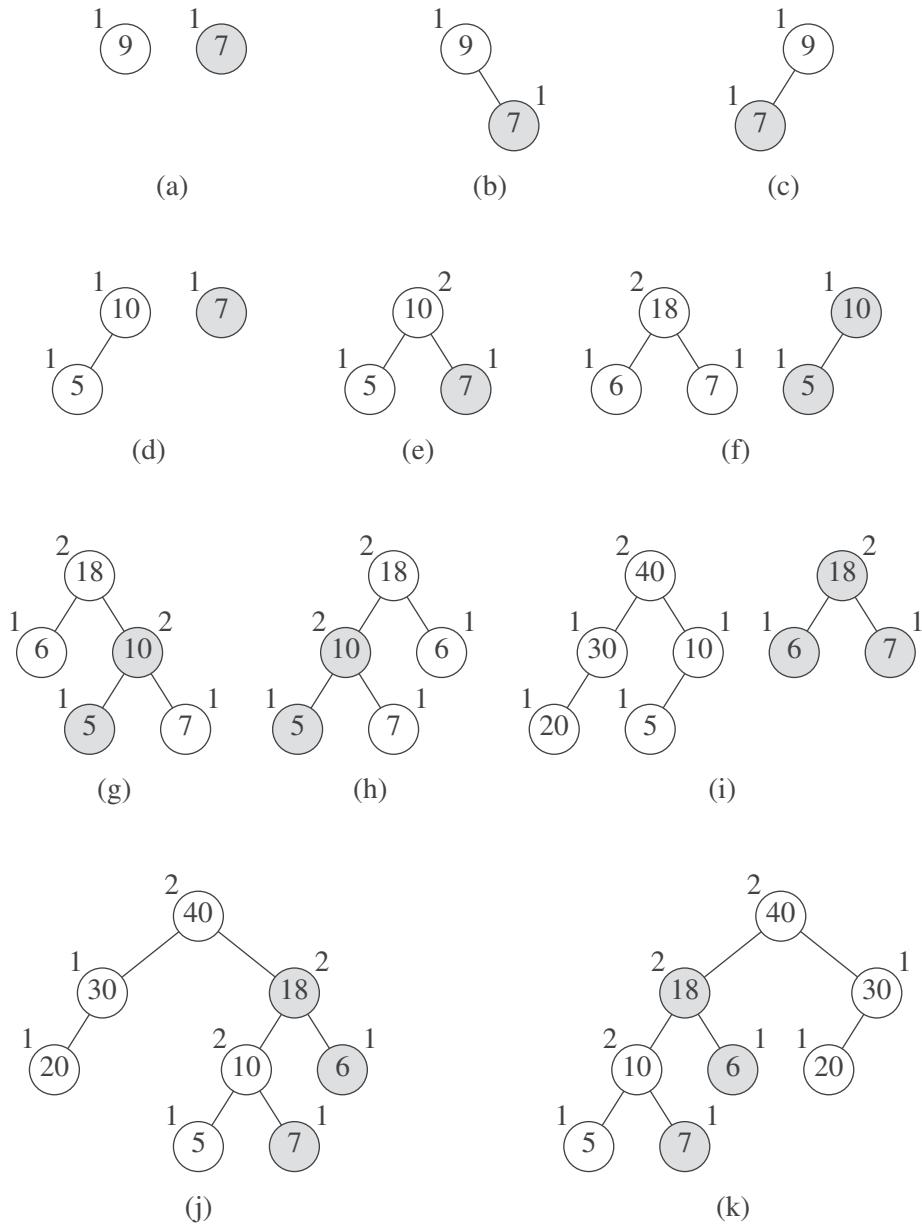

FIGURE 5.4 Melding max HBLTs.

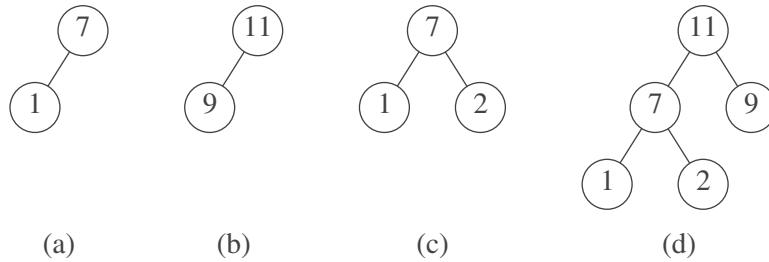

FIGURE 5.5 Initializing a max HBLT.

5.2.6 Deletion of Arbitrary Element from a Max HBLT

Although deleting an element other than the max (min) element is not a standard operation for a max (min) priority queue, an efficient implementation of this operation is required when one wishes to use the generic methods of Cho and Sahni [9] and Chong and Sahni [10] to derive efficient mergeable double-ended priority queue data structures from efficient single-ended priority queue data structures. From a max or min leftist tree, we may remove the element in any specified node *theNode* in $O(\log n)$ time, making the leftist tree a suitable base structure from which an efficient mergeable double-ended priority queue data structure may be obtained [9,10].

To remove the element in the node *theNode* of a height-biased leftist tree, we must do the following:

1. Detach the subtree rooted at *theNode* from the tree and replace it with the meld of the subtrees of *theNode*.
2. Update *s* values on the path from *theNode* to the root and swap subtrees on this path as necessary to maintain the leftist tree property.

To update *s* on the path from *theNode* to the root, we need parent pointers in each node. This upward updating pass stops as soon as we encounter a node whose *s* value does not change. The changed *s* values (with the exception of possibly $O(\log n)$ values from moves made at the beginning from right children) must form an ascending sequence (actually, each must be one more than the preceding one). Since the maximum *s* value is $O(\log n)$ and since all *s* values are positive integers, at most $O(\log n)$ nodes are encountered in the updating pass. At each of these nodes, we spend $O(1)$ time. Therefore, the overall complexity of removing the element in node *theNode* is $O(\log n)$.

5.3 Weight-Biased Leftist Trees

5.3.1 Definition

We arrive at another variety of leftist tree by considering the number of nodes in a subtree, rather than the length of a shortest root to external node path. Define the weight $w(x)$ of node *x* to be the number of internal nodes in the subtree with root *x*. Notice that if *x* is an external node, its weight is 0. If *x* is an internal node, its weight is 1 more than the sum of the weights of its children. The weights of the nodes of the binary tree of Figure 5.1a appear in Figure 5.1d

Definition 5.4: (Cho and Sahni [1]).

A binary tree is a **weight-biased leftist tree (WBLT)** iff at every internal node the *w* value of the left child is greater than or equal to the *w* value of the right child. A max (min) WBLT is a max (min) tree that is also a WBLT.

Note that the binary tree of Figure 5.1a is not a WBLT. However, all three of the binary trees of Figure 5.2 are WBLTs.

Theorem 5.2

Let *x* be any internal node of a weight-biased leftist tree. The length, *rightmost(x)*, of the right-most path from *x* to an external node satisfies

$$rightmost(x) \leq \log_2(w(x) + 1).$$

Proof. The proof is by induction on *w(x)*. When *w(x) = 1*, *rightmost(x) = 1* and $\log_2(w(x) + 1) = \log_2 2 = 1$. For the induction hypothesis, assume that $rightmost(x) \leq \log_2(w(x) + 1)$ whenever $w(x) < n$. Let *RightChild(x)* denote the right child of

x (note that this right child may be an external node). When $w(x) = n$, $w(\text{RightChild}(x)) \leq (n - 1)/2$ and $\text{rightmost}(x) = 1 + \text{rightmost}(\text{RightChild}(x)) \leq 1 + \log_2((n - 1)/2 + 1) = 1 + \log_2(n + 1) - 1 = \log_2(n + 1)$. \blacksquare

5.3.2 Max WBLT Operations

Insert, delete max, and initialization are analogous to the corresponding max HBLT operation. However, the meld operation can be done in a single top-to-bottom pass (recall that the meld operation of an HBLT performs a top-to-bottom pass as the recursion unfolds and then a bottom-to-top pass in which subtrees are possibly swapped and s -values updated). A single-pass meld is possible for WBLTs because we can determine the w values on the way down and so, on the way down, we can update w -values and swap subtrees as necessary. For HBLTs, a node's new s value cannot be determined on the way down the tree.

Since the meld operation of a WBLT may be implemented using a single top-to-bottom pass, inserts and deletes also use a single top-to-bottom pass. Because of this, inserts and deletes are faster, by a constant factor, in a WBLT than in an HBLT [1]. However, from a WBLT, we cannot delete the element in an arbitrarily located node, theNode , in $O(\log n)$ time. This is because theNode may have $O(n)$ ancestors whose w value is to be updated. So, WBLTs are not suitable for mergeable double-ended priority queue applications [8,9].

C++ and Java codes for HBLTs and WBLTs may be obtained from [11,12], respectively.

6.1 Introduction

Priority Queue is one of the most extensively studied *Abstract Data Types* (ADT) due to its fundamental importance in the context of resource managing systems, such as operating systems. *Priority Queues* work on finite subsets of a totally ordered universal set U . Without any loss of generality we assume that U is simply the set of all non-negative integers. In its simplest form, a *Priority Queue* supports two operations, namely,

- $\text{insert}(x, S)$: update S by adding an arbitrary $x \in U$ to S .
- $\text{delete-min}(S)$: update S by removing from S the minimum element of S .

We will assume for the sake of simplicity, all the items of S are distinct. Thus, we assume that $x \notin S$ at the time of calling $\text{insert}(x, S)$. This increases the cardinality of S , denoted usually by $|S|$, by one. The well-known data structure *Heaps*, provide an elegant and efficient implementation of *Priority Queues*. In the *Heap* based implementation, both $\text{insert}(x, S)$ and $\text{delete-min}(S)$ take $O(\log n)$ time where $n = |S|$.

Several extensions for the basic *Priority Queues* were proposed and studied in response to the needs arising in several applications. For example, if an operating system maintains a set of jobs, say print requests, in a priority queue, then, always, the jobs with “high priority” are serviced irrespective of when the job was queued up. This might mean some kind of “unfairness” for low priority jobs queued up earlier. In order to straighten up the situation, we may extend priority queue to support *delete-max* operation and arbitrarily mix *delete-min* and *delete-max* operations to avoid any undue stagnation in the queue. Such priority queues are called *Double Ended Priority Queues*. It is easy to see that *Heap* is not an appropriate data structure for *Double Ended Priority Queues*. Several interesting alternatives are available in the literature [1–3]. You may also refer [Chapter 8](#) of this handbook for a comprehensive discussion on these structures.

In another interesting extension, we consider adding an operation called *melding*. A *meld* operation takes two disjoint sets, S_1 and S_2 , and produces the set $S = S_1 \cup S_2$. In terms of an implementation, this requirement translates to building a data structure for S , given the data structures of S_1 and S_2 . A *Priority Queue* with this extension is called a *Meldable Priority Queue*. Consider a scenario where an operating system maintains two different priority queues for two printers and one of the printers is down with some problem during operation. *Meldable Priority Queues* naturally model such a situation.

Again, maintaining the set items in *Heaps* results in very inefficient implementation of *Meldable Priority Queues*. Specifically, designing a data structure with $O(\log n)$ bound for each of the *Meldable Priority Queue* operations calls for more sophisticated ideas and approaches. An interesting data structure called *Leftist Trees*, implements all the operations of *Meldable Priority Queues* in $O(\log n)$ time. *Leftist Trees* are discussed in [Chapter 5](#) of this handbook.

The main objective behind the design of a data structure for an ADT is to implement the ADT operations as efficiently as possible. Typically, efficiency of a structure is judged by its worst-case performance. Thus, when designing a data structure, we seek to minimize the worst case complexity of each operation. While this is a most desirable goal and has been theoretically realized for a number of data structures for key ADTs, the data structures optimizing worst-case costs of ADT operations are

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

often very complex and pretty tedious to implement. Hence, computer scientists were exploring alternative design criteria that would result in simpler structures without losing much in terms of performance. In [Chapter 14](#) of this handbook, we show that incorporating randomness provides an attractive alternative avenue for designers of the data structures. In this chapter we will explore yet another design goal leading to simpler structural alternatives without any degrading in overall performance.

Since the data structures are used as basic building blocks for implementing algorithms, a typical execution of an algorithm might consist of a sequence of operations using the data structure over and again. In the worst case complexity based design, we seek to reduce the cost of each operation as much as possible. While this leads to an overall reduction in the cost for the sequence of operations, this poses some constraints on the designer of data structure. We may relax the requirement that the cost of each operation be minimized and perhaps design data structures that seek to minimize the total cost of any sequence of operations. Thus, in this new kind of design goal, we will not be terribly concerned with the cost of any individual operations, but worry about the total cost of any sequence of operations. At first thinking, this might look like a formidable goal as we are attempting to minimize the cost of an arbitrary mix of ADT operations and it may not even be entirely clear how this design goal could lead to simpler data structures. Well, it is typical of a novel and deep idea; at first attempt it may puzzle and bamboozle the learner and with practice one tends to get a good intuitive grasp of the intricacies of the idea. This is one of those ideas that requires some getting used to. In this chapter, we discuss about a data structure called *Skew heaps*. For any sequence of a *Meldable Priority Queue* operations, its total cost on *Skew Heaps* is asymptotically same as its total cost on *Leftist Trees*. However, *Skew Heaps* are a bit simpler than *Leftist Trees*.

6.2 Basics of Amortized Analysis

We will now clarify the subtleties involved in the new design goal with an example. Consider a typical implementation of *Dictionary* operations. The so called Balanced Binary Search Tree structure (BBST) implements these operations in $O(m \log n)$ worst case bound. Thus, the total cost of an arbitrary sequence of m dictionary operations, each performed on a tree of size at most n , will be $O(\log n)$. Now we may turn around and ask: Is there a data structure on which the cost of a sequence of m dictionary operations is $O(m \log n)$ but individual operations are not constrained to have $O(\log n)$ bound? Another more pertinent question to our discussion - Is that structure simpler than BBST, at least in principle? An affirmative answer to both the questions is provided by a data structure called *Splay Trees*. *Splay Tree* is the theme of [Chapter 13](#) of this handbook.

Consider for example a sequence of m dictionary operations S_1, S_2, \dots, S_m , performed using a BBST. Assume further that the size of the tree has never exceeded n during the sequence of operations. It is also fairly reasonable to assume that we begin with an empty tree and this would imply $n \leq m$. Let the actual cost of executing S_i be C_i . Then the total cost of the sequence of operations is $C_1 + C_2 + \dots + C_m$. Since each C_i is $O(\log n)$ we easily conclude that the total cost is $O(m \log n)$. No big arithmetic is needed and the analysis is easily finished. Now, assume that we execute the same sequence of m operations but employ a *Splay Tree* in stead of a BBST. Assuming that c_i is the actual cost of S_i in a *Splay Tree*, the total cost for executing the sequence of operation turns out to be $c_1 + c_2 + \dots + c_m$. This sum, however, is tricky to compute. This is because a wide range of values are possible for each of c_i and no upper bound other than the trivial bound of $O(n)$ is available for c_i . Thus, a naive, worst case cost analysis would yield only a weak upper bound of $O(nm)$ whereas the actual bound is $O(m \log n)$. But how do we arrive at such improved estimates?

This is where we need yet another powerful tool called *potential function*.

The potential function is purely a conceptual entity and this is introduced only for the sake of computing a sum of widely varying quantities in a convenient way. Suppose there is a function $f:D \rightarrow R^+ \cup \{0\}$, that maps a configuration of the data structure to a non-negative real number. We shall refer to this function as potential function. Since the data type as well as data structures are typically dynamic, an operation may change the configuration of data structure and hence there may be change of potential value due to this change of configuration. Referring back to our sequence of operations S_1, S_2, \dots, S_m , let D_{i-1} denote the configuration of data structure before the executing the operation S_i and D_i denote the configuration after the execution of S_i . The potential difference due to this operation is defined to be the quantity $f(D_i) - f(D_{i-1})$. Let c_i denote the actual cost of S_i . We will now introduce yet another quantity, a_i , defined by

$$a_i = c_i + f(D_i) - f(D_{i-1}).$$

What is the consequence of this definition?

Note that $\sum_{i=1}^m a_i = \sum_{i=1}^m c_i + f(D_m) - f(D_0)$.

Let us introduce one more reasonable assumption that $f(D_0) = f(\phi) = 0$. Since $f(D) \geq 0$ for all non empty structures, we obtain,

$$\sum a_i = \sum c_i + f(D_m) \geq \sum c_i$$

If we are able to choose cleverly a “good” potential function so that a_i ’s have tight, uniform bound, then we can evaluate the sum $\sum a_i$ easily and this bounds the actual cost sum $\sum c_i$. In other words, we circumvent the difficulties posed by wide variations

in c_i by introducing new quantities a_i which have uniform bounds. A very neat idea indeed! However, care must be exercised while defining the potential function. A poor choice of potential function will result in a_i s whose sum may be a trivial or useless bound for the sum of actual costs. In fact, arriving at the right potential function is an ingenious task, as you will understand by the end of this chapter or by reading the chapter on *Splay Trees*.

The description of the data structures such as *Splay Trees* will not look any different from the description of a typical data structures—it comprises of a description of the organization of the primitive data items and a bunch of routines implementing ADT operations. The key difference is that the routines implementing the ADT operations will not be analyzed for their individual worst case complexity. We will only be interested in the cumulative effect of these routines in an arbitrary sequence of operations. Analyzing the average potential contribution of an operation in an arbitrary sequence of operations is called *amortized analysis*. In other words, the routines implementing the ADT operations will be analyzed for their *amortized cost*. Estimating the amortized cost of an operation is rather an intricate task. The major difficulty is in accounting for the wide variations in the costs of an operation performed at different points in an arbitrary sequence of operations. Although our design goal is influenced by the costs of sequence of operations, defining the notion of amortized cost of an operation in terms of the costs of sequences of operations leads one nowhere. As noted before, using a potential function to offset the variations in the actual costs is a neat way of handling the situation.

In the next definition we formalize the notion of amortized cost.

Definition 6.1: (Amortized Cost)

Let A be an ADT with basic operations $O = \{O_1, O_2, \dots, O_k\}$ and let D be a data structure implementing A . Let f be a potential function defined on the configurations of the data structures to non-negative real number. Assume further that $f(\Phi) = 0$. Let D' denote a configuration we obtain if we perform an operation O_k on a configuration D and let c denote the actual cost of performing O_k on D . Then, the amortized cost of O_k operating on D , denoted as $a(O_k, D)$, is given by

$$a(O_k, D) = c + f(D') - f(D)$$

If $a(O_k, D) \leq c'g(n)$ for all configuration D of size n , then we say that the amortized cost of O_k is $O(g(n))$.

Theorem 6.1

Let D be a data structure implementing an ADT and let s_1, s_2, \dots, s_m denote an arbitrary sequence of ADT operations on the data structure starting from an empty structure D_0 . Let c_i denote actual cost of the operation s_i and D_i denote the configuration obtained which s_i operated on D_{i-1} , for $1 \leq i \leq m$. Let a_i denote the amortized cost of s_i operating on D_{i-1} with respect to an arbitrary potential function. Then,

$$\sum_{i=1}^m c_i \leq \sum_{i=1}^m a_i.$$

Proof. Since a_i is the amortized cost of s_i working on the configuration D_{i-1} , we have

$$a_i = a(s_i, D_{i-1}) = c_i + f(D_i) - f(D_{i-1})$$

Therefore,

$$\begin{aligned} \sum_{i=1}^m a_i &= \sum_{i=1}^m c_i + (f(D_m) - f(D_0)) \\ &= f(D_m) + \sum_{i=1}^m c_i \quad (\text{since } f(D_0) = 0) \\ &\geq \sum_{i=1}^m c_i \end{aligned}$$

■

Remark 6.1

The potential function is common to the definition of amortized cost of all the ADT operations. Since $\sum_{i=1}^m a_i \geq \sum_{i=1}^m c_i$ holds good for any potential function, a clever choice of the potential function will yield tight upper bound for the sum of actual cost of a sequence of operations.

6.3 Meldable Priority Queues and Skew Heaps

Definition 6.2: (Skew Heaps)

A Skew Heap is simply a binary tree. Values are stored in the structure, one per node, satisfying the *heap-order property*: A value stored at a node is larger than the value stored at its parent, except for the root (as root has no parent).

Remark 6.2

Throughout our discussion, we handle sets with distinct items. Thus a set of n items is represented by a skew heap of n nodes. The minimum of the set is always at the root. On any path starting from the root and descending towards a leaf, the values are in increasing order.

6.3.1 Meldable Priority Queue Operations

Recall that a *Meldable Priority queue* supports three key operations: *insert*, *delete-min* and *meld*. We will first describe the *meld* operation and then indicate how other two operations can be performed in terms of the *meld* operation.

Let S_1 and S_2 be two sets and H_1 and H_2 be *Skew Heaps* storing S_1 and S_2 respectively. Recall that $S_1 \cap S_2 = \emptyset$. The *meld* operation should produce a single *Skew Heap* storing the values in $S_1 \cup S_2$. The procedure *meld* (H_1, H_2) consists of two phases. In the first phase, the two right most paths are merged to obtain a single right most path. This phase is pretty much like the merging algorithm working on sorted sequences. In this phase, the left subtrees of nodes in the right most paths are not disturbed. In the second phase, we simply swap the children of every node on the merged path except for the lowest. This completes the process of *melding*.

[Figures 6.1–6.3](#) clarify the phases involved in the *meld* routine.

[Figure 6.1](#) shows two *Skew Heaps* H_1 and H_2 . In [Figure 6.2](#) we have shown the scenario after the completion of the first phase. Notice that right most paths are merged to obtain the right most path of a single tree, keeping the respective left subtrees intact. The final *Skew Heap* is obtained in [Figure 6.3](#). Note that left and right child of every node on the right most path of the tree in [Figure 6.2](#) (except the lowest) are swapped to obtain the final *Skew Heap*.

It is easy to implement *delete-min* and *insert* in terms of the *meld* operation. Since minimum is always found at the root, *delete-min* is done by simply removing the root and *melding* its left subtree and right subtree. To *insert* an item x in a *Skew Heap* H_1 , we create a *Skew Heap* H_2 consisting of only one node containing x and then *meld* H_1 and H_2 . From the above discussion, it is clear that cost of *meld* essentially determines the cost of *insert* and *delete-min*. In the next section, we analyze the amortized cost of *meld* operation.

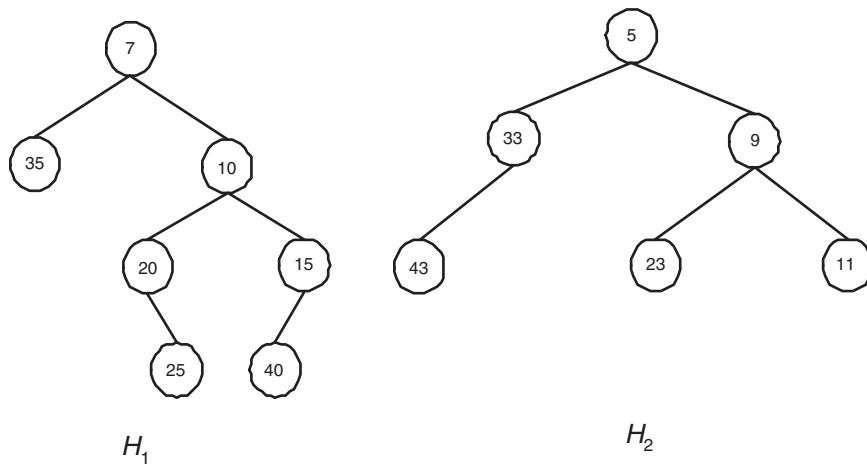

FIGURE 6.1 Skew Heaps for *meld* operation.

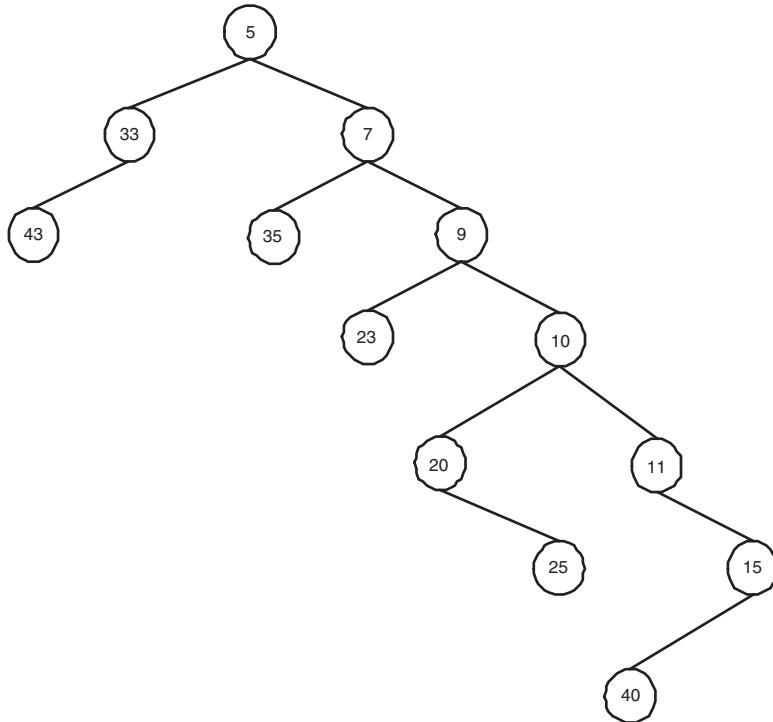

FIGURE 6.2 Rightmost paths are merged. Left subtrees of nodes in the merged path are intact.

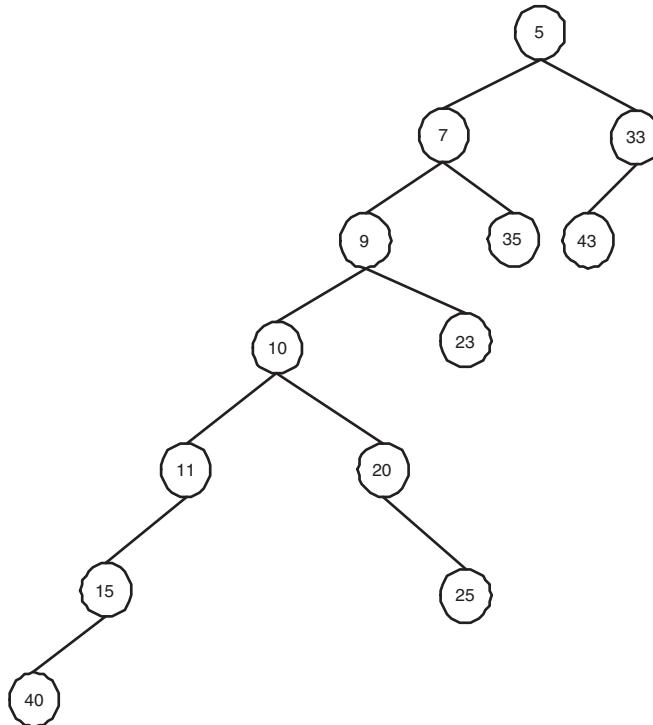

FIGURE 6.3 Left and right children of nodes (5), (7), (9), (10), (11) of Figure 6.2 are swapped. Notice that the children of (15) which is the lowest node in the merged path, are not swapped.

6.3.2 Amortized Cost of Meld Operation

At this juncture we are left with the crucial task of identifying a suitable potential function. Before proceeding further, perhaps one should try the implication of certain simple potential functions and experiment with the resulting amortized cost. For example, you may try the function $f(D) = \text{number of nodes in } D$ (and discover how ineffective it is!).

We need some definitions to arrive at our potential function.

Definition 6.3

For any node x in a binary tree, the weight of x , denoted $wt(x)$, is the number of descendants of x , including itself. A non-root node x is said to be heavy if $wt(x) > wt(\text{parent}(x))/2$. A non-root node that is not heavy is called light. The root is neither light nor heavy.

The next lemma is an easy consequence of the definition given above. All logarithms in this section have base 2.

Lemma 6.1

For any node, at most one of its children is heavy. Furthermore, any root to leaf path in a n -node tree contains at most $\lfloor \log n \rfloor$ light nodes.

Definition 6.4: (Potential Function)

A non-root is called *right* if it is the right child of its parent; it is called *left* otherwise. The potential of a skew heap is the number of right heavy node it contains. That is, $f(H) = \text{number of right heavy nodes in } H$. We extend the definition of potential function to a collection of skew heaps as follows: $f(H_1, H_2, \dots, H_t) = \sum_{i=1}^t f(H_i)$.

Here is the key result of this chapter.

Theorem 6.2

Let H_1 and H_2 be two heaps with n_1 and n_2 nodes respectively. Let $n = n_1 + n_2$. The amortized cost of meld (H_1, H_2) is $O(\log n)$.

Proof. Let h_1 and h_2 denote the number of heavy nodes in the right most paths of H_1 and H_2 respectively. The number of light nodes on them will be at most $\lfloor \log n_1 \rfloor$ and $\lfloor \log n_2 \rfloor$ respectively. Since a node other than root is either heavy or light, and there are two root nodes here that are neither heavy or light, the total number of nodes in the right most paths is at most

$$2 + h_1 + h_2 + \lfloor \log n_1 \rfloor + \lfloor \log n_2 \rfloor \leq 2 + h_1 + h_2 + 2 \lfloor \log n \rfloor$$

Thus we get a bound for actual cost c as

$$c \leq 2 + h_1 + h_2 + 2 \lfloor \log n \rfloor \quad (6.1)$$

In the process of swapping, the $h_1 + h_2$ nodes that were *right heavy*, will lose their status as *right heavy*. While they remain heavy, they become left children for their parents hence they do not contribute for the potential of the output tree and this means a drop in potential by $h_1 + h_2$. However, the swapping might have created new heavy nodes and let us say, the number of new heavy nodes created in the swapping process is h_3 . First, observe that all these h_3 new nodes are attached to the left most path of the output tree. Secondly, by Lemma 6.1, for each one of these right heavy nodes, its sibling in the left most path is a light node. However, the number of light nodes in the left most path of the output tree is less than or equal to $\lfloor \log n \rfloor$ by Lemma 6.1.

Thus $h_3 \leq \lfloor \log n \rfloor$. Consequently, the net change in the potential is $h_3 - h_1 - h_2 \leq \lfloor \log n \rfloor - h_1 - h_2$.

$$\begin{aligned} \text{The amortized cost} &= c + \text{potential difference} \\ &\leq 2 + h_1 + h_2 + 2 \lfloor \log n \rfloor + \lfloor \log n \rfloor - h_1 - h_2 \\ &= 3 \lfloor \log n \rfloor + 2. \end{aligned}$$

Hence, the amortized cost of meld operation is $O(\log n)$ and this completes the proof. ■

Since *insert* and *delete-min* are handled as special cases of *meld* operation, we conclude

Theorem 6.3

The amortized cost complexity of all the Meldable Priority Queue operations is $O(\log n)$ where n is the number of nodes in skew heap or heaps involved in the operation.

6.4 Bibliographic Remarks

Skew Heaps were introduced by Sleator and Tarjan [4]. *Leftist Trees* have $O(\log n)$ worst case complexity for all the *Meldable Priority Queue* operations but they require heights of each subtree to be maintained as additional information at each node. *Skew Heaps* are simpler than *Leftist Trees* in the sense that no additional ‘balancing’ information need to be maintained and the *meld* operation simply swaps the children of the right most path without any constraints and this results in a simpler code. The bound $3 \log_2 n + 2$ for *melding* was significantly improved to $\log_\phi n$ (here ϕ denotes the well-known *golden ratio* $(\sqrt{5} + 1)/2$ which is roughly 1.6) by using a different potential function and an intricate analysis in Reference 5. Recently, this bound was shown to be tight in Reference 6. *Pairing Heap*, introduced by Fredman et al. [7], is yet another self-adjusting heap structure and its relation to *Skew Heaps* is explored in Chapter 7 of this handbook.

7.1 Introduction

This chapter presents three algorithmically related data structures for implementing meldable priority queues: binomial heaps, Fibonacci heaps, and pairing heaps. What these three structures have in common is that (a) they are comprised of heap-ordered trees, (b) the comparisons performed to execute extractmin operations exclusively involve keys stored in the roots of trees, and (c) a common side effect of a comparison between two root keys is the linking of the respective roots: one tree becomes a new subtree joined to the other root.

A tree is considered heap-ordered provided that each node contains one item, and the key of the item stored in the parent $p(x)$ of a node x never exceeds the key of the item stored in x . Thus when two roots get linked, the root storing the larger key becomes a child of the other root. By convention, a linking operation positions the new child of a node as its leftmost child. [Figure 7.1](#) illustrates these notions.

Of the three data structures, the binomial heap structure was the first to be invented [1], designed to efficiently support the operations: insert, extractmin, delete, and meld. The binomial heap has been highly appreciated as an elegant and conceptually simple data structure, particularly given its ability to support the meld operation. The Fibonacci heap data structure [2] was inspired by and can be viewed as a generalization of the binomial heap structure. The raison d'être of the Fibonacci heap structure is its ability to efficiently execute decrease-key operations. A decrease-key operation replaces the key of an item, specified by location, by a smaller value, for example, $\text{decrease-key}(P, k_{\text{new}}, H)$. (The arguments specify that the item is located in node P of the priority queue H and that its new key value is k_{new} .) Decrease-key operations are prevalent in many network optimization algorithms, including minimum spanning tree and shortest path. The pairing heap data structure [3] was devised as a self-adjusting analogue of the Fibonacci heap and has proved to be more efficient in practice [4].

Binomial heaps and Fibonacci heaps are primarily of theoretical and historical interest. The pairing heap is the more efficient and versatile data structure from a practical standpoint. The following three sections describe the respective data structures.

7.2 Binomial Heaps

We begin with an informal overview. A single binomial heap structure consists of a forest of specially structured trees, referred to as binomial trees. The number of nodes in a binomial tree is always a power of two. Defined recursively, the binomial tree B_0 consists of a single node. The binomial tree B_k , for $k > 0$, is obtained by linking two trees B_{k-1} together: one tree becomes the leftmost subtree of the other. In general, B_k has 2^k nodes. [Figures 7.2a](#) and b illustrate the recursion and show several trees in the series. An alternative and useful way to view the structure of B_k is depicted in [Figure 7.2c](#): B_k consists of a root and subtrees (in order from left to right) $B_{k-1}, B_{k-2}, \dots, B_0$. The root of the binomial tree B_k has k children, and the tree is said to have rank k .

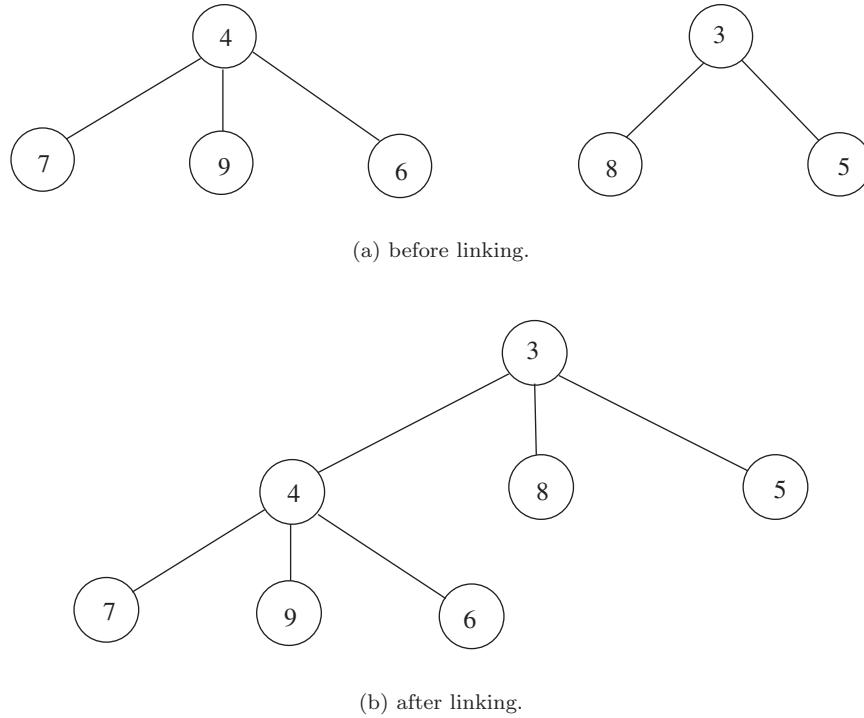

FIGURE 7.1 Two heap-ordered trees and the result of their linking: (a) before linking and (b) after linking.

We also observe that the height of B_k (maximum number of edges on any path directed away from the root) is k . The name “binomial heap” is inspired by the fact that the root of B_k has $\binom{k}{j}$ descendants at distance j .

Because binomial trees have restricted sizes, a forest of trees is required to represent a priority queue of arbitrary size. A key observation, indeed a motivation for having tree sizes being powers of two, is that a priority queue of arbitrary size can be represented as a union of trees of *distinct* sizes. (In fact, the sizes of the constituent trees are uniquely determined and correspond to the powers of two that define the binary expansion of n , the size of the priority queue.) Moreover, because the tree sizes are unique, the number of trees in the forest of a priority queue of size n is at most $\lg(n+1)$. Thus finding the minimum key in the priority queue, which clearly lies in the root of one of its constituent trees (due to the heap-order condition), requires searching among at most $\lg(n+1)$ tree roots. [Figure 7.3](#) gives an example of binomial heap.

Now let’s consider, from a high-level perspective, how the various heap operations are performed. As with leftist heaps (cf. [Chapter 5](#)), the various priority queue operations are to a large extent comprised of melding operations, and so we consider first the melding of two heaps.

The melding of two heaps proceeds as follows: (a) the trees of the respective forests are combined into a single forest and then (b) *consolidation* takes place: pairs of trees having common rank are linked together until all remaining trees have distinct ranks. [Figure 7.4](#) illustrates the process. An actual implementation mimics binary addition and proceeds in much the same was as merging two sorted lists in ascending order. We note that insertion is a special case of melding.

The extractmin operation is performed in two stages. First, the *minimum root*, the node containing the minimum key in the data structure, is found by examining the tree roots of the appropriate forest, and this node is removed. Next, the forest consisting of the subtrees of this removed root, whose ranks are distinct (see [Figure 7.2c](#)) and thus viewable as constituting a binomial heap, is melded with the forest consisting of the trees that remain from the original forest. [Figure 7.5](#) illustrates the process.

Finally, we consider arbitrary deletion. We assume that the node v containing the item to be deleted is specified. Proceeding up the path to the root of the tree containing v , we permute the items among the nodes on this path, placing in the root the item x originally in v , and shifting each of the other items down one position (away from the root) along the path. This is accomplished through a sequence of exchange operations that move x towards the root. The process is referred to as a *sift-up* operation. Upon reaching the root r , r is then removed from the forest as though an extractmin operation is underway. Observe that the repositioning of items in the ancestors of v serves to maintain the heap-order property among the remaining nodes of the forest. [Figure 7.6](#) illustrates the repositioning of the item being deleted to the root.

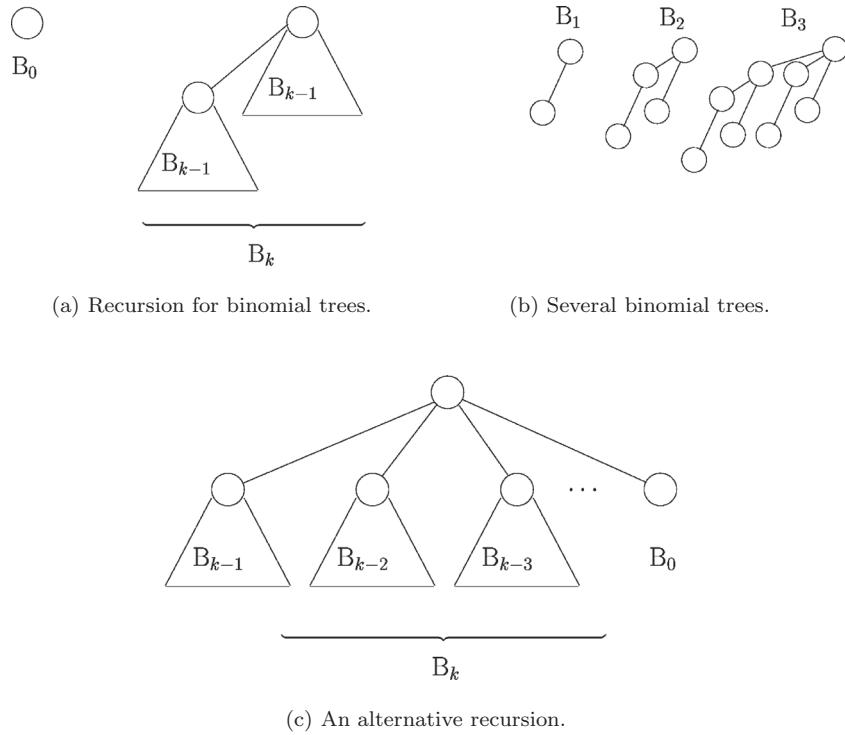

FIGURE 7.2 Binomial trees and their recursions: (a) recursion for binomial trees, (b) several binomial trees, and (c) an alternative recursion.

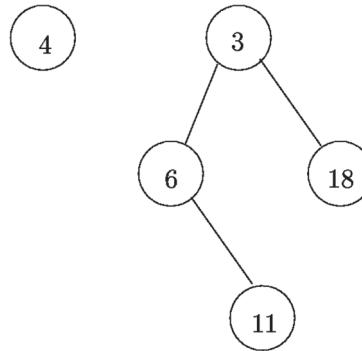

FIGURE 7.3 A binomial heap (showing placement of keys among forest nodes).

This completes our high-level descriptions of the heap operations. For navigational purposes, each node contains a leftmost child pointer and a sibling pointer that points to the next sibling to its right. The children of a node are thus stored in the linked list defined by sibling pointers among these children, and the head of this list can be accessed by the leftmost child pointer of the parent. This provides the required access to the children of a node for the purpose of implementing extractmin operations. Note that when a node obtains a new child as a consequence of a linking operation, the new child is positioned at the head of its list of siblings. To facilitate arbitrary deletions, we need a third pointer in each node pointing to its parent. To facilitate access to the ranks of trees, we maintain in each node the number of children it has, and refer to this quantity as the node rank. Node ranks are readily maintained under linking operations; the node rank of the root gaining a child gets incremented. [Figure 7.7](#) depicts these structural features.

As seen in [Figure 7.2c](#), the ranks of the children of a node form a descending sequence in the children's linked list. However, since the melding operation is implemented by accessing the tree roots in ascending rank order, when deleting a root we first reverse the list order of its children before proceeding with the melding.

Each of the priority queue operations requires in the worst case $O(\log n)$ time, where n is the size of the heap that results from the operation. This follows, for melding, from the fact that its execution time is proportional to the combined lengths of the forest

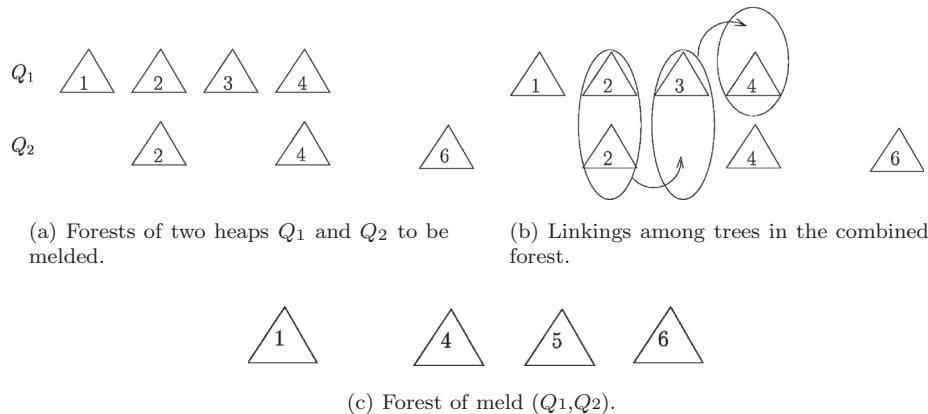

FIGURE 7.4 Melding of two binomial heaps. The encircled objects reflect trees of common rank being linked. (Ranks are shown as numerals positioned within triangles which in turn represent individual trees.) Once linking takes place, the resulting tree becomes eligible for participation in further linkings, as indicated by the arrows that identify these linking results with participants of other linkings. (a) Forests of two heaps Q_1 and Q_2 to be melded. (b) Linkings among trees in the combined forest. (c) Forest of meld (Q_1, Q_2).

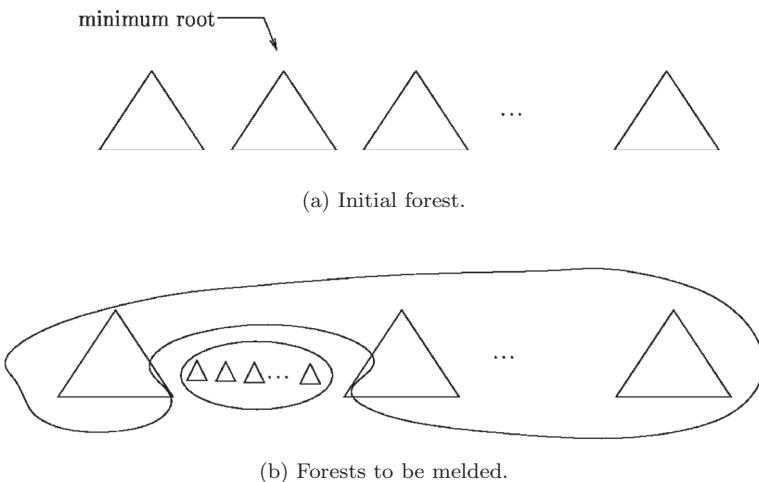

FIGURE 7.5 Extractmin operation: The location of the minimum key is indicated in (a). The two encircled sets of trees shown in (b) represent forests to be melded. The smaller trees were initially subtrees of the root of the tree referenced in (a).

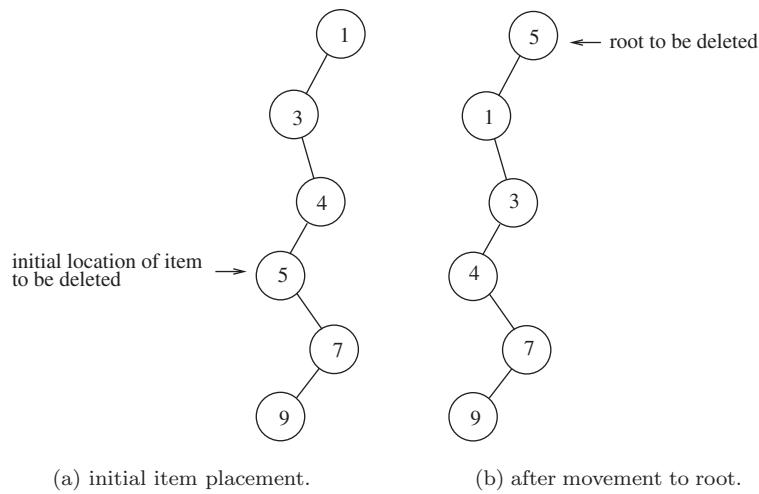

FIGURE 7.6 Initial phase of deletion—sift-up operation: (a) initial item placement and (b) after movement to root.

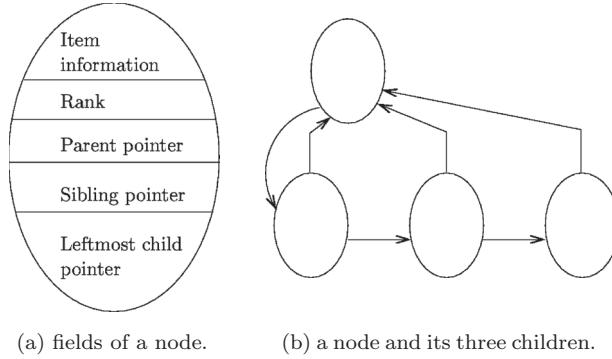

FIGURE 7.7 Structure associated with a binomial heap node: (a) fields of a node and (b) a node and its three children.

lists being merged. For extractmin, this follows from the time for melding, along with the fact that a root node has only $O(\log n)$ children. For arbitrary deletion, the time required for the sift-up operation is bounded by an amount proportional to the height of the tree containing the item. Including the time required for extractmin, it follows that the time required for arbitrary deletion is $O(\log n)$.

A detailed code for manipulating binomial heaps can be found in Weiss [5].

7.3 Fibonacci Heaps

Fibonacci heaps were specifically designed to efficiently support decrease-key operations. For this purpose, the binomial heap can be regarded as a natural starting point. Why? Consider the class of priority queue data structures that are implemented as forests of heap-ordered trees, as will be the case for Fibonacci heaps. One way to immediately execute a decrease-key operation, remaining within the framework of heap-ordered forests, is to simply change the key of the specified data item and sever its link to its parent, inserting the severed subtree as a new tree in the forest. [Figure 7.8](#) illustrates the process. (Observe that the link to the parent only needs to be cut if the new key value is smaller than the key in the parent node, violating heap order.) Fibonacci heaps accomplish this without degrading the asymptotic efficiency with which other priority queue operations can be supported. Observe that to accommodate node cuts, the list of children of a node needs to be doubly linked. Hence, the nodes of a Fibonacci heap require two sibling pointers.

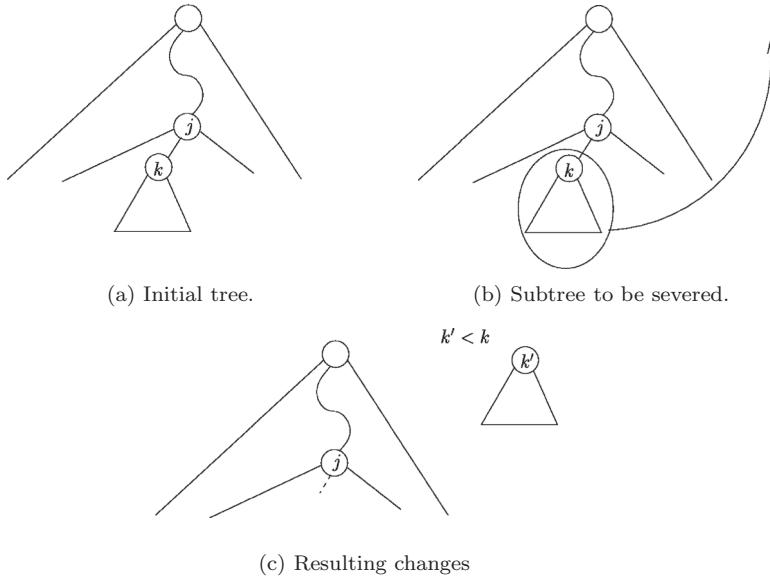

FIGURE 7.8 Immediate decrease-key operation. The subtree severing (b and c) is necessary only when $k' < j$. (a) Initial tree. (b) Subtree to be severed. (c) Resulting changes.

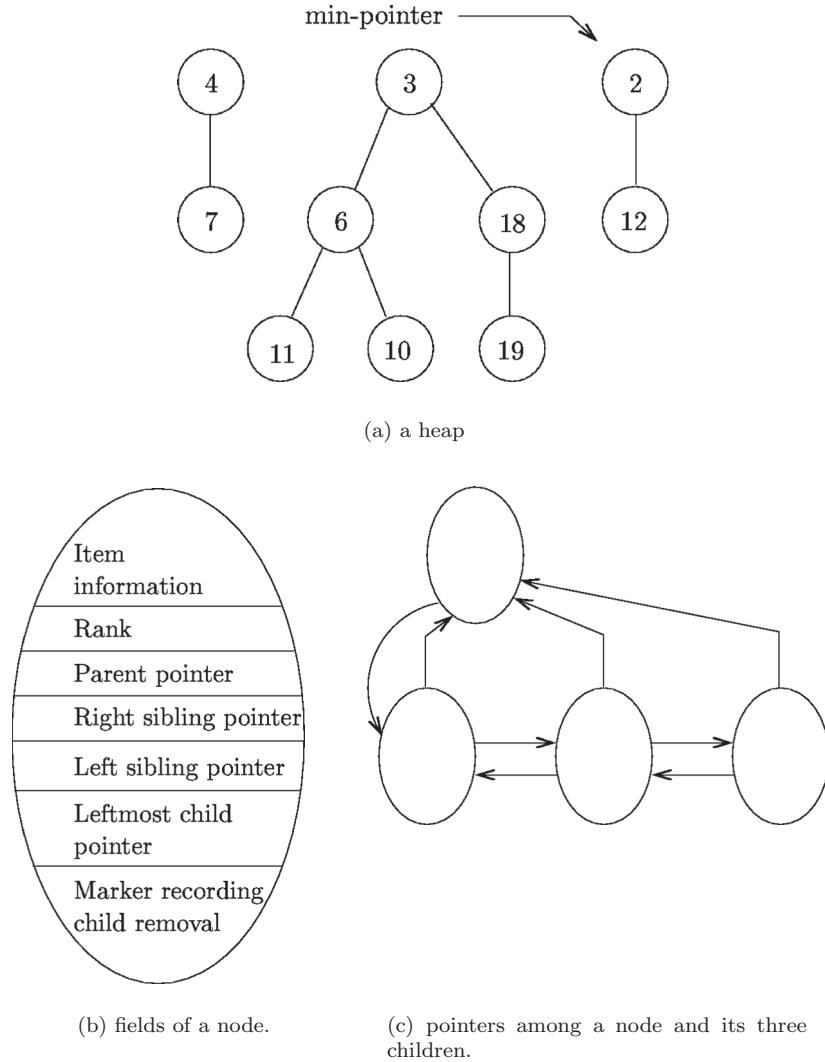

FIGURE 7.9 A Fibonacci heap and associated structure: (a) a heap, (b) fields of a node, and (c) pointers among a node and its three children.

Fibonacci heaps support *findmin*, *insertion*, *meld*, and *decrease-key* operations in constant amortized time, and deletion operations in $O(\log n)$ amortized time. For many applications, the distinction between worst-case times versus amortized times is of little significance. A Fibonacci heap consists of a forest of heap-ordered trees. As we shall see, Fibonacci heaps differ from binomial heaps in that there may be many trees in a forest of the same rank, and there is no constraint on the ordering of the trees in the forest list. The heap also includes a pointer to the tree root containing the minimum item, referred to as the *min-pointer*, that facilitates *findmin* operations. Figure 7.9 provides an example of a Fibonacci heap and illustrates certain structural aspects.

The impact of severing subtrees is clearly incompatible with the pristine structure of the binomial tree that is the hallmark of the binomial heap. Nevertheless, the tree structures that can appear in the Fibonacci heap data structure must sufficiently approximate binomial trees in order to satisfy the performance bounds we seek. The linking constraint imposed by binomial heaps, that trees being linked must have the same size, ensures that the number of children a node has (its rank), grows no faster than the logarithm of the size of the subtree rooted at the node. This *rank versus subtree size* relation is the key to obtaining the $O(\log n)$ deletion time bound. Fibonacci heap manipulations are designed with this in mind.

Fibonacci heaps utilize a protocol referred to as *cascading cuts* to enforce the required rank versus subtree size relation. Once a node v has had two of its children removed as a result of cuts, v 's contribution to the rank of its parent is then considered suspect in terms of rank versus subtree size. The cascading cut protocol requires that the link to v 's parent be cut, with the subtree rooted at v then being inserted into the forest as a new tree. If v 's parent has, as a result, had a second child removed, then it in turn needs to be cut, and the cuts may thus cascade. Cascading cuts ensure that no nonroot node has had more than one child removed subsequent to being linked to its parent.

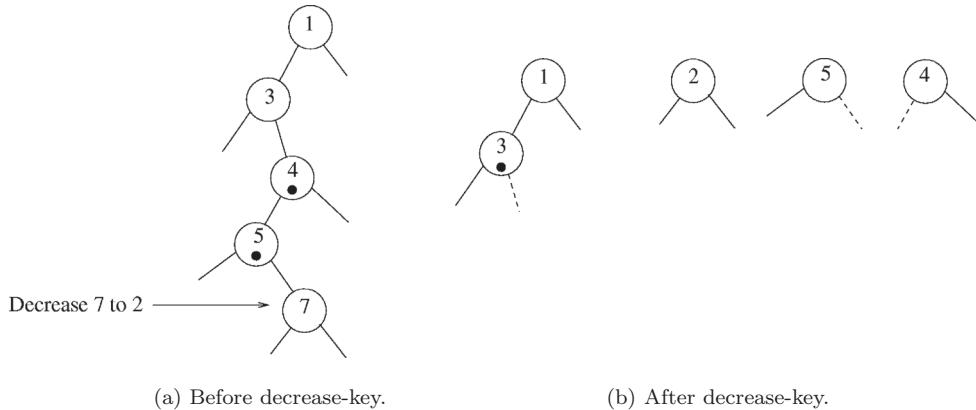

FIGURE 7.10 Illustration of cascading cuts. In (b), the dashed lines reflect cuts that have taken place, two nodes marked in (a) get unmarked, and a third node gets marked. (a) Before decrease-key, (b) after decrease-key.

We keep track of the removal of children by marking a node if one of its children has been cut. A marked node that has another child removed is then subject to being cut from its parent. When a marked node becomes linked as a child to another node, or when it gets cut from its parent, it gets unmarked. Figure 7.10 illustrates the protocol of cascading cuts.

Now the induced node cuts under the cascading cuts protocol, in contrast with those primary cuts immediately triggered by decrease-key operations, are bounded in number by the number of primary cuts. (This follows from consideration of a potential function defined to be the total number of marked nodes.) Therefore, the burden imposed by cascading cuts can be viewed as effectively only doubling the number of cuts taking place in the absence of the protocol. One can therefore expect that the performance asymptotics are not degraded as a consequence of proliferating cuts. As with binomial heaps, two trees in a Fibonacci heap can only be linked if they have equal rank. With the cascading cuts protocol in place, we claim that the required rank versus subtree size relation holds, a matter which we address next.

Let's consider how *small* the subtree rooted at a node v having rank k can be. Let ω be the m th child of v from the right. At the time it was linked to v , v had at least $m - 1$ other children (those currently to the right of ω were certainly present). Therefore, ω had rank at least $m - 1$ when it was linked to v . Under the cascading cuts protocol, the rank of ω could have decreased by at most one after its linking to v ; otherwise it would have been removed as a child. Therefore, the current rank of ω is at least $m - 2$. We minimize the size of the subtree rooted at v by minimizing the sizes (and ranks) of the subtrees rooted at v 's children. Now let F_j be the minimum possible size of the subtree rooted at a node of rank j , so that the size of the subtree rooted at v is F_k . We conclude that (for $k \geq 2$)

$$F_k = \underbrace{F_{k-2} + F_{k-3} + \cdots + F_0 + 1}_{k \text{ terms}} + 1$$

where the final term, 1, reflects the contribution of v to the subtree size. Clearly, $F_0 = 1$ and $F_1 = 2$. See Figure 7.11 for an illustration of this construction. Based on the preceding recurrence, it is readily shown that F_k is given by the $(k+2)$ th Fibonacci number (from whence the name “Fibonacci heap” was inspired). Moreover, since the Fibonacci numbers grow exponentially fast, we conclude that the rank of a node is indeed bounded by the logarithm of the size of the subtree rooted at the node.

We proceed next to describe how the various operations are performed.

Since we are not seeking worst-case bounds, there are economies to be exploited that could also be applied to obtain a variant of Binomial heaps. (In the absence of cuts, the individual trees generated by Fibonacci heap manipulations would all be binomial trees.) In particular, we shall adopt a lazy approach to melding operations: the respective forests are simply combined by concatenating their tree lists and retaining the appropriate min-pointer. This requires only constant time.

An item is deleted from a Fibonacci heap by deleting the node that originally contains it, in contrast with Binomial heaps. This is accomplished by (a) cutting the link to the node's parent (as in decrease-key) if the node is not a tree root and (b) appending the list of children of the node to the forest. Now if the deleted node happens to be referenced by the min-pointer, considerable work is required to restore the min-pointer—the work previously deferred by the lazy approach to the operations. In the course of searching among the roots of the forest to discover the new minimum key, we also link trees together in a *consolidation* process.

Consolidation processes the trees in the forest, linking them in pairs until there are no longer two trees having the same rank, and then places the remaining trees in a new forest list (naturally extending the melding process employed by binomial heaps). This can be accomplished in time proportional to the number of trees in forest plus the maximum possible node rank. Let max-rank denotes the maximum possible node rank. (The preceding discussion implies that $\text{max-rank} = O(\log \text{heap-size})$.)

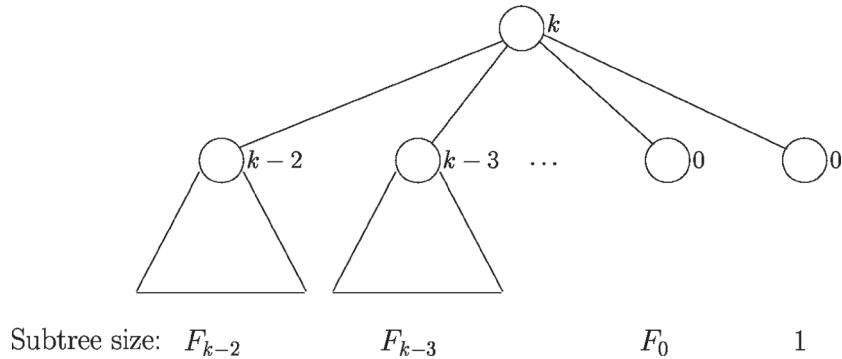

FIGURE 7.11 Minimal tree of rank k . Node ranks are shown adjacent to each node.

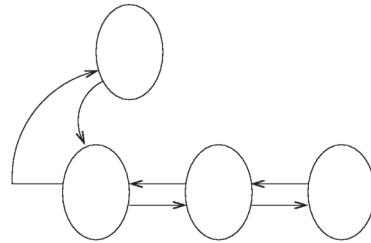

FIGURE 7.12 Pointers among a pairing heap node and its three children.

Consolidation is initialized by setting up an array A of trees (initially empty) indexed by the range $[0, \text{max-rank}]$. A nonempty position $A[d]$ of A contains a tree of rank d . The trees of the forest are then processed using the array A as follows. To process a tree T of rank d , we insert T into $A[d]$ if this position of A is empty, completing the processing of T . However, if $A[d]$ already contains a tree U , then T and U are linked together to form a tree W , and the processing continues as before, but with W in place of T , until eventually an empty location of A is accessed, completing the processing associated with T . After all of the trees have been processed in this manner, the array A is scanned, placing each of its stored trees in a new forest. Apart from the final scanning step, the total time necessary to consolidate a forest is proportional to its number of trees, since the total number of tree pairings that can take place is bounded by this number (each pairing reduces by one the total number of trees present). The time required for the final scanning step is given by $\text{max-rank} = \log(\text{heap-size})$.

The amortized timing analysis of Fibonacci heaps considers a potential function defined as the total number of trees in the forests of the various heaps being maintained. Ignoring consolidation, each operation takes constant actual time, apart from an amount of time proportional to the number of subtree cuts due to cascading (which, as noted above, is only constant in amortized terms). These cuts also contribute to the potential. The children of a deleted node increase the potential by $O(\log \text{heap-size})$. Deletion of a minimum heap node additionally incurs the cost of consolidation. However, consolidation reduces our potential, so that the amortized time it requires is only $O(\log \text{heap-size})$. We conclude therefore that all nondeletion operations require constant amortized time, and deletion requires $O(\log n)$ amortized time.

An interesting and unresolved issue concerns the protocol of cascading cuts. How would the performance of Fibonacci heaps be affected by the absence of this protocol?

A detailed code for manipulating Fibonacci heaps can be found in Knuth [6].

7.4 Pairing Heaps

The pairing heap was designed to be a self-adjusting analogue of the Fibonacci heap, in much the same way that the skew heap is a self-adjusting analogue of the leftist heap (see Chapters 5 and 6). The only structure maintained in a pairing heap node, besides item information, consists of three pointers: leftmost child and two sibling pointers. (The leftmost child of a node uses its left sibling pointer to point to its parent, to facilitate updating the leftmost child pointer its parent.) See Figure 7.12 for an illustration of pointer structure.

There are no cascading cuts—only simple cuts for decrease-key and deletion operations. With the absence of parent pointers, decrease-key operations uniformly require a single cut (removal from the sibling list, in actuality), as there is no efficient way

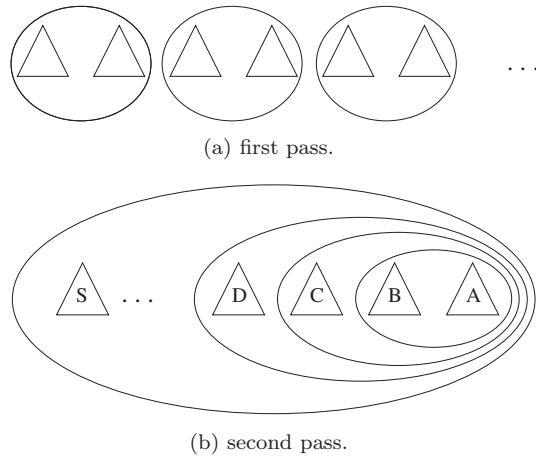

FIGURE 7.13 Two-pass pairing. The encircled trees get linked. For example, in (b) trees A and B get linked, and the result then gets linked with the tree C, and so on: (a) first pass, (b) second pass.

to check whether heap order would otherwise be violated. Although there are several varieties of pairing heaps, our discussion presents the two-pass version (the simplest), for which a given heap consists of only a single tree. The minimum element is thus uniquely located, and melding requires only a single linking operation. Similarly, a decrease-key operation consists of a subtree cut followed by a linking operation. Extractmin is implemented by removing the tree root and then linking the root's subtrees in a manner described later. Other deletions involve (a) a subtree cut, (b) an extractmin operation on the cut subtree, and (c) linking the remnant of the cut subtree with the original root.

The extractmin operation combines the subtrees of the root using a process referred to as *two-pass pairing*. Let x_1, \dots, x_k be the subtrees of the root in left-to-right order. The first pass begins by linking x_1 and x_2 . Then x_3 and x_4 are linked, followed by x_5 and x_6 , and so on, so that the odd positioned trees are linked with neighboring even positioned trees. Let y_1, \dots, y_h , $h = \lceil k/2 \rceil$, be the resulting trees, respecting left-to-right order. (If k is odd, then $y_{\lceil k/2 \rceil}$ is x_k .) The second pass reduces these to a single tree with linkings that proceed from right-to-left. The rightmost pair of trees, y_h and y_{h-1} are linked first, followed by the linking of y_{h-2} with the result of the preceding linking, and so on, until finally we link y_1 with the structure formed from the linkings of y_2, \dots, y_h (see Figure 7.13).

Since two-pass pairing is not particularly intuitive, a few motivating remarks are offered. The first pass is natural enough, and one might consider simply repeating the process on the remaining trees, until, after logarithmically many such passes, only one tree remains. Indeed, this is known as the multipass variation. Unfortunately, its behavior is less understood than that of the two-pass pairing variation.

The second (right-to-left) pass is also quite natural. Let H be a binomial heap with exactly 2^k items, so that it consists of a single tree. Now suppose that an extractmin followed by an insertion operation are executed. The linkings that take place among the subtrees of the deleted root (after the new node is linked with the rightmost of these subtrees) entail the right-to-left processing that characterizes the second pass. So why not simply rely upon a single right-to-left pass and omit the first? The reason is that although the second pass preserves existing balance within the structure, it doesn't improve upon poorly balanced situations (manifested when most linkings take place between trees of disparate sizes). For example, using a single-right-to-left-pass version of a pairing heap to sort an increasing sequence of length n (n insertions followed by n extractmin operations) would result in an n^2 sorting algorithm. (Each of the extractmin operations yields a tree of height 1 or less.) See Section 7.5, however, for an interesting twist.

In actuality two-pass pairing was inspired [3] by consideration of splay trees (see Chapter 13). If we consider the child, sibling representation that maps a forest of arbitrary trees into a binary tree, then two-pass pairing can be viewed as a splay operation on a search tree path with no bends [3]. The analysis for splay trees then carries over to provide an amortized analysis for pairing heaps.

A detailed code for manipulating pairing heaps can be found in Weiss [5].

The asymptotic behavior of pairing heaps is an interesting and unresolved matter. In the original paper [3], it was demonstrated that the operations require only $O(\log n)$ amortized time. The fact that decrease-key operations require only constant actual time makes seemingly plausible the possibility that the amortized costs of the various operations match those of Fibonacci heaps. This line of thought, however, requires addressing the possibility that the presence of decrease-key operations might degrade the efficiency with which extractmin operations can be performed. On the positive side, Pettie [7] has derived a $2^{O(\sqrt{\log \log n})}$

amortized bound for decrease-key and insertion operations (in the presence of a $O(\log n)$ bound for the extractmin operation), and it is known that for those applications for which decrease-key operations are highly predominant, pairing heaps provably meet the optimal asymptotic bounds characteristic of Fibonacci heaps [8].

Despite the above positive considerations, as a theoretical matter pairing heaps do not match the asymptotic bounds of Fibonacci heaps. More precisely, it has been demonstrated [8] that there exist operation sequences for which the aggregate execution cost via pairing heaps is *not* consistent with amortized costs of $O(\log n)$ for extractmin and insertion operations, and $O(\log \log n)$ for decrease-key operations. (We observe that Pettie's upper bound [7] on the amortized cost of decrease-key operations, cited above, exceeds any fixed power of $\log \log n$.) The derivation of this negative result takes place in an information-theoretic framework, so that it is applicable to all data structures encompassed in a suitably defined model of computation, a matter that we shall return to shortly.

In terms of practice, because the pairing heap design dispenses with the rather complicated, carefully crafted constructs put in place primarily to facilitate proving the time bounds enjoyed by Fibonacci heaps, we can expect efficiency gains at the level of elementary steps such as linking operations. The study of Moret and Shapiro [4] provides experimental evidence in support of the conclusion that pairing heaps are superior to Fibonacci heaps in practice.

7.5 Related Developments

7.5.1 Other Variations of Pairing Heaps

The reader may wonder whether some alternative to two-pass pairing might provably attain the asymptotic performance bounds satisfied by Fibonacci heaps. The strongest result to date is attained by a variation of pairing heap devised by Elmasry [9], for which extractmin is supported with $O(\log n)$ amortized cost and decrease-key with $O(\log \log n)$ amortized cost (and insertion with $O(1)$ amortized cost), thereby matching the known lower bound applicable for two-pass pairing heaps. The information-theoretic framework [8] under which these lower bounds for two-pass pairing heaps have been established, however, does not encompass structures such as Elmasry's, so there remains the possibility that some other alternative to two-pass pairing might further improve the upper bounds attained by Elmasry's structure. We mention that Iacono and Özkan [10] have extended the reach of this information-theoretic framework, developing a "Pure Heap Model" that broadens the class of data structures to which the lower bounds established for two-pass pairing apply. The pure heap model, however, does *not* encompass Elmasry's data structure, and moreover the Elmasry *upper* bounds (matching the lower bounds established for two-pass pairing) have not been demonstrated for any data structure in the pure heap model, though one data structure, the "sort heap" [11], comes close.

7.5.2 Adaptive Properties of Pairing Heaps

Consider the problem of merging k sorted lists of respective lengths n_1, n_2, \dots, n_k , with $\sum n_i = n$. The standard merging strategy that performs $\lg k$ rounds of pairwise list merges requires $n \lg k$ time. However, a merge pattern based upon the binary Huffman tree, having minimal external path length for the weights n_1, n_2, \dots, n_k , is more efficient when the lengths n_i are nonuniform and provides a near-optimal solution. Pairing heaps can be utilized to provide a rather different solution as follows. Treat each sorted list as a linearly structured pairing heap. Then (a) meld these k heaps together and (b) repeatedly execute extractmin operations to retrieve the n items in their sorted order. The number of comparisons that take place is bounded by

$$O\left(\log \binom{n}{n_1, \dots, n_k}\right)$$

Since the above multinomial coefficient represents the number of possible merge patterns, the information-theoretic bound implies that this result is optimal to within a constant factor. The pairing heap thus self-organizes the sorted list arrangement to approximate an optimal merge pattern. Iacono has derived a "working-set" theorem that quantifies a similar adaptive property satisfied by pairing heaps. Given a sequence of insertion and extractmin operations initiated with an empty heap, at the time a given item x is deleted we can attribute to x a contribution bounded by $O(\log \text{op}(x))$ to the total running time of the sequence, where $\text{op}(x)$ is the number of heap operations that have taken place since x was inserted (see Reference 12 for a slightly tighter estimate).

7.5.3 Soft Heaps

An interesting development [13] that builds upon and extends binomial heaps in a different direction is a data structure referred to as a *soft heap*. The soft heap departs from the standard notion of priority queue by allowing for a type of error, referred to as *corruption*, which confers enhanced efficiency. When an item becomes corrupted, its key value gets increased. Findmin returns

the minimum current key, which might or might not be corrupted. The user has no control over which items become corrupted, this prerogative belonging to the data structure. But the user does control the overall amount of corruption in the following sense.

The user specifies a parameter, $0 < \epsilon \leq 1/2$, referred to as the error rate, that governs the behavior of the data structure as follows. The operations `findmin` and deletion are supported in constant amortized time, and insertion is supported in $O(\log 1/\epsilon)$ amortized time. Moreover, no more than an ϵ fraction of the items present in the heap are corrupted at any given time.

To illustrate the concept, let x be an item returned by `findmin`, from a soft heap of size n . Then there are no more than ϵn items in the heap whose original keys are less than the original key of x .

Soft heaps are rather subtle, and we won't attempt to discuss specifics of their design. Soft heaps have been used to construct an optimal comparison-based minimum spanning tree algorithm [14], although its actual running time has not been determined. Soft heaps have also been used to construct a comparison-based algorithm with known running time $ma(m, n)$ on a graph with n vertices and m edges [15], where $\alpha(m, n)$ is a functional inverse of the Ackermann function. Chazelle [13] has also observed that soft heaps can be used to implement median selection in linear time, a significant departure from previous methods.

8.1 Definition and an Application

A *double-ended priority queue (DEPQ)* is a collection of zero or more elements. Each element has a priority or value. The operations performed on a double-ended priority queue are:

1. *getMin()* ... return element with minimum priority
2. *getMax()* ... return element with maximum priority
3. *put(x)* ... insert the element x into the DEPQ
4. *removeMin()* ... remove an element with minimum priority and return this element
5. *removeMax()* ... remove an element with maximum priority and return this element

One application of a DEPQ is to the adaptation of quick sort, which has the best expected run time of all known internal sorting methods, to external sorting. The basic idea in quick sort is to partition the elements to be sorted into three groups L , M , and R . The middle group M contains a single element called the *pivot*, all elements in the left group L are \leq the pivot, and all elements in the right group R are \geq the pivot. Following this partitioning, the left and right element groups are sorted recursively.

In an external sort, we have more elements than can be held in the memory of our computer. The elements to be sorted are initially on a disk and the sorted sequence is to be left on the disk. When the internal quick sort method outlined above is extended to an external quick sort, the middle group M is made as large as possible through the use of a DEPQ. The external quick sort strategy is:

1. Read in as many elements as will fit into an internal DEPQ. The elements in the DEPQ will eventually be the middle group of elements.
2. Read in the remaining elements. If the next element is \leq the smallest element in the DEPQ, output this next element as part of the left group. If the next element is \geq the largest element in the DEPQ, output this next element as part of the right group. Otherwise, remove either the max or min element from the DEPQ (the choice may be made randomly or

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

alternately); if the max element is removed, output it as part of the right group; otherwise, output the removed element as part of the left group; insert the newly input element into the DEPQ.

3. Output the elements in the DEPQ, in sorted order, as the middle group.
4. Sort the left and right groups recursively.

In this chapter, we describe four implicit data structures—symmetric min-max heaps, interval heaps, min-max heaps, and deaps—for DEPQs. Also, we describe generic methods to obtain efficient DEPQ data structures from efficient data structures for single-ended priority queues (PQ).*

8.2 Symmetric Min-Max Heaps

Several simple and efficient implicit data structures have been proposed for the representation of a DEPQ [1–7]. All of these data structures are adaptations of the classical heap data structure (Chapter 2) for a PQ. Further, in all of these DEPQ data structures, *getMax* and *getMin* take $O(1)$ time and the remaining operations take $O(\log n)$ time each (n is the number of elements in the DEPQ). The symmetric min-max heap structure of Arvind and Pandu Rangan [1] is the simplest of the implicit data structures for DEPQs. Therefore, we describe this data structure first.

A *symmetric min-max heap* (SMMH) is a complete binary tree in which each node other than the root has exactly one element. The root of an SMMH is empty and the total number of nodes in the SMMH is $n + 1$, where n is the number of elements. Let x be any node of the SMMH. Let *elements*(x) be the elements in the subtree rooted at x but excluding the element (if any) in x . Assume that $\text{elements}(x) \neq \emptyset$. x satisfies the following properties:

1. The left child of x has the minimum element in *elements*(x).
2. The right child of x (if any) has the maximum element in *elements*(x).

Figure 8.1 shows an example SMMH that has 12 elements. When x denotes the node with 80, $\text{elements}(x) = \{6, 14, 30, 40\}$; the left child of x has the minimum element 6 in *elements*(x); and the right child of x has the maximum element 40 in *elements*(x). You may verify that every node x of this SMMH satisfies the stated properties.

Since an SMMH is a complete binary tree, it is stored as an implicit data structure using the standard mapping of a complete binary tree into an array. When $n = 1$, the minimum and maximum elements are the same and are in the left child of the root of the SMMH. When $n > 1$, the minimum element is in the left child of the root and the maximum is in the right child of the root. So the *getMin* and *getMax* operations take $O(1)$ time.

It is easy to see that an $n + 1$ -node complete binary tree with an empty root and one element in every other node is an SMMH iff the following are true:

- P1: For every node x that has a right sibling, the element in x is less than or equal to that in the right sibling of x .
- P2: For every node x that has a grandparent, the element in the left child of the grandparent is less than or equal to that in x .
- P3: For every node x that has a grandparent, the element in the right child of the grandparent is greater than or equal to that in x .

Notice that if property P1 is satisfied at node x , then at most one of P2 and P3 may be violated at x . Using properties P1 through P3 we arrive at simple algorithms to insert and remove elements. These algorithms are simple adaptations of the corresponding algorithms for min and max heaps. Their complexity is $O(\log n)$. We describe only the insert operation. Suppose we wish to insert

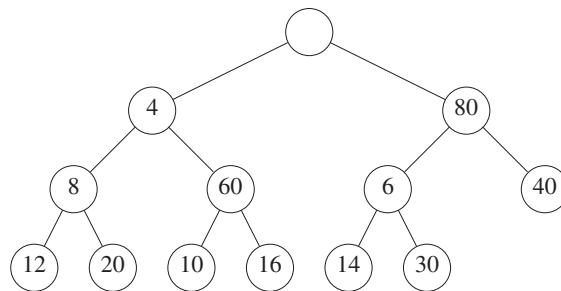

FIGURE 8.1 A symmetric min-max heap.

* A *minPQ* supports the operations *getmin()*, *put(x)*, and *removeMin()* while a *maxPQ* supports the operations *getMax()*, *put(x)*, and *removeMax()*.

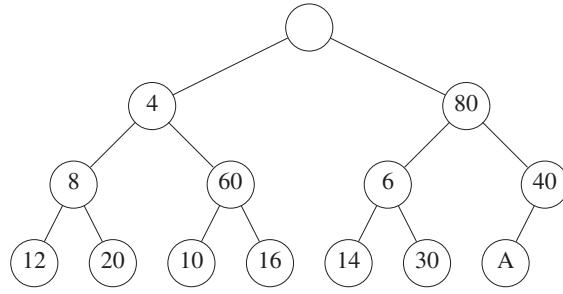

FIGURE 8.2 The SMMH of Figure 8.1 with a node added.

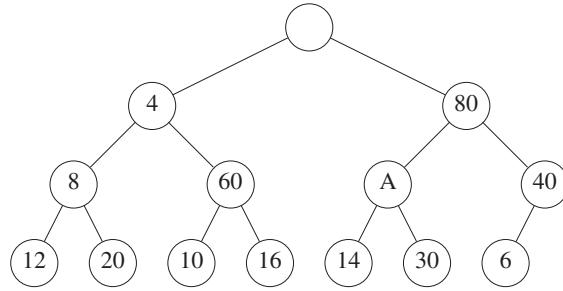

FIGURE 8.3 The SMMH of Figure 8.2 with 6 moved down.

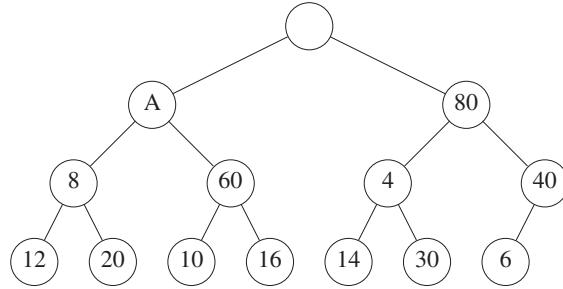

FIGURE 8.4 The SMMH of Figure 8.3 with 4 moved down.

2 into the SMMH of Figure 8.1. Since an SMMH is a complete binary tree, we must add a new node to the SMMH in the position shown in Figure 8.2; the new node is labeled A. In our example, A will denote an empty node.

If the new element 2 is placed in node A, property P2 is violated as the left child of the grandparent of A has 6. So we move the 6 down to A and obtain Figure 8.3.

Now we see if it is safe to insert the 2 into node A. We first notice that property P1 cannot be violated, because the previous occupant of node A was greater than 2. Similarly, property P3 cannot be violated. Only P2 can be violated only when $x = A$. So we check P2 with $x = A$. We see that P2 is violated because the left child of the grandparent of A has the element 4. So we move the 4 down to A and obtain the configuration shown in Figure 8.4.

For the configuration of Figure 8.4 we see that placing 2 into node A cannot violate property P1, because the previous occupant of node A was greater than 2. Also properties P2 and P3 cannot be violated, because node A has no grandparent. So we insert 2 into node A and obtain Figure 8.5.

Let us now insert 50 into the SMMH of Figure 8.5. Since an SMMH is a complete binary tree, the new node must be positioned as in Figure 8.6.

Since A has a right child of its parent, we first check P1 at node A. If the new element (in this case 50) is smaller than that in the left sibling of A, we swap the new element and the element in the left sibling. In our case, no swap is done. Then we check P2 and P3. We see that placing 50 into A would violate P3. So the element 40 in the right child of the grandparent of A is moved down to node A. Figure 8.7 shows the resulting configuration. Placing 50 into node A of Figure 8.7 cannot create a P1 violation

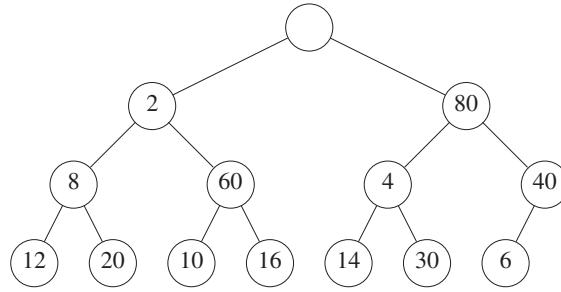

FIGURE 8.5 The SMMH of Figure 8.4 with 2 inserted.

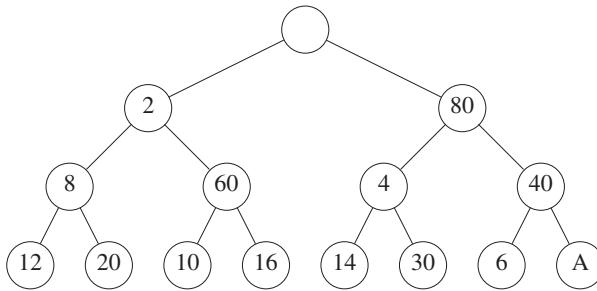

FIGURE 8.6 The SMMH of Figure 8.5 with a node added.

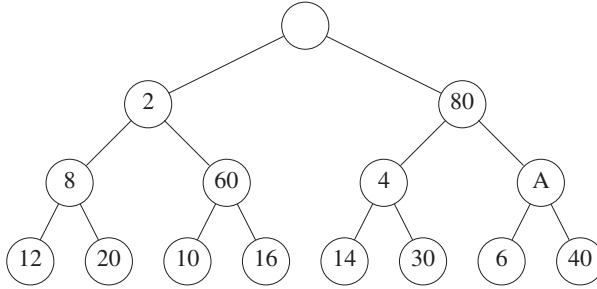

FIGURE 8.7 The SMMH of Figure 8.6 with 40 moved down.

because the previous occupant of node A was smaller. Also, a P2 violation isn't possible either. So only P3 needs to be checked at A. Since there is no P3 violation at A, 50 is placed into A.

The algorithm to remove either the min or max element is a similar adaptation of the trickle-down algorithm used to remove an element from a min or max heap.

8.3 Interval Heaps

The twin heaps of [7], the min-max pair heaps of [6], the interval heaps of [5,8], and the diamond deques of [4] are virtually identical data structures. In each of these structures, an n element DEPQ is represented by a min heap with $\lceil n/2 \rceil$ elements and a max heap with the remaining $\lfloor n/2 \rfloor$ elements. The two heaps satisfy the property that each element in the min heap is \leq the corresponding element (two elements correspond if they occupy the same position in their respective binary trees) in the max heap. When the number of elements in the DEPQ is odd, the min heap has one element (i.e., element $\lceil n/2 \rceil$) that has no corresponding element in the max heap. In the twin heaps of [7], this is handled as a special case and one element is kept outside of the two heaps. In min-max pair heaps, interval heaps, and diamond deques, the case when n is odd is handled by requiring element $\lceil n/2 \rceil$ of the min heap to be \leq element $\lfloor n/4 \rfloor$ of the max heap.

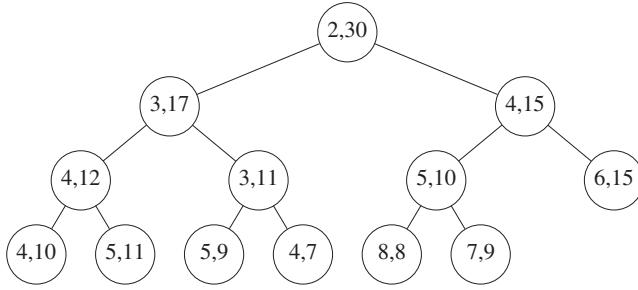

FIGURE 8.8 An interval heap.

In the twin heaps of [7], the min and max heaps are stored in two arrays *min* and *max* using the standard array representation of a complete binary tree^{*} [9]. The correspondence property becomes $\text{min}[i] \leq \text{max}[i]$, $1 \leq i \leq \lfloor n/2 \rfloor$. In the min-max pair heaps of [6] and the interval heaps of [5], the two heaps are stored in a single array *minmax* and we have *minmax*[*i*].*min* being the *i*'th element of the min heap, $1 \leq i \leq \lfloor n/2 \rfloor$ and *minmax*[*i*].*max* being the *i*'th element of the max heap, $1 \leq i \leq \lfloor n/2 \rfloor$. In the diamond deque [4], the two heaps are mapped into a single array with the min heap occupying even positions (beginning with position 0) and the max heap occupying odd positions (beginning with position 1). Since this mapping is slightly more complex than the ones used in twin heaps, min-max pair heaps, and interval heaps, actual implementations of the diamond deque are expected to be slightly slower than implementations of the remaining three structures.

Since the twin heaps of [7], the min-max pair heaps of [6], the interval heaps of [5], and the diamond deques of [4] are virtually identical data structures, we describe only one of these—interval heaps—in detail. An *interval heap* is a complete binary tree in which each node, except possibly the last one (the nodes of the complete binary tree are ordered using a level order traversal), contains two elements. Let the two elements in node *P* be *a* and *b*, where $a \leq b$. We say that the node *P* represents the closed interval $[a, b]$. *a* is the left end point of the interval of *P*, and *b* is its right end point.

The interval $[c, d]$ is contained in the interval $[a, b]$ iff $a \leq c \leq d \leq b$. In an interval heap, the intervals represented by the left and right children (if they exist) of each node *P* are contained in the interval represented by *P*. When the last node contains a single element *c*, then $a \leq c \leq b$, where $[a, b]$ is the interval of the parent (if any) of the last node.

Figure 8.8 shows an interval heap with 26 elements. You may verify that the intervals represented by the children of any node *P* are contained in the interval of *P*.

The following facts are immediate:

1. The left end points of the node intervals define a min heap, and the right end points define a max heap. In case the number of elements is odd, the last node has a single element which may be regarded as a member of either the min or max heap. Figure 8.9 shows the min and max heaps defined by the interval heap of Figure 8.8.
2. When the root has two elements, the left end point of the root is the minimum element in the interval heap and the right end point is the maximum. When the root has only one element, the interval heap contains just one element. This element is both the minimum and maximum element.
3. An interval heap can be represented compactly by mapping into an array as is done for ordinary heaps. However, now, each array position must have space for two elements.
4. The height of an interval heap with *n* elements is $\Theta(\log n)$.

8.3.1 Inserting an Element

Suppose we are to insert an element into the interval heap of Figure 8.8. Since this heap currently has an even number of elements, the heap following the insertion will have an additional node *A* as is shown in Figure 8.10.

The interval for the parent of the new node *A* is $[6, 15]$. Therefore, if the new element is between 6 and 15, the new element may be inserted into node *A*. When the new element is less than the left end point 6 of the parent interval, the new element is inserted into the min heap embedded in the interval heap. This insertion is done using the min heap insertion procedure starting at node *A*. When the new element is greater than the right end point 15 of the parent interval, the new element is inserted into the max heap embedded in the interval heap. This insertion is done using the max heap insertion procedure starting at node *A*.

^{*} In a *full* binary tree, every non-empty level has the maximum number of nodes possible for that level. Number the nodes in a full binary tree 1, 2, ... beginning with the root level and within a level from left to right. The nodes numbered 1 through *n* define the unique *complete binary tree* that has *n* nodes.

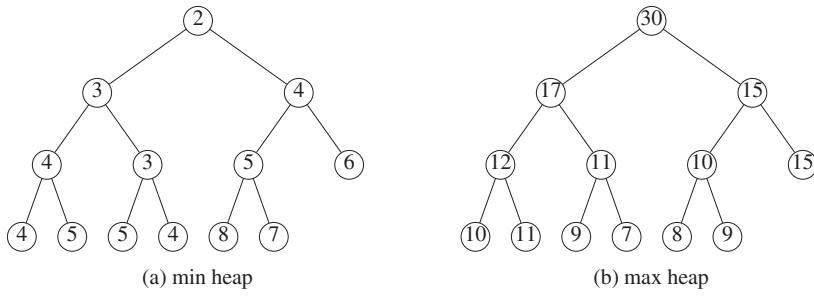

FIGURE 8.9 Min and max heaps embedded in Figure 8.8.

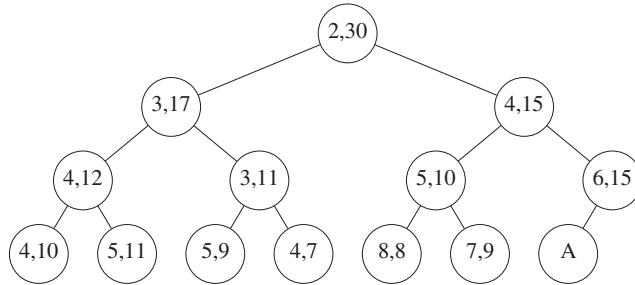

FIGURE 8.10 Interval heap of Figure 8.8 after one node is added.

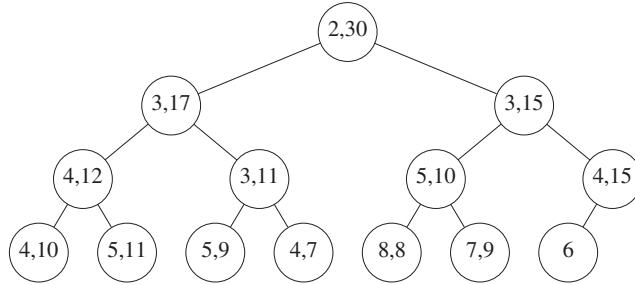

FIGURE 8.11 The interval heap of Figure 8.8 with 3 inserted.

If we are to insert the element 10 into the interval heap of Figure 8.8, this element is put into the node A shown in Figure 8.10. To insert the element 3, we follow a path from node A towards the root, moving left end points down until we either pass the root or reach a node whose left end point is ≤ 3 . The new element is inserted into the node that now has no left end point. Figure 8.11 shows the resulting interval heap.

To insert the element 40 into the interval heap of Figure 8.8, we follow a path from node A (see Figure 8.10) towards the root, moving right end points down until we either pass the root or reach a node whose right end point is ≥ 40 . The new element is inserted into the node that now has no right end point. Figure 8.12 shows the resulting interval heap.

Now, suppose we wish to insert an element into the interval heap of Figure 8.12. Since this interval heap has an odd number of elements, the insertion of the new element does not increase the number of nodes. The insertion procedure is the same as for the case when we initially have an even number of elements. Let A denote the last node in the heap. If the new element lies within the interval $[6, 15]$ of the parent of A , then the new element is inserted into node A (the new element becomes the left end point of A if it is less than the element currently in A). If the new element is less than the left end point 6 of the parent of A , then the new element is inserted into the embedded min heap; otherwise, the new element is inserted into the embedded max heap. Figure 8.13 shows the result of inserting the element 32 into the interval heap of Figure 8.12.

8.3.2 Removing the Min Element

The removal of the minimum element is handled as several cases:

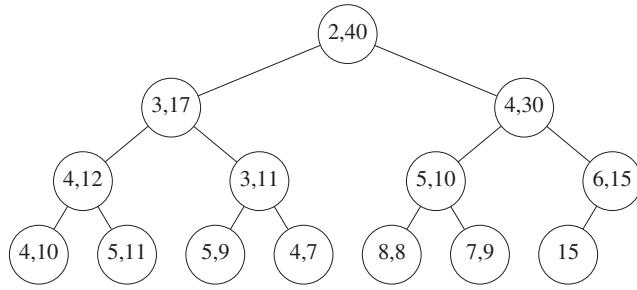

FIGURE 8.12 The interval heap of Figure 8.8 with 40 inserted.

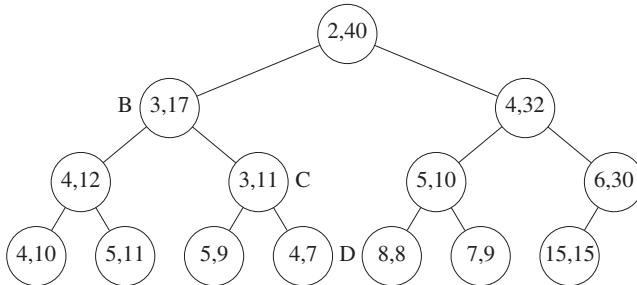

FIGURE 8.13 The interval heap of Figure 8.12 with 32 inserted.

1. When the interval heap is empty, the *removeMin* operation fails.
2. When the interval heap has only one element, this element is the element to be returned. We leave behind an empty interval heap.
3. When there is more than one element, the left end point of the root is to be returned. This point is removed from the root. If the root is the last node of the interval heap, nothing more is to be done. When the last node is not the root node, we remove the left point p from the last node. If this causes the last node to become empty, the last node is no longer part of the heap. The point p removed from the last node is reinserted into the embedded min heap by beginning at the root. As we move down, it may be necessary to swap the current p with the right end point r of the node being examined to ensure that $p \leq r$. The reinsertion is done using the same strategy as used to reinsert into an ordinary heap.

Let us remove the minimum element from the interval heap of Figure 8.13. First, the element 2 is removed from the root. Next, the left end point 15 is removed from the last node and we begin the reinsertion procedure at the root. The smaller of the min heap elements that are the children of the root is 3. Since this element is smaller than 15, we move the 3 into the root (the 3 becomes the left end point of the root) and position ourselves at the left child B of the root. Since, $15 \leq 17$ we do not swap the right end point of B with the current $p = 15$. The smaller of the left end points of the children of B is 3. The 3 is moved from node C into node B as its left end point and we position ourselves at node C . Since $p = 15 > 11$, we swap the two and 15 becomes the right end point of node C . The smaller of left end points of C 's children is 4. Since this is smaller than the current $p = 11$, it is moved into node C as this node's left end point. We now position ourselves at node D . First, we swap $p = 11$ and D 's right end point. Now, since D has no children, the current $p = 7$ is inserted into node D as D 's left end point. Figure 8.14 shows the result.

The max element may be removed using an analogous procedure.

8.3.3 Initializing an Interval Heap

Interval heaps may be initialized using a strategy similar to that used to initialize ordinary heaps—work your way from the heap bottom to the root ensuring that each subtree is an interval heap. For each subtree, first order the elements in the root; then reinsert the left end point of this subtree's root using the reinsertion strategy used for the *removeMin* operation, then reinsert the right end point of this subtree's root using the strategy used for the *removeMax* operation.

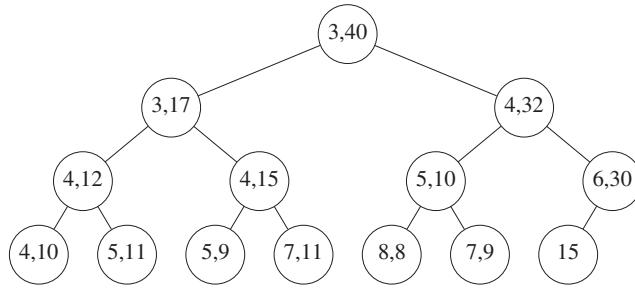

FIGURE 8.14 The interval heap of Figure 8.13 with minimum element removed.

8.3.4 Complexity of Interval Heap Operations

The operations `isEmpty()`, `size()`, `getMin()`, and `getMax()` take $O(1)$ time each; `put(x)`, `removeMin()`, and `removeMax()` take $O(\log n)$ each; and initializing an n element interval heap takes $O(n)$ time.

8.3.5 The Complementary Range Search Problem

In the *complementary range search* problem, we have a dynamic collection (i.e., points are added and removed from the collection as time goes on) of one-dimensional points (i.e., points have only an x -coordinate associated with them) and we are to answer queries of the form: what are the points outside of the interval $[a, b]$? For example, if the point collection is 3, 4, 5, 6, 8, 12, the points outside the range $[5, 7]$ are 3, 4, 8, 12.

When an interval heap is used to represent the point collection, a new point can be inserted or an old one removed in $O(\log n)$ time, where n is the number of points in the collection. Note that given the location of an arbitrary element in an interval heap, this element can be removed from the interval heap in $O(\log n)$ time using an algorithm similar to that used to remove an arbitrary element from a heap.

The complementary range query can be answered in $\Theta(k)$ time, where k is the number of points outside the range $[a, b]$. This is done using the following recursive procedure:

1. If the interval tree is empty, `return`.
2. If the root interval is contained in $[a, b]$, then all points are in the range (therefore, there are no points to report), `return`.
3. Report the end points of the root interval that are not in the range $[a, b]$.
4. Recursively search the left subtree of the root for additional points that are not in the range $[a, b]$.
5. Recursively search the right subtree of the root for additional points that are not in the range $[a, b]$.
6. `return`

Let us try this procedure on the interval heap of Figure 8.13. The query interval is $[4, 32]$. We start at the root. Since the root interval is not contained in the query interval, we reach step 3 of the procedure. Whenever step 3 is reached, we are assured that at least one of the end points of the root interval is outside the query interval. Therefore, each time step 3 is reached, at least one point is reported. In our example, both points 2 and 40 are outside the query interval and so are reported. We then search the left and right subtrees of the root for additional points. When the left subtree is searched, we again determine that the root interval is not contained in the query interval. This time only one of the root interval points (i.e., 3) is to be outside the query range. This point is reported and we proceed to search the left and right subtrees of B for additional points outside the query range. Since the interval of the left child of B is contained in the query range, the left subtree of B contains no points outside the query range. We do not explore the left subtree of B further. When the right subtree of B is searched, we report the left end point 3 of node C and proceed to search the left and right subtrees of C . Since the intervals of the roots of each of these subtrees is contained in the query interval, these subtrees are not explored further. Finally, we examine the root of the right subtree of the overall tree root, that is the node with interval $[4, 32]$. Since this node's interval is contained in the query interval, the right subtree of the overall tree is not searched further.

The complexity of the above six step procedure is $\Theta(\text{number of interval heap nodes visited})$. The nodes visited in the preceding example are the root and its two children, node B and its two children, and node C and its two children. Thus, 7 nodes are visited and a total of 4 points are reported.

We show that the total number of interval heap nodes visited is at most $3k + 1$, where k is the number of points reported. If a visited node reports one or two points, give the node a count of one. If a visited node reports no points, give it a count of zero and add one to the count of its parent (unless the node is the root and so has no parent). The number of nodes with a nonzero

count is at most k . Since no node has a count more than 3, the sum of the counts is at most $3k$. Accounting for the possibility that the root reports no point, we see that the number of nodes visited is at most $3k + 1$. Therefore, the complexity of the search is $\Theta(k)$. This complexity is asymptotically optimal because every algorithm that reports k points must spend at least $\Theta(1)$ time per reported point.

In our example search, the root gets a count of 2 (1 because it is visited and reports at least one point and another 1 because its right child is visited but reports no point), node B gets a count of 2 (1 because it is visited and reports at least one point and another 1 because its left child is visited but reports no point), and node C gets a count of 3 (1 because it is visited and reports at least one point and another 2 because its left and right children are visited and neither reports a point). The count for each of the remaining nodes in the interval heap is 0.

8.4 Min-Max Heaps

In the min-max heap structure [2], all n DEPQ elements are stored in an n -node complete binary tree with alternating levels being min levels and max levels (Figure 8.15, nodes at max levels are shaded). The root level of a min-max heap is a min level. Nodes on a min level are called min nodes while those on a max level are max nodes. Every min (max) node has the property that its value is the smallest (largest) value in the subtree of which it is the root. Since 5 is in a min node of Figure 8.15, it is the smallest value in its subtree. Also, since 30 and 26 are in max nodes, these are the largest values in the subtrees of which they are the root.

The following observations are a direct consequence of the definition of a min-max heap.

1. When $n = 0$, there is no min nor max element.
2. When $n = 1$, the element in the root is both the min and the max element.
3. When $n > 1$, the element in the root is the min element; the max element is one of the up to two children of the root.

From these observations, it follows that `getMin()` and `getMax()` can be done in $O(1)$ time each.

8.4.1 Inserting an Element

When inserting an element `newElement` into a min-max heap that has n elements, we go from a complete binary tree that has n nodes to one that has $n + 1$ nodes. So, for example, an insertion into the 12-element min-max heap of Figure 8.15 results in the 13-node complete binary tree of Figure 8.16.

When $n = 0$, the insertion simply creates a min-max heap that has a single node that contains the new element. Assume that $n > 0$ and let the element in the parent, `parentNode`, of the new node j be `parentElement`. If `newElement` is placed in the new node j , the min- and max-node property can be violated only for nodes on the path from the root to `parentNode`. So, the insertion of an element need only be concerned with ensuring that nodes on this path satisfy the required min- and max-node property. There are three cases to consider.

1. `parentElement = newElement`

In this case, we may place `newElement` into node j . With such a placement, the min- and max-node properties of all nodes on the path from the root to `parentNode` are satisfied.

2. `parentNode > newElement`

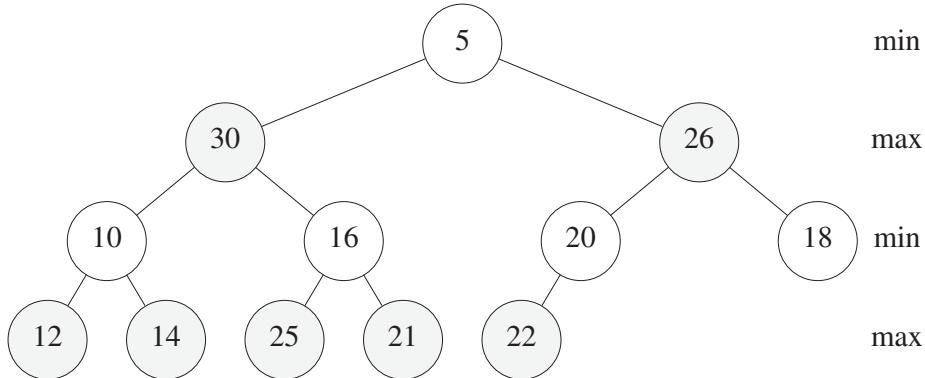

FIGURE 8.15 A 12-element min-max heap.

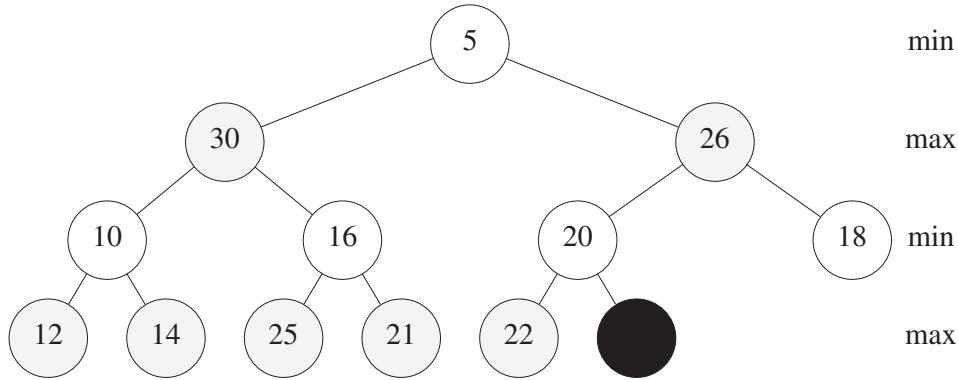

FIGURE 8.16 A 13-node complete binary tree.

If *parentNode* is a min node, we get a min-node violation. When a min-node violation occurs, we know that all max nodes on the path from the root to *parentNode* are greater than *newElement*. So, a min-node violation may be fixed by using the trickle-up process used to insert into a min heap; this trickle-up process involves only the min nodes on the path from the root to *parentNode*. For example, suppose that we are to insert *newElement* = 2 into the min-max heap of Figure 8.15. The min nodes on the path from the root to *parentNode* have values 5 and 20. The 20 and the 5 move down on the path and the 2 trickles up to the root node. Figure 8.17 shows the result. When *newElement* = 15, only the 20 moves down and the sequence of min nodes on the path from the root to *j* have values 5, 15, 20.

The case when *parentNode* is a max node is similar.

3. *parentNode* < *newElement*

When *parentNode* is a min node, we conclude that all min nodes on the path from the root to *parentNode* are smaller than *newElement*. So, we need be concerned only with the max nodes (if any) on the path from the root to *parentNode*. A trickle-up process is used to correctly position *newElement* with respect to the elements in the max nodes of this path. For the example of Figure 8.16, there is only one max node on the path to *parentNode*. This max node has the element 26. If *newElement* > 26, the 26 moves down to *j* and *newElement* trickles up to the former position of 26 (Figure 8.18 shows the case when *newElement* = 32). If *newElement* < 26, *newElement* is placed in *j*.

The case when *parentNode* is a max node is similar.

Since the height of a min-max heap is $\Theta(\log n)$ and a trickle-up examines a single element at at most every other level of the min-max heap, an insert can be done in $O(\log n)$ time.

8.4.2 Removing the Min Element

When $n = 0$, there is no min element to remove. When $n = 1$, the min-max heap becomes empty following the removal of the min element, which is in the root. So assume that $n > 1$. Following the removal of the min element, which is in the root, we need to go from an n -element complete binary tree to an $(n - 1)$ -element complete binary tree. This causes the element in position n

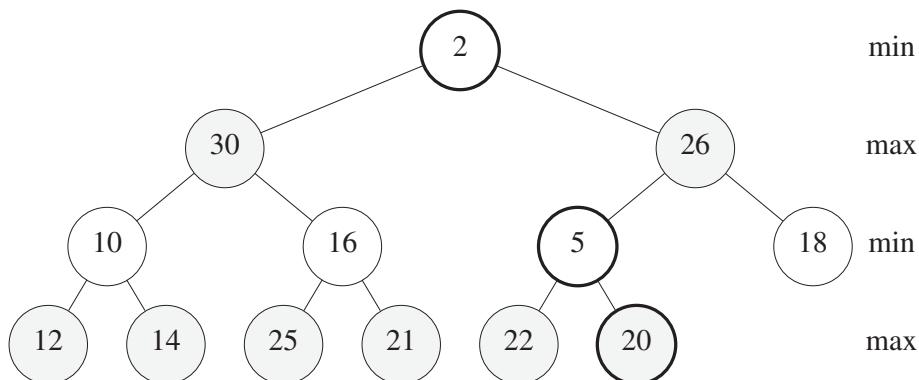

FIGURE 8.17 Min-max heap of Figure 8.15 following insertion of 2.

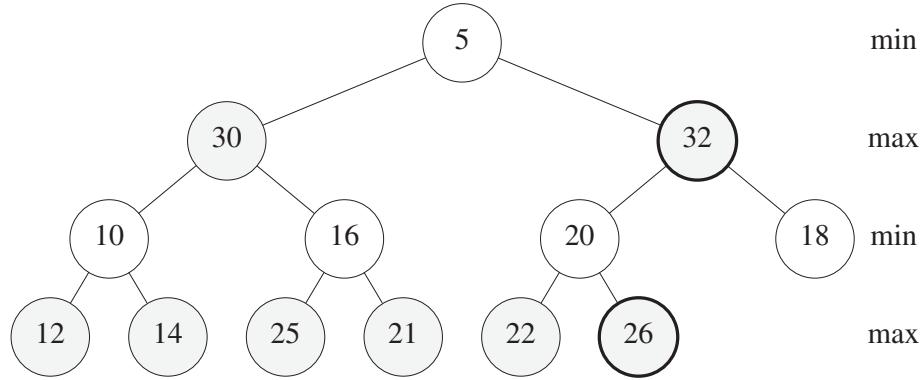

FIGURE 8.18 The min-max heap of Figure 8.15 following the insertion of 32.

of the min-max heap array to drop out of the min-max heap. Figure 8.17 shows the situation following the removal of the 5, which was the min element and which has been removed from the min-max heap, the 22 that was in position $n = 12$ of the min-max heap array has dropped out of the min-max heap. To get the dropped-out element 22 back into the min-max heap, we perform a trickle-down operation that begins at the root of the min-max heap.

The trickle-down operation for min-max heaps is similar to that for min and max heaps. The root is to contain the smallest element. To ensure this, we determine the smallest element in a child or grandchild of the root. If 22 is \leq the smallest of these children and grandchildren, the 22 is placed in the root. If not, the smallest of the children and grandchildren is moved to the root; the trickle-down process is continued from the position vacated by the just moved smallest element.

In our example, examining the children and grandchildren of the root of Figure 8.19, we determine that the smallest of these is 10. Since $10 < 22$, the 10 moves to the root and the 22 trickles down (Figure 8.20). A special case arises when this trickle down of the 22 by 2 levels causes the 22 to trickle past a smaller element (in our example, we trickle past a larger element 30). When this special case arises, we simply exchange the 22 and the smaller element being trickled past. The trickle-down process applied at the vacant node of Figure 8.20 results in the 22 being placed into the vacant node.

Suppose that *droppedElement* is the element dropped from *minmaxHeap[n]* when a remove min is done from an *n*-element min-max heap. The following describes the trickle-down process used to reinsert the dropped element.

1. *The root has no children.*

In this case *droppedElement* is inserted into the root and the trickle down terminates.

2. *The root has at least one child.*

Now the smallest key in the min-max heap is in one of the children or grandchildren of the root. We determine which of these nodes has the smallest key. Let this be node *k*. The following possibilities need to be considered:

- a. *droppedElement \leq minmaxHeap[k].*

droppedElement may be inserted into the root, as there is no smaller element in the heap. The trickle down terminates.

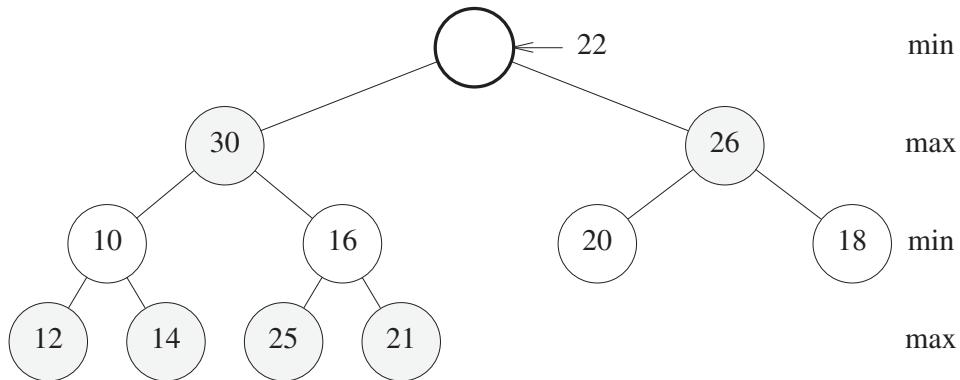

FIGURE 8.19 Situation following a remove min from Figure 8.15.

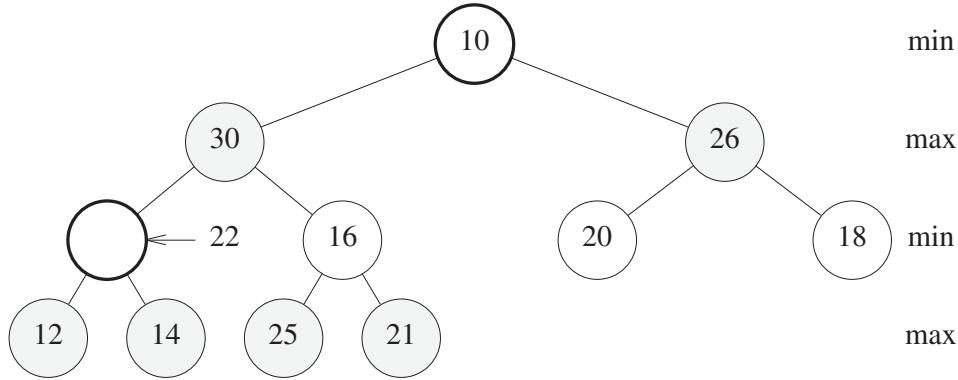

FIGURE 8.20 Situation following one iteration of the trickle-down process.

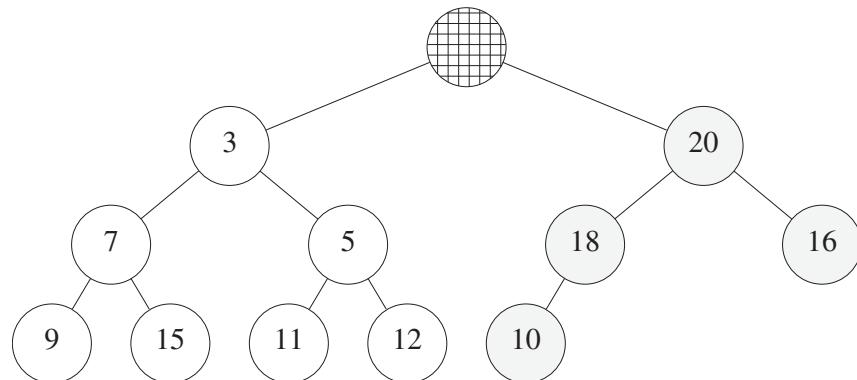

FIGURE 8.21 An 11-element deap.

- c. $droppedElement > minmaxHeap[k]$ and k is a child of the root.

Since k is a max node, it has no descendants larger than $\text{minmaxHeap}[k]$. Hence, node k has no descendants larger than droppedElement . So, the $\text{minmaxHeap}[k]$ may be moved to the root, and droppedElement placed into node k . The trickle down terminates.

- e. $droppedElement > minmaxHeap[k]$ and k is a grandchild of the root.

$\minmaxHeap[k]$ is moved to the root. Let p be the parent of k . If $\text{droppedElement} > \minmaxHeap[p]$, then $\minmaxHeap[p]$ and droppedElement are interchanged. This interchange ensures that the max node p contains the largest key in the subheap with root p . The trickle down continues with k as the root of a min-max (sub) heap into which an element is to be inserted.

The complexity of the remove-min operation is readily seen to be $O(\log n)$. The remove-max operation is similar to the remove-min operation, and min-max heaps may be initialized in $\Theta(n)$ time using an algorithm similar to that used to initialize min and max heaps [9].

8.5 Deaps

The deap structure of [3] is similar to the two-heap structures of [4–7]. At the conceptual level, we have a min heap and a max heap. However, the distribution of elements between the two is not $\lceil n/2 \rceil$ and $\lfloor n/2 \rfloor$. Rather, we begin with an $(n+1)$ -node complete binary tree. Its left subtree is the min heap and its right subtree is the max heap (Figure 8.21, max-heap nodes are shaded). The correspondence property for deaps is slightly more complex than that for the two-heap structures of [4–7].

A **heap** is a complete binary tree that is either empty or satisfies the following conditions:

1. The root is empty.
 2. The left subtree is a min heap and the right subtree is a max heap.

3. *Correspondence property.* Suppose that the right subtree is not empty. For every node x in the left subtree, define its corresponding node y in the right subtree to be the node in the same position as x . In case such a y doesn't exist, let y be the corresponding node for the parent of x . The element in x is \leq the element in y .

For the example complete binary tree of [Figure 8.21](#), the corresponding nodes for the nodes with 3, 7, 5, 9, 15, 11, and 12, respectively, have 20, 18, 16, 10, 18, 16, and 16.

Notice that every node y in the max heap has a unique corresponding node x in the min heap. The correspondence property for max-heap nodes is that the element in y be \geq the element in x . When the correspondence property is satisfied for all nodes in the min heap, this property is also satisfied for all nodes in the max heap.

We see that when $n = 0$, there is no min or max element, when $n = 1$, the root of the min heap has both the min and the max element, and when $n > 1$, the root of the min heap is the min element and the root of the max heap is the max element. So, both `getMin()` and `getMax()` may be implemented to work in $O(1)$ time.

8.5.1 Inserting an Element

When an element is inserted into an n -element deap, we go form a complete binary tree that has $n + 1$ nodes to one that has $n + 2$ nodes. So, the shape of the new deap is well defined. Following an insertion, our 11-element deap of [Figure 8.21](#) has the shape shown in [Figure 8.22](#). The new node is node j and its corresponding node is node i .

To insert `newElement`, temporarily place `newElement` into the new node j and check the correspondence property for node j . If the property isn't satisfied, swap `newElement` and the element in its corresponding node; use a trickle-up process to correctly position `newElement` in the heap for the corresponding node i . If the correspondence property is satisfied, do not swap `newElement`; instead use a trickle-up process to correctly place `newElement` in the heap that contains node j .

Consider the insertion of `newElement` = 2 into [Figure 8.22](#). The element in the corresponding node i is 15. Since the correspondence property isn't satisfied, we swap 2 and 15. Node j now contains 15 and this swap is guaranteed to preserve the max-heap properties of the right subtree of the complete binary tree. To correctly position the 2 in the left subtree, we use the standard min-heap trickle-up process beginning at node i . This results in the configuration of [Figure 8.23](#).

To insert `newElement` = 19 into the deap of [Figure 8.22](#), we check the correspondence property between 15 and 19. The property is satisfied. So, we use the trickle-up process for max heaps to correctly position `newElement` in the max heap. [Figure 8.24](#) shows the result.

Since the height of a deap is $\Theta(\log n)$, the time to insert into a deap is $O(\log n)$.

8.5.2 Removing the Min Element

Assume that $n > 0$. The min element is in the root of the min heap. Following its removal, the deap size reduces to $n - 1$ and the element in position $n + 1$ of the deap array is dropped from the deap. In the case of our example of [Figure 8.21](#), the min element 3 is removed and the 10 is dropped. To reinsert the dropped element, we first trickle the vacancy in the root of the min heap down to a leaf of the min heap. This is similar to a standard min-heap trickle down with ∞ as the reinsert element. For our example, this trickle down causes 5 and 11 to, respectively, move to their parent nodes. Then, the dropped element 10 is inserted using a trickle-up process beginning at the vacant leaf of the min heap. The resulting deap is shown in [Figure 8.25](#).

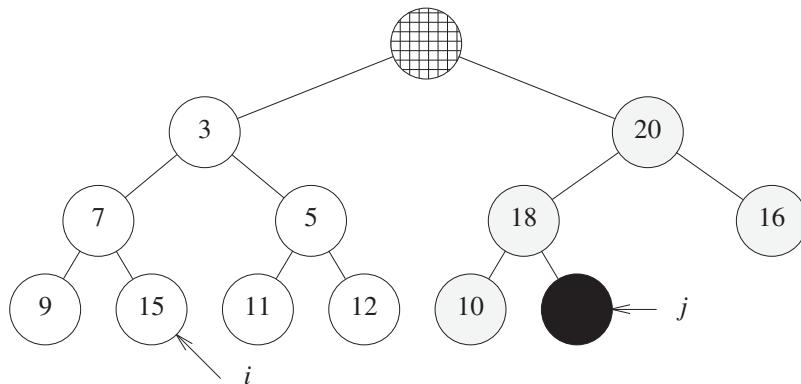

FIGURE 8.22 Shape of a 12-element deap.

Since a *removeMin* requires a trickle-down pass followed by a trickle-up pass and since the height of a deap is $\Theta(\log n)$, the time for a *removeMin* is $O(\log n)$. A *removeMax* is similar. Also, we may initialize a deap in $\Theta(n)$ time using an algorithm similar to that used to initialize a min or max heap [9].

8.6 Generic Methods for DEPQs

8.6.1 Dual Priority Queues

General methods [10] exist to arrive at efficient DEPQ data structures from single-ended priority queue data structures that also provide an efficient implementation of the *remove(theNode)* operation (this operation removes the node *theNode* from the PQ). The simplest of these methods, *dual structure method*, maintains both a min PQ (called *minPQ*) and a max PQ (called *maxPQ*) of all the DEPQ elements together with *correspondence pointers* between the nodes of the min PQ and the max PQ that contain the same element. Figure 8.26 shows a dual heap structure for the elements 6, 7, 2, 5, 4. Correspondence pointers are shown as double-headed arrows.

Although Figure 8.26 shows each element stored in both the min and the max heap, it is necessary to store each element in only one of the two heaps.

The minimum element is at the root of the min heap and the maximum element is at the root of the max heap. To insert an element x , we insert x into both the min and the max heaps and then set up correspondence pointers between the locations of x in the min and max heaps. To remove the minimum element, we do a *removeMin* from the min heap and a *remove(theNode)*, where *theNode* is the corresponding node for the removed element, from the max heap. The maximum element is removed in an analogous way.

8.6.2 Total Correspondence

The notion of total correspondence borrows heavily from the ideas used in a twin heap [7]. In the twin heap data structure n elements are stored in a min heap using an array $\text{minHeap}[1:n]$ and n other elements are stored in a max heap using the array $\text{maxHeap}[1:n]$. The min and max heaps satisfy the inequality $\text{minHeap}[i] \leq \text{maxHeap}[i]$, $1 \leq i \leq n$. In this way, we can represent a DEPQ with $2n$ elements. When we must represent a DEPQ with an odd number of elements, one element is stored in a buffer, and the remaining elements are divided equally between the arrays minHeap and maxHeap .

In total correspondence, we remove the positional requirement in the relationship between pairs of elements in the min heap and max heap. The requirement becomes: for each element a in minPQ there is a distinct element b in maxPQ such that $a \leq b$ and vice versa. (a, b) is a corresponding pair of elements. Figure 8.27a shows a twin heap with 11 elements and Figure 8.27b shows a total correspondence heap. The broken arrows connect corresponding pairs of elements.

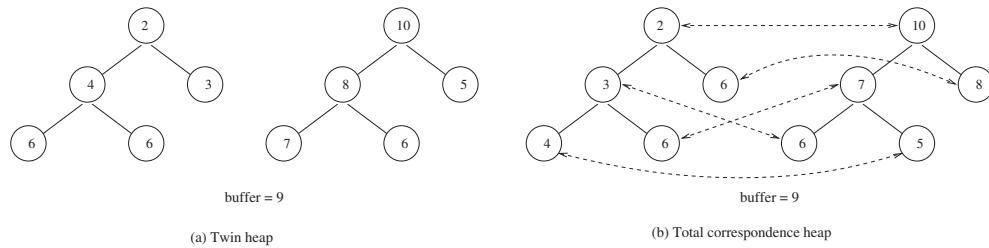

FIGURE 8.27 Twin heap and total correspondence heap.

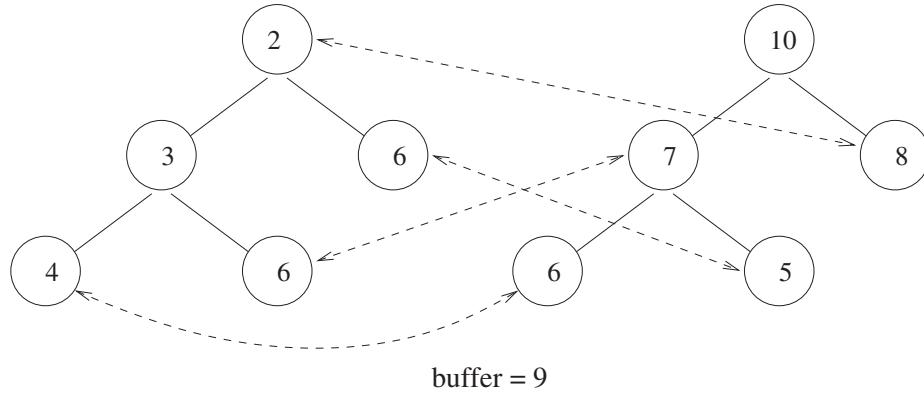

FIGURE 8.28 Leaf correspondence heap.

In a twin heap the corresponding pairs ($\min\text{Heap}[i], \max\text{Heap}[i]$) are implicit, whereas in a total correspondence heap these pairs are represented using explicit pointers.

In a total correspondence DEPQ, the number of nodes is either n or $n - 1$. The space requirement is half that needed by the dual priority queue representation. The time required is also reduced. For example, if we do a sequence of inserts, every other one simply puts the element in the buffer. The remaining inserts put one element in $\max\text{PQ}$ and one in $\min\text{PQ}$. So, on average, an insert takes time comparable to an insert in either $\max\text{PQ}$ or $\min\text{PQ}$. Recall that when dual priority queues are used the insert time is the sum of the times to insert into $\max\text{PQ}$ and $\min\text{PQ}$. Note also that the size of $\max\text{PQ}$ and $\min\text{PQ}$ together is half that of a dual priority queue.

If we assume that the complexity of the insert operation for priority queues as well as 2 *remove(theNode)* operations is no more than that of the delete max or min operation (this is true for all known priority queue structures other than weight biased leftist trees [11]), then the complexity of *removeMax* and *removeMin* for total correspondence DEPQs is the same as for the *removeMax* and *removeMin* operation of the underlying priority queue data structure.

Using the notion of total correspondence, we trivially obtain efficient DEPQ structures starting with any of the known priority queue structures (other than weight biased leftist trees [11]).

The *removeMax* and *removeMin* operations can generally be programmed to run faster than suggested by our generic algorithms. This is because, for example, a *removeMax()* and *put(x)* into a max priority queue can often be done faster as a single operation *changeMax(x)*. Similarly a *remove(theNode)* and *put(x)* can be programmed as a *change(theNode, x)* operation.

8.6.3 Leaf Correspondence

In leaf correspondence DEPQs, for every leaf element a in $\min\text{PQ}$, there is a distinct element b in $\max\text{PQ}$ such that $a \leq b$ and for every leaf element c in $\max\text{PQ}$ there is a distinct element d in $\min\text{PQ}$ such that $d \leq c$. Figure 8.28 shows a leaf correspondence heap.

Efficient leaf correspondence DEPQs may be constructed easily from PQs that satisfy the following requirements [10]:

- The PQ supports the operation *remove(Q, p)* efficiently.
- When an element is inserted into the PQ, no nonleaf node becomes a leaf node (except possibly the node for the newly inserted item).
- When an element is deleted (using *remove*, *removeMax* or *removeMin*) from the PQ, no nonleaf node (except possibly the parent of the deleted node) becomes a leaf node.

Some of the PQ structures that satisfy these requirements are height-biased leftist trees (Chapter 5) [9,12, 13], pairing heaps (Chapter 7) [14,15], and Fibonacci heaps [16] (Chapter 7). Requirements (b) and (c) are not satisfied, for example, by ordinary heaps and the FMPQ structure of [17]. Although heaps and Brodal's FMPQ structure do not satisfy the requirements of our generic approach to build a leaf correspondence DEPQ structure from a priority queue, we can nonetheless arrive at leaf correspondence heaps and leaf correspondence FMPQs using a customized approach.

8.7 Meldable DEPQs

A *meldable DEPQ* (*MDEPQ*) is a DEPQ that, in addition to the DEPQ operations listed above, includes the operation

meld(x, y) . . . meld the DEPQs x and y into a single DEPQ.

The result of melding the double-ended priority queues x and y is a single double-ended priority queue that contains all elements of x and y . The meld operation is destructive in that following the meld, x and y do not remain as independent DEPQs.

To meld two DEPQs in less than linear time, it is essential that the DEPQs be represented using explicit pointers (rather than implicit ones as in the array representation of a heap) as otherwise a linear number of elements need to be moved from their initial to their final locations. Olariu et al. [6] have shown that when the min-max pair heap is represented in such a way, an n element DEPQ may be melded with a k element one ($k \leq n$) in $O(\log(n/k) * \log k)$ time. When $k = \sqrt{n}$, this is $O(\log^2 n)$. Hasham and Sack [18] have shown that the complexity of melding two min-max heaps of size n and k , respectively, is $\Omega(n+k)$. Brodal [17] has developed an MDEPQ implementation that allows one to find the min and max elements, insert an element, and meld two priority queues in $O(1)$ time. The time needed to delete the minimum or maximum element is $O(\log n)$. Although the asymptotic complexity provided by this data structure are the best one can hope for [17], the data structure has practical limitations. First, each element is represented twice using a total of 16 fields per element. Second, even though the delete operations have $O(\log n)$ complexity, the constant factors are very high and the data structure will not perform well unless find, insert, and meld are the primary operations.

Cho and Sahni [19] have shown that leftist trees [9, 12, 13] may be adapted to obtain a simple representation for MDEPQs in which *meld* takes logarithmic time and the remaining operations have the same asymptotic complexity as when any of the aforementioned DEPQ representations is used. Chong and Sahni [10] study MDEPQs based on pairing heaps [14, 15], Binomial and Fibonacci heaps [16], and FMPQ [17].

Since leftist heaps, pairing heaps, Binomial and Fibonacci heaps, and FMPQs are meldable priority queues that also support the *remove(theNode)* operation, the MDEPQs of [10, 19] use the generic methods of Section 8.6 to construct an MDEPQ data structure from the corresponding MPQ (meldable PQ) structure.

It is interesting to note that if we use the FMPQ structure of [17] as the base MPQ structure, we obtain a total correspondence MDEPQ structure in which *removeMax* and *removeMin* take logarithmic time, and the remaining operations take constant time. This adaptation is superior to the dual priority queue adaptation proposed in Reference 17 because the space requirements are almost half. Additionally, the total correspondence adaptation is faster. Although Brodal's FMPQ structure does not satisfy the requirements of the generic approach to build a leaf correspondence MDEPQ structure from a priority queue, we can nonetheless arrive at leaf correspondence FMPQs using a customized approach.

9.1 Introduction

A *set abstract data type* (*set ADT*) is an abstract data type that maintains a set S under the following three operations:

1. $\text{INSERT}(x)$: Add the key x to the set.
2. $\text{DELETE}(x)$: Remove the key x from the set.
3. $\text{SEARCH}(x)$: Determine if x is contained in the set, and if so, return a pointer to x .

One of the most practical and widely used methods of implementing the set ADT is with *hash tables*.

Note that the three set ADT operations can easily be implemented to run in $O(\log n)$ time per operation using balanced binary search trees (See [Chapter 11](#)). If we assume that the input data are integers in the set $U = \{0, \dots, u - 1\}$ then they can even be implemented to run in sub-logarithmic time using data structures for integer searching ([Chapter 40](#)). However, these data structures actually do more than the three basic operations we require. In particular if we search for an element x that is not present in S then these data structures can report the smallest item in S that is larger than x (the *successor* of x) and/or the largest item in S that is smaller than x (the *predecessor* of x).

Hash tables do away with this extra functionality of finding predecessors and successors and only perform exact searches. If we search for an element x in a hash table and x is not present then the only information we obtain is that $x \notin S$. By dropping this extra functionality hash tables can give better performance bounds. Indeed, any reasonable hash table implementation performs each of the three set ADT operations in $O(1)$ expected time.

The main idea behind all hash table implementations discussed in this chapter is to store a set of $n = |S|$ elements in an array (the hash table) A of length $m \geq n$. In doing this, we require a function that maps any element x to an array location. This function is called a *hash function* h and the value $h(x)$ is called the *hash value* of x . That is, the element x gets stored at the array location $A[h(x)]$. The *occupancy* of a hash table is the ratio $\alpha = n/m$ of stored elements to the length of A .

The study of hash tables follows two very different lines. Many implementations of hash tables are based on the *integer universe assumption*: All elements stored in the hash table come from the universe $U = \{0, \dots, u - 1\}$. In this case, the goal is to design a hash function $h : U \rightarrow \{0, \dots, m - 1\}$ so that for each $i \in \{0, \dots, m - 1\}$, the number of elements $x \in S$ such that $h(x) = i$ is as small as possible. Ideally, the hash function h would be such that each element of S is mapped to a unique value in $\{0, \dots, m - 1\}$. Most of the hash functions designed under the integer universe assumption are number-theoretic constructions. Several of these are described in Section 9.2.

^{*} This chapter has been reprinted from first edition of this Handbook, without any content updates.

Historically, the integer universe assumption seems to have been justified by the fact that any data item in a computer is represented as a sequence of bits that can be interpreted as a binary number. However, many complicated data items require a large (or variable) number of bits to represent and this make u the size of the universe very large. In many applications u is much larger than the largest integer that can fit into a single word of computer memory. In this case, the computations performed in number-theoretic hash functions become inefficient.

This motivates the second major line of research into hash tables. This research work is based on the random probing assumption: Each element x that is inserted into a hash table is a black box that comes with an infinite random *probe sequence* x_0, x_1, x_2, \dots where each of the x_i is independently and uniformly distributed in $\{0, \dots, m - 1\}$. Hash table implementations based on the random probing assumption are described in Section 9.3.

Both the integer universe assumption and the random probing assumption have their place in practice. When there is an easily computing mapping of data elements onto machine word sized integers then hash tables for integer universes are the method of choice. When such a mapping is not so easy to compute (variable length strings are an example) it might be better to use the bits of the input items to build a good pseudorandom sequence and use this sequence as the probe sequence for some random probing data structure.

To guarantee good performance, many hash table implementations require that the occupancy α be a constant strictly less than 1. Since the number of elements in a hash table changes over time, this requires that the array A be resized periodically. This is easily done, without increasing the amortized cost of hash table operations by choosing three constants $0 < \alpha_1 < \alpha_2 < \alpha_3 < 1$ so that, whenever n/m is not the interval (α_1, α_3) the array A is resized so that its size is n/α_2 . A simple amortization argument (Chapter 1) shows that the amortized cost of this resizing is $O(1)$ per update (Insert/Delete) operation.

9.2 Hash Tables for Integer Keys

In this section we consider hash tables under the integer universe assumption, in which the key values x come from the universe $U = \{0, \dots, u - 1\}$. A *hash function* h is a function whose domain is U and whose range is the set $\{0, \dots, m - 1\}$, $m \leq u$. A hash function h is said to be a *perfect hash function* for a set $S \subseteq U$ if, for every $x \in S$, $h(x)$ is unique. A perfect hash function h for S is *minimal* if $m = |S|$, that is, h is a bijection between S and $\{0, \dots, m - 1\}$. Obviously a minimal perfect hash function for S is desirable since it allows us to store all the elements of S in a single array of length n . Unfortunately, perfect hash functions are rare, even for m much larger than n . If each element of S is mapped independently and uniformly to a random element of $\{0, \dots, m - 1\}$ then the birthday paradox (see, e.g., Feller [1]) states that, if m is much less than n^2 then there will almost surely exist two elements of S that have the same hash value.

We begin our discussion with two commonly used hashing schemes that are heuristic in nature. That is, we can not make any non-trivial statements about the performance of these schemes when storing an arbitrary set S . We then discuss several schemes that have provably good performance.

9.2.1 Hashing by Division

In *hashing by division*, we use the hash function

$$h(x) = x \bmod m.$$

To use this hash function in a data structure, we maintain an array $A[0], \dots, A[m - 1]$ where each element of this array is a pointer to the head of a linked list (Chapter 2). The linked list L_i pointed to by the array element $A[i]$ contains all the elements x such that $h(x) = i$. This technique of maintaining an array of lists is called *hashing with chaining*.

In such a hash table, inserting an element x takes $O(1)$ time; we compute $i = h(x)$ and append (or prepend) x to the list L_i . However, searching for and/or deleting an element x is not so easy. We have to compute $i = h(x)$ and then traverse the list L_i until we either find x or reach the end of the list. The cost of this is proportional to the length of L_i . Obviously, if our set S consists of the elements $0, m, 2m, 3m, \dots, nm$ then all elements are stored in the list L_0 and searches and deletions take linear time.

However, one hopes that such pathological cases do not occur in practice. For example, if the elements of S are uniformly and independently distributed in U and u is a multiple of m then the expected size of any list L_i is only n/m . In this case, searches and deletions take $O(1 + \alpha)$ expected time. To help avoid pathological cases, the choice of m is important. In particular, m a power of 2 is usually avoided since, in a binary computer, taking the remainder modulo a power of 2 means simply discarding some high-order bits. Taking m to be a prime not too close to a power of 2 is recommended [2].

9.2.2 Hashing by Multiplication

The implementation of a hash table using *hashing by multiplication* is exactly the same as that of hashing by division except that the hash function

$$h(x) = \lfloor mxA \rfloor \bmod m$$

is used. Here A is a real-valued constant whose choice we discuss below. The advantage of the multiplication method is that the value of m is not critical. We can take m to be a power of 2, which makes it convenient for use on binary computers.

Although any value of A gives a hash function, some values of A are better than others. (Setting $A = 0$ is clearly not a good idea.)

Knuth [2] suggests using the *golden ratio* for A , that is, setting

$$A = (\sqrt{5} - 1)/2 = 0.6180339887\dots$$

This choice of A is motivated by a theorem, first conjectured by Oderfeld and later proven by ŚSierczkowski [3]. This theorem states that the sequence

$$mA \bmod m, \quad 2mA \bmod m, \quad 3mA \bmod m, \dots, nmA \bmod m$$

partitions the interval $(0, m)$ into $n + 1$ intervals having only three distinct lengths. Furthermore, the next element $(n + 1)mA \bmod m$ in the sequence is always contained in one of the largest intervals.*

Of course, no matter what value of A we select, the pigeonhole principle implies that for $u \geq nm$ then there will always exist some hash value i and some $S \subseteq U$ of size n such that $h(x) = i$ for all $x \in S$. In other words, we can always find a set S all of whose elements get stored in the same list L_i . Thus, the worst case of hashing by multiplication is as bad as hashing by division.

9.2.3 Universal Hashing

The argument used at the end of the previous section applies equally well to any hash function h . That is, if the table size m is much smaller than the universe size u then for any hash function there is some large (of size at least $\lceil u/m \rceil$) subset of U that has the same hash value. To get around this difficulty we need a collection of hash functions from which we can choose one that works well for S . Even better would be a collection of hash functions such that, for any given S , most of the hash functions work well for S . Then we could simply pick one of the functions at random and have a good chance of it working well.

Let \mathcal{H} be a collection of hash functions, that is, functions from U onto $\{0, \dots, m - 1\}$. We say that \mathcal{H} is *universal* if, for each $x, y \in U$ the number of $h \in \mathcal{H}$ such that $h(x) = h(y)$ is at most $|\mathcal{H}|/m$. Consider any $S \subseteq U$ of size n and suppose we choose a random hash function h from a universal collection of hash functions. Consider some value $x \in U$. The probability that any key $y \in S$ has the same hash value as x is only $1/m$. Therefore, the expected number of keys in S , not equal to x , that have the same hash value as x is only

$$n_{h(x)} = \begin{cases} (n-1)/m & \text{if } x \in S \\ n/m & \text{if } x \notin S \end{cases}$$

Therefore, if we store S in a hash table using the hash function h then the expected time to search for, or delete, x is $O(1 + \alpha)$.

From the preceding discussion, it seems that a universal collection of hash functions from which we could quickly select one at random would be very handy indeed. With such a collection at our disposal we get an implementation of the set ADT that has $O(1)$ insertion time and $O(1)$ expected search and deletion time.

Carter and Wegman [5] describe three different collections of universal hash functions. If the universe size u is a prime number† then

$$\mathcal{H} = \{h_{k_1, k_2, m}(x) = ((k_1 x + k_2) \bmod u) \bmod m : 1 \leq k_1 < u, 0 \leq k_2 < u\}$$

is a collection of universal hash functions. Clearly, choosing a function uniformly at random from \mathcal{H} can be done easily by choosing two random values $k_1 \in \{1, \dots, u - 1\}$ and $k_2 \in \{0, \dots, u - 1\}$. Thus, we have an implementation of the set ADT with $O(1)$ expected time per operation.

9.2.4 Static Perfect Hashing

The result of Carter and Wegman on universal hashing is very strong, and from a practical point of view, it is probably the strongest result most people will ever need. The only thing that could be improved about their result is to make it deterministic, so that the running times of all operations are $O(1)$ *worst-case*. Unfortunately, this is not possible, as shown by Dietzfelbinger et al. [6].

Since there is no hope of getting $O(1)$ worst-case time for all three set ADT operations, the next best thing would be to have searches that take $O(1)$ worst-case time. In this section we describe the method of Fredman, Komlós and Szemerédi [7]. This is a static data structure that takes as input a set $S \subseteq U$ and builds a data structure of size $O(n)$ that can test if an element x is in S

* In fact, any irrational number has this property [4]. The golden ratio is especially good because it is not too close to a whole number.

† This is not a major restriction since, for any $u > 1$, there always exists a prime number in the set $\{u, u + 1, \dots, 2u\}$. Thus we can enforce this assumption by increasing the value of u by a constant factor.

in $O(1)$ worst-case time. Like the universal hash functions from the previous section, this method also requires that u be a prime number. This scheme uses hash functions of the form

$$h_{k,m}(x) = (kx \bmod u) \bmod m.$$

Let $B_{k,m}(S, i)$ be the number of elements $x \in S$ such that $h_{k,m}(x) = i$, that is, the number of elements of S that have hash value i when using the hash function $h_{k,m}$. The function $B_{k,m}$ gives complete information about the distribution of hash values of S . The main lemma used by Fredman et al. is that, if we choose $k \in U$ uniformly at random then

$$E \left[\sum_{i=0}^{m-1} \binom{B_{k,m}(S, i)}{2} \right] < \frac{n^2}{m}. \quad (9.1)$$

There are two important special cases of this result.

In the *sparse case* we take $m = n^2/\alpha$, for some constant $0 < \alpha < 1$. In this case, the expectation in Equation 9.1 is less than α . Therefore, by Markov's inequality, the probability that this sum is greater than or equal to 1 is at most α . But, since this sum is a non-negative integer, then with probability at least $1 - \alpha$ it must be equal to 0. In other words, with probability at least $1 - \alpha$, $B_{k,m}(S, i) \leq 1$ for all $0 \leq i \leq m - 1$, that is, the hash function $h_{k,m}$ is perfect for S . Of course this implies that we can find a perfect hash function very quickly by trying a small number of random elements $k \in U$ and testing if they result in perfect hash functions. (The expected number of elements that we will have to try is only $1/(1 - \alpha)$.) Thus, if we are willing to use quadratic space then we can perform searches in $O(1)$ worst-case time.

In the *dense case* we assume that m is close to n and discover that, for many values of k , the hash values are distributed fairly evenly among the set $1, \dots, m$. More precisely, if we use a table of size $m = n$, then

$$E \left[\sum_{i=0}^{m-1} B_{k,m}(S, i)^2 \right] \leq 3n.$$

By Markov's inequality this means that

$$\Pr \left\{ \sum_{i=0}^{m-1} B_{k,m}(S, i)^2 \leq 3n/\alpha \right\} \geq 1 - \alpha. \quad (9.2)$$

Again, we can quickly find a value of k satisfying (9.2) by testing a few randomly chosen values of k .

These two properties are enough to build a two-level data structure that uses linear space and executes searches in worst-case constant time. We call the following data structure the FKS- α data structure, after its inventors Fredman, Komlós and Szemerédi. At the top level, the data structure consists of an array $A[0], \dots, A[m-1]$ where $m = n$. The elements of this array are pointers to other arrays A_0, \dots, A_{m-1} , respectively. To decide what will be stored in these other arrays, we build a hash function $h_{k,m}$ that satisfies the conditions of Equation 9.2. This gives us the top-level hash function $h_{k,m}(x) = (kx \bmod u) \bmod m$. Each element $x \in S$ gets stored in the array pointed to by $A[h_{k,m}(x)]$.

What remains is to describe how we use the arrays A_0, \dots, A_{m-1} . Let S_i denote the set of elements $x \in S$ such that $h_{k,m}(x) = i$. The elements of S_i will be stored in A_i . The size of S_i is $n_i = B_{k,m}(S, i)$. To store the elements of S_i we set the size of A_i to $m_i = n_i^2/\alpha = B_{k,n}(S, i)^2/\alpha$. Observe that, by Equation 9.2, all the A_i 's take up a total space of $O(n)$, that is, $\sum_{i=0}^{m-1} m_i = O(n)$. Furthermore, by trying a few randomly selected integers we can quickly find a value k_i such that the hash function h_{k_i, m_i} is perfect for S_i . Therefore, we store the element $x \in S_i$ at position $A_i[h_{k_i, m_i}(x)]$ and x is the unique element stored at that location. With this scheme we can search for any value $x \in U$ by computing two hash values $i = h_{k,m}(x)$ and $j = h_{k_i, m_i}(x)$ and checking if x is stored in $A_i[j]$.

Building the array A and computing the values of n_0, \dots, n_{m-1} takes $O(n)$ expected time since for a given value k we can easily do this in $O(n)$ time and the expected number of values of k that we must try before finding one that satisfies (9.2) is $O(1)$. Similarly, building each subarray A_i takes $O(n_i^2)$ expected time, resulting in an overall expected running time of $O(n)$. Thus, for any constant $0 < \alpha < 1$, an FKS- α data structure can be constructed in $O(n)$ expected time and this data structure can execute a search for any $x \in U$ in $O(1)$ worst-case time.

9.2.5 Dynamic Perfect Hashing

The FKS- α data structure is nice in that it allows for searches in $O(1)$ time, in the worst case. Unfortunately, it is only static; it does not support insertions or deletions of elements. In this section we describe a result of Dietzfelbinger et al. [6] that shows how the FKS- α data structure can be made dynamic with some judicious use of partial rebuilding (Chapter 11).

* Actually, it turns out that any universal hash function also works in the FKS scheme [8, Section 11.5].

The main idea behind the scheme is simple: be lazy at both the upper and lower levels of the FKS- α data structure. That is, rebuild parts of the data structure only when things go wrong. At the top level, we relax the condition that the size m of the upper array A is exactly n and allow A to have size anywhere between n and $2n$. Similarly, at the lower level we allow the array A_i to have a size m_i anywhere between n_i^2/α and $2n_i^2/\alpha$.

Periodically, we will perform a *global rebuilding* operation in which we remove all n elements from the hash table. Some elements which have previously been marked as deleted will be discarded, thereby reducing the value of n . We put the remaining elements in a list, and recompute a whole new FKS- $(\alpha/2)$ data structure for the elements in the list. This data structure is identical to the standard FKS- $(\alpha/2)$ data structure except that, at the top level we use an array of size $m = 2n$.

Searching in this data structure is exactly the same as for the static data structure. To search for an element x we compute $i = h_{k,m}(x)$ and $j = h_{k_i, m_i}(x)$ and look for x at location $A_i[j]$. Thus, searches take $O(1)$ worst-case time.

Deleting in this data structure is done in the laziest manner possible. To delete an element we only search for it and then mark it as deleted. We will use the convention that this type of deletion does not change the value of n since it does not change the number of elements actually stored in the data structure. While doing this, we also keep track of the number of elements that are marked as deleted. When this number exceeds $n/2$ we perform a global rebuilding operation. The global rebuilding operation takes $O(n)$ expected time, but only occurs during one out of every $n/2$ deletions. Therefore, the amortized cost of this operation is $O(1)$ per deletion.

The most complicated part of the data structure is the insertion algorithm and its analysis. To insert a key x we know, because of how the search algorithm works, that we must ultimately store x at location $A_i[j]$ where $i = h_{k,m}(x)$ and $j = h_{k_i, m_i}(x)$. However, several things can go wrong during the insertion of x :

1. The value of n increases by 1, so it may be that n now exceeds m . In this case we perform a global rebuilding operation and we are done.
2. We compute $i = h_{k,m}(x)$ and discover that $\sum_{j=0}^{m-1} n_j^2 > 3n/\alpha$. In this case, the hash function $h_{k,m}$ used at the top level is no longer any good since it is producing an overall hash table that is too large. In this case we perform a global rebuilding operation and we are done.
3. We compute $i = h_{k,m}(x)$ and discover that, since the value of n_i just increased by one, $n_i^2/\alpha > m_i$. In this case, the array A_i is too small to guarantee that we can quickly find a perfect hash function. To handle this, we copy the elements of A_i into a list L and allocate a new array A_i with the new size $m_i = 2n_i^2/\alpha$. We then find a new value k_i such that h_{k_i, m_i} is a perfect hash function for the elements of L and we are done.
4. The array location $A_i[j]$ is already occupied by some other element y . But in this case, we know that A_i is large enough to hold all the elements (otherwise we would already be done after Case 3), but the value k_i being used in the hash function h_{k_i, m_i} is the wrong one since it doesn't give a perfect hash function for S_i . Therefore we simply try new values for k_i until we find a find a value k_i that yields a perfect hash function and we are done.

If none of the preceding 4 cases occurs then we can simply place x at location $A_i[j]$ and we are done.

Handling Case 1 takes $O(n)$ expected time since it involves a global rebuild of the entire data structure. However, Case 1 only happens during one out of every $\Theta(n)$ insertions, so the amortized cost of all occurrences of Case 1 is only $O(1)$ per insertion.

Handling Case 2 also takes $O(n)$ expected time. The question is: How often does Case 2 occur? To answer this question, consider the *phase* that occurs between two consecutive occurrences of Case 1. During this phase, the data structure holds at most m distinct elements. Call this set of elements S . With probability at least $(1 - \alpha)$ the hash function $h_{k,m}$ selected at the beginning of the phase satisfies (9.2) so that Case 2 never occurs during the phase. Similarly, the probability that Case 2 occurs exactly once during the phase is at most $\alpha(1 - \alpha)$. In general, the probability that Case 2 occurs exactly i times during a phase is at most $\alpha^i(1 - \alpha)$. Thus, the expected cost of handling all occurrences of Case 2 during the entire phase is at most

$$\sum_{i=0}^{\infty} \alpha^i(1 - \alpha)^i \times O(n) = O(n).$$

But since a phase involves $\Theta(n)$ insertions this means that the amortized expected cost of handling Case 2 is $O(1)$ per insertion.

Next we analyze the total cost of handling Case 3. Define a *subphase* as the period of time between two global rebuilding operations triggered either as a result of a deletion, Case 1 or Case 2. We will show that the total cost of handling all occurrences of Case 3 during a subphase is $O(n)$ and since a subphase takes $\Theta(n)$ time anyway this does not contribute to the cost of a subphase by more than a constant factor. When Case 3 occurs at the array A_i it takes $O(m_i)$ time. However, while handling Case 3, m_i increases by a constant factor, so the total cost of handling Case 3 for A_i is dominated by the value of m_i at the end of the subphase. But we maintain the invariant that $\sum_{i=0}^{m-1} m_i = O(n)$ during the entire subphase. Thus, handling all occurrences of Case 3 during a subphase only requires $O(n)$ time.

Finally, we consider the cost of handling Case 4. For a particular array A_i , consider the *subsubphase* between which two occurrences of Case 3 cause A_i to be rebuilt or a global rebuilding operation takes place. During this subsubphase the number of distinct elements that occupy A_i is at most $\alpha\sqrt{m_i}$. Therefore, with probability at least $1 - \alpha$ any randomly chosen value of $k_i \in U$ is a perfect hash function for this set. Just as in the analysis of Case 2, this implies that the expected cost of handling all occurrences of Case 3 at A_i during a subsubphase is only $O(m_i)$. Since a subsubphase ends with rebuilding all of A_i or a global rebuilding, at a cost of $\Omega(m_i)$ all the occurrences of Case 4 during a subsubphase do not contribute to the expected cost of the subsubphase by more than a constant factor.

To summarize, we have shown that the expected cost of handling all occurrences of Case 4 is only a constant factor times the cost of handling all occurrences of Case 3. The cost of handling all occurrences of Case 3 is no more than a constant factor times the expected cost of all global rebuilds. The cost of handling all the global rebuilds that occur as a result of Case 2 is no more than a constant factor times the cost of handling all occurrences of global rebuilds that occur as a consequence of Case 1. And finally, the cost of all global rebuilds that occur as a result of Case 1 or of deletions is $O(n)$ for a sequence of n update operations. Therefore, the total expected cost of n update operation is $O(n)$.

9.3 Random Probing

Next we consider hash table implementations under the random probing assumption: Each element x stored in the hash table comes with a random sequence x_0, x_1, x_2, \dots where each of the x_i is independently and uniformly distributed in $\{1, \dots, m\}$.^{*} We begin with a discussion of the two basic paradigms: hashing with chaining and open addressing. Both these paradigms attempt to store the key x at array position $A[x_0]$. The difference between these two algorithms is their *collision resolution strategy*, that is, what the algorithms do when a user inserts the key value x but array position $A[x_0]$ already contains some other key.

9.3.1 Hashing with Chaining

In *hashing with chaining*, a collision is resolved by allowing more than one element to live at each position in the table. Each entry in the array A is a pointer to the head of a linked list. To insert the value x , we simply append it to the list $A[x_0]$. To search for the element x , we perform a linear search in the list $A[x_0]$. To delete the element x , we search for x in the list $A[x_0]$ and splice it out.

It is clear that insertions take $O(1)$ time, even in the worst case. For searching and deletion, the running time is proportional to a constant plus the length of the list stored at $A[x_0]$. Notice that each of the at most n elements not equal to x is stored in $A[x_0]$ with probability $1/m$, so the expected length of $A[x_0]$ is either $\alpha = n/m$ (if x is not contained in the table) or $1 + (n-1)/m$ (if x is contained in the table). Thus, the expected cost of searching for or deleting an element is $O(1 + \alpha)$.

The above analysis shows us that hashing with chaining supports the three set ADT operations in $O(1)$ expected time per operation, as long as the occupancy, α , is a constant. It is worth noting that this does not require that the value of α be less than 1.

If we would like more detailed information about the cost of searching, we might also ask about the *worst-case search time* defined as

$$W = \max\{\text{length of the list stored at } A[i] : 0 \leq i \leq m-1\}.$$

It is very easy to prove something quite strong about W using only the fact that the length of each list $A[i]$ is a binomial($n, 1/m$) random variable. Using Chernoff's bounds on the tail of the binomial distribution [9], this immediately implies that

$$\Pr\{\text{length of } A[i] \geq \alpha c \ln n\} \leq n^{-\Omega(c)}.$$

Combining this with Boole's inequality ($\Pr\{A \text{ or } B\} \leq \Pr\{A\} + \Pr\{B\}$) we obtain

$$\Pr\{W \geq \alpha c \ln n\} \leq n \times n^{-\Omega(c)} = n^{-\Omega(c)}.$$

Thus, with very high probability, the worst-case search time is logarithmic in n . This also implies that $E[W] = O(\log n)$. The distribution of W has been carefully studied and it is known that, *with high probability*, that is, with probability $1 - o(1)$, $W = (1 + o(1))\ln n / \ln \ln n$ [10,11].[†] Gonnet has proven a more accurate result that $W = \Gamma^{-1}(n) - 3/2 + o(1)$ with high probability. Devroye [12] shows that similar results hold even when the distribution of x_0 is not uniform.

^{*} A variant of the random probing assumption, referred to as the *uniform hashing* assumption, assumes that x_0, \dots, x_{m-1} is a random permutation of $0, \dots, m-1$.

[†] Here, and throughout this chapter, if an asymptotic notation does not contain a variable then the variable that tends to infinity is implicitly n . Thus, for example, $o(1)$ is the set of non-negative functions of n that tend to 0 as $n \rightarrow \infty$.

9.3.2 Hashing with Open Addressing

Hashing with open addressing differs from hashing with chaining in that each table position $A[i]$ is allowed to store only one value. When a collision occurs at table position i , one of the two elements involved in the collision must move on to the next element in its probe sequence. In order to implement this efficiently and correctly we require a method of marking elements as deleted. This method could be an auxiliary array that contains one bit for each element of A , but usually the same result can be achieved by using a special key value **del** that does not correspond to any valid key.

To search for an element x in the hash table we look for x at positions $A[x_0], A[x_1], A[x_2]$, and so on until we either (1) find x , in which case we are done or (2) find an empty table position $A[x_i]$ that is not marked as deleted, in which case we can be sure that x is not stored in the table (otherwise it would be stored at position x_i). To delete an element x from the hash table we first search for x . If we find x at table location $A[x_i]$ we then simply mark $A[x_i]$ as deleted. To insert a value x into the hash table we examine table positions $A[x_0], A[x_1], A[x_2]$, and so on until we find a table position $A[x_i]$ that is either empty or marked as deleted and we store the value x in $A[x_i]$.

Consider the cost of inserting an element x using this method. Let i_x denote the smallest value i such that x_{i_x} is either empty or marked as deleted when we insert x . Thus, the cost of inserting x is a constant plus i_x . The probability that the table position x_0 is occupied is at most α so, with probability at least $1 - \alpha$, $i_x = 0$. Using the same reasoning, the probability that we store x at position x_i is at most

$$\Pr\{i_x = i\} \leq \alpha^i(1 - \alpha) \quad (9.3)$$

since the table locations x_0, \dots, x_{i-1} must be occupied, the table location x_i must not be occupied and the x_i are independent. Thus, the expected number of steps taken by the insertion algorithm is

$$\sum_{i=1}^{\infty} i \Pr\{i_x = i\} = (1 - \alpha) \sum_{i=1}^{\infty} i \alpha^{i-1} = 1/(1 - \alpha)$$

for any constant $0 < \alpha < 1$. The cost of searching for x and deleting x are both proportional to the cost of inserting x , so the expected cost of each of these operations is $O(1/(1 - \alpha))$.*

We should compare this with the cost of hashing with chaining. In hashing with chaining, the occupancy α has very little effect on the cost of operations. Indeed, any constant α , even greater than 1 results in $O(1)$ time per operation. In contrast, open addressing is very dependent on the value of α . If we take $\alpha > 1$ then the expected cost of insertion using open addressing is infinite since the insertion algorithm never finds an empty table position. Of course, the advantage of hashing with chaining is that it does not require lists at each of the $A[i]$. Therefore, the overhead of list pointers is saved and this extra space can be used instead to maintain the invariant that the occupancy α is a constant strictly less than 1.

Next we consider the worst case search time of hashing with open addressing. That is, we study the value $W = \max\{i_x : x \text{ is stored in the table at location } i_x\}$. Using Equation 9.3 and Boole's inequality it follows almost immediately that

$$\Pr\{W > c \log n\} \leq n^{-\Omega(c)}.$$

Thus, with very high probability, W , the worst case search time, is $O(\log n)$. Tighter bounds on W are known when the probe sequences x_0, \dots, x_{m-1} are random permutations of $0, \dots, m-1$. In this case, Gonnet [13] shows that

$$E[W] = \log_{1/\alpha} n - \log_{1/\alpha} (\log_{1/\alpha} n) + O(1).$$

Open addressing under the random probing assumption has many nice theoretical properties and is easy to analyze. Unfortunately, it is often criticized as being an unrealistic model because it requires a long random sequences x_0, x_1, x_2, \dots for each element x that is to be stored or searched for. Several variants of open addressing discussed in the next few sections try to overcome this problem by using only a few random values.

9.3.3 Linear Probing

Linear probing is a variant of open addressing that requires less randomness. To obtain the probe sequence x_0, x_1, x_2, \dots we start with a random element $x_0 \in \{0, \dots, m-1\}$. The element x_i , $i > 0$ is given by $x_i = (i + x_0) \bmod m$. That is, one first tries to find x at location x_0 and if that fails then one looks at $(x_0 + 1) \bmod m, (x_0 + 2) \bmod m$ and so on.

* Note that the expected cost of searching for or deleting an element x is proportional to the value of α at the time x was inserted. If many deletions have taken place, this may be quite different than the current value of α .

The performance of linear probing is discussed by Knuth [2] who shows that the expected number of probes performed during an unsuccessful search is at most

$$(1 + 1/(1 - \alpha)^2)/2$$

and the expected number of probes performed during a successful search is at most

$$(1 + 1/(1 - \alpha))/2.$$

This is not quite as good as for standard hashing with open addressing, especially in the unsuccessful case.

Linear probing suffers from the problem of *primary clustering*. If j consecutive array entries are occupied then a newly inserted element will have probability j/m of hashing to one of these entries. This results in $j + 1$ consecutive array entries being occupied and increases the probability (to $(j + 1)/m$) of another newly inserted element landing in this cluster. Thus, large clusters of consecutive elements have a tendency to grow larger.

9.3.4 Quadratic Probing

Quadratic probing is similar to linear probing; an element x determines its entire probe sequence based on a single random choice, x_0 . Quadratic probing uses the probe sequence $x_0, (x_0 + k_1 + k_2) \bmod m, (x_0 + 2k_1 + 2^2k_2) \bmod m, \dots$. In general, the i th element in the probe sequence is $x_i = (x_0 + ik_1 + i^2k_2) \bmod m$. Thus, the final location of an element depends quadratically on how many steps were required to insert it. This method seems to work much better in practice than linear probing, but requires a careful choice of m, k_1 and k_2 so that the probe sequence contains every element of $\{0, \dots, m - 1\}$.

The improved performance of quadratic probing is due to the fact that if there are two elements x and y such that $x_i = y_j$ then it is not necessarily true (as it is with linear probing) that $x_{i+1} = y_{j+1}$. However, if $x_0 = y_0$ then x and y will have exactly the same probe sequence. This lesser phenomenon is called *secondary clustering*. Note that this secondary clustering phenomenon implies that neither linear nor quadratic probing can hope to perform any better than hashing with chaining. This is because all the elements that have the same initial hash x_0 are contained in an implicit chain. In the case of linear probing, this chain is defined by the sequence $x_0, x_0 + 1, x_0 + 2, \dots$ while for quadratic probing it is defined by the sequence $x_0, x_0 + k_1 + k_2, x_0 + 2k_1 + 4k_2, \dots$

9.3.5 Double Hashing

Double hashing is another method of open addressing that uses two hash values x_0 and x_1 . Here x_0 is in the set $\{0, \dots, m - 1\}$ and x_1 is in the subset of $\{1, \dots, m - 1\}$ that is relatively prime to m . With double hashing, the probe sequence for element x becomes $x_0, (x_0 + x_1) \bmod m, (x_0 + 2x_1) \bmod m, \dots$. In general, $x_i = (x_0 + ix_1) \bmod m$, for $i > 0$. The expected number of probes required by double hashing seems difficult to determine exactly. Guibas has proven that, asymptotically, and for occupancy $\alpha \leq 0.31$, the performance of double hashing is asymptotically equivalent to that of uniform hashing. Empirically, the performance of double hashing matches that of open addressing with random probing regardless of the occupancy α [2].

9.3.6 Brent's Method

Brent's method [14] is a heuristic that attempts to minimize the average time for a successful search in a hash table with open addressing. Although originally described in the context of double hashing (Section 9.3.5) Brent's method applies to any open addressing scheme. The *age* of an element x stored in an open addressing hash table is the minimum value i such that x is stored at $A[x_i]$. In other words, the age is one less than the number of locations we will probe when searching for x .

Brent's method attempts to minimize the total age of all elements in the hash table. To insert the element x we proceed as follows: We find the smallest value i such that $A[x_i]$ is empty; this is where standard open-addressing would insert x . Consider the element y stored at location $A[x_{i-2}]$. This element is stored there because $y_j = x_{i-2}$, for some $j \geq 0$. We check if the array location $A[y_{j+1}]$ is empty and, if so, we move y to location $A[y_{j+1}]$ and store x at location $A[x_{i-2}]$. Note that, compared to standard open addressing, this decreases the total age by 1. In general, Brent's method checks, for each $2 \leq k \leq i$ the array entry $A[x_{i-k}]$ to see if the element y stored there can be moved to any of $A[y_{j+1}], A[y_{j+2}], \dots, A[y_{j+k-1}]$ to make room for x . If so, this represents a decrease in the total age of all elements in the table and is performed.

Although Brent's method seems to work well in practice, it is difficult to analyze theoretically. Some theoretical analysis of Brent's method applied to double hashing is given by Gonnet and Munro [15]. Lyon [16], Munro and Celis [17] and Poblete [18] describe some variants of Brent's method.

9.3.7 Multiple-Choice Hashing

It is worth stepping back at this point and revisiting the comparison between hash tables and binary search trees. For balanced binary search trees, the average cost of searching for an element is $O(\log n)$. Indeed, it is easy to see that for at least $n/2$ of the elements, the cost of searching for those elements is $\Omega(\log n)$. In comparison, for both the random probing schemes discussed so far, the expected cost of search for an element is $O(1)$. However, there are a handful of elements whose search cost is $\Theta(\log n/\log \log n)$ or $\Theta(\log n)$ depending on whether hashing with chaining or open addressing is used, respectively. Thus there is an inversion: Most operations on a binary search tree cost $\Theta(\log n)$ but a few elements (close to the root) can be accessed in $O(1)$ time. Most operations on a hash table take $O(1)$ time but a few elements (in long chains or with long probe sequences) require $\Theta(\log n/\log \log n)$ or $\Theta(\log n)$ time to access. In the next few sections we consider variations on hashing with chaining and open addressing that attempt to reduce the worst-case search time W .

Multiple-choice hashing is hashing with chaining in which, during insertion, the element x has the choice of $d \geq 2$ different lists in which it can be stored. In particular, when we insert x we look at the lengths of the lists pointed to by $A[x_0], \dots, A[x_{d-1}]$ and append x to $A[x_i]$, $0 \leq i < d$ such that the length of the list pointed to by $A[x_i]$ is minimum. When searching for x , we search for x in each of the lists $A[x_0], \dots, A[x_{d-1}]$ in parallel. That is, we look at the first elements of each list, then the second elements of each list, and so on until we find x . As before, to delete x we first search for it and then delete it from whichever list we find it in.

It is easy to see that the expected cost of searching for an element x is $O(d)$ since the expected length of each the d lists is $O(1)$. More interestingly, the worst case search time is bounded by $O(dW)$ where W is the length of the longest list. Azar et al. [19] show that

$$E[W] = \frac{\ln \ln n}{\ln d} + O(1). \quad (9.4)$$

Thus, the expected worst case search time for multiple-choice hashing is $O(\log \log n)$ for any constant $d \geq 2$.

9.3.8 Asymmetric Hashing

Asymmetric hashing is a variant of multiple-choice hashing in which the hash table is split into d blocks, each of size n/d . (Assume, for simplicity, that n is a multiple of d .) The probe value x_i , $0 \leq i < d$ is drawn uniformly from $\{in/d, \dots, (i+1)n/d - 1\}$. As with multiple-choice hashing, to insert x the algorithm examines the lengths of the lists $A[x_0], A[x_1], \dots, A[x_{d-1}]$ and appends x to the shortest of these lists. In the case of ties, it appends x to the list with smallest index. Searching and deletion are done exactly as in multiple-choice hashing.

Vöcking [20] shows that, with asymmetric hashing the expected length of the longest list is

$$E[W] \leq \frac{\ln \ln n}{d \ln \phi_d} + O(1).$$

The function ϕ_d is a generalization of the *golden ratio*, so that $\phi_2 = (1 + \sqrt{5})/2$. Note that this improves significantly on standard multiple-choice hashing (9.4) for larger values of d .

9.3.9 LCFS Hashing

LCFS hashing is a form of open addressing that changes the collision resolution strategy.^{*} Reviewing the algorithm for hashing with open addressing reveals that when two elements collide, priority is given to the first element inserted into the hash table and subsequent elements must move on. Thus, hashing with open addressing could also be referred to as *FCFS (first-come first-served) hashing*.

With LCFS (last-come first-served) hashing, collision resolution is done in exactly the opposite way. When we insert an element x , we always place it at location x_0 . If position x_0 is already occupied by some element y because $y_j = x_0$ then we place y at location y_{j+1} , possibly displacing some element z , and so on.

Poblete and Munro [22] show that, after inserting n elements into an initially empty table, the expected worst case search time is bounded above by

$$E[W] \leq 1 + \Gamma^{-1}(\alpha n) \left(1 + \frac{\ln \ln(1/(1-\alpha))}{\ln \Gamma^{-1}(\alpha n)} + O\left(\frac{1}{\ln^2 \Gamma^{-1}(\alpha n)}\right) \right),$$

where Γ is the gamma function and

$$\Gamma^{-1}(\alpha n) = \frac{\ln n}{\ln \ln n} \left(1 + \frac{\ln \ln \ln n}{\ln \ln n} + O\left(\frac{1}{\ln \ln n}\right) \right).$$

^{*} Amble and Knuth [21] were the first to suggest that, with open addressing, any collision resolution strategy could be used.

Historically, LCFS hashing is the first version of open addressing that was shown to have an expected worst-case search time that is $o(\log n)$.

9.3.10 Robin-Hood Hashing

Robin-Hood hashing [23–25] is a form of open addressing that attempts to equalize the search times of elements by using a fairer collision resolution strategy. During insertion, if we are trying to place element x at position x_i and there is already an element stored at position $y_j = x_i$ then the “younger” of the two elements must move on. More precisely, if $i \leq j$ then we will try to insert x at position x_{i+1}, x_{i+2} and so on. Otherwise, we will store x at position x_i and try to insert y at positions y_{j+1}, y_{j+2} and so on.

Devroye et al. [26] show that, after performing n insertions on an initially empty table of size $m = \alpha n$ using the Robin-Hood insertion algorithm, the worst case search time has expected value

$$E[W] = \Theta(\log \log n)$$

and this bound is tight. Thus, Robin-Hood hashing is a form of open addressing that has doubly-logarithmic worst-case search time. This makes it competitive with the multiple-choice hashing method of Section 9.3.7.

9.3.11 Cuckoo Hashing

Cuckoo hashing [27] is a form of multiple choice hashing in which each element x lives in one of two tables A or B , each of size $m = n/\alpha$. The element x will either be stored at location $A[x_A]$ or $B[x_B]$. There are no other options. This makes searching for x an $O(1)$ time operation since we need only check two array locations.

The insertion algorithm for cuckoo hashing proceeds as follows*: Store x at location $A[x_A]$. If $A[x_A]$ was previously occupied by some element y then store y at location $B[y_B]$. If $B[y_B]$ was previously occupied by some element z then store z at location $A[z_A]$, and so on. This process ends when we place an element into a previously empty table slot or when it has gone on for more than $c \log n$ steps. In the former case, the insertion of x completes successfully. In the latter case the insertion is considered a failure, and the entire hash table is reconstructed from scratch using a new probe sequence for each element in the table. That is, if this reconstruction process has happened i times then the two hash values we use for an element x are $x_A = x_{2i}$ and $x_B = x_{2i+1}$.

Pham and Rodler [27] (see also Devroye and Morin [28]) show that, during the insertion of n elements, the probability of requiring a reconstruction is $O(1/n)$. This, combined with the fact that the expected insertion time is $O(1)$ shows that the expected cost of n insertions in a Cuckoo hashing table is $O(n)$. Thus, Cuckoo hashing offers a somewhat simpler alternative to the dynamic perfect hashing algorithms of Section 9.2.5.

9.4 Historical Notes

In this section we present some of the history of hash tables. The idea of hashing seems to have been discovered simultaneously by two groups of researchers. Knuth [2] cites an internal IBM memorandum in January 1953 by H. P. Luhn that suggested the use of hashing with chaining. Building on Luhn’s work, A. D. Linh suggested a method of open addressing that assigns the probe sequence $x_0, \lfloor x_0/10 \rfloor, \lfloor x_0/100 \rfloor, \lfloor x_0/1000 \rfloor, \dots$ to the element x .

At approximately the same time, another group of researchers at IBM: G. M. Amdahl, E. M. Boehme, N. Rochester and A. L. Samuel implemented hashing in an assembly program for the IBM 701 computer. Amdahl is credited with the idea of open addressing with linear probing.

The first published work on hash tables was by A. I. Dumey [29], who described hashing with chaining and discussed the idea of using remainder modulo a prime as a hash function. Ershov [30], working in Russia and independently of Amdahl, described open addressing with linear probing.

Peterson [31] wrote the first major article discussing the problem of searching in large files and coined the term “open addressing.” Buchholz [32] also gave a survey of the searching problem with a very good discussion of hashing techniques at the time. Theoretical analyses of linear probing were first presented by Konheim and Weiss [33] and Podderjugin. Another, very influential, survey of hashing was given by Morris [34]. Morris’ survey is the first published use of the word “hashing” although it was already in common use by practitioners at that time.

* The algorithm takes its name from the large but lazy cuckoo bird which, rather than building its own nest, steals the nest of another bird forcing the other bird to move on.

9.5 Other Developments

The study of hash tables has a long history and many researchers have proposed methods of implementing hash tables. Because of this, the current chapter is necessarily incomplete. (At the time of writing, the hash.bib bibliography on hashing contains over 800 entries.) We have summarized only a handful of the major results on hash tables in internal memory. In this section we provide a few references to the literature for some of the other results. For more information on hashing, Knuth [2], Vitter and Flajolet [35], Vitter and Chen [36], and Gonnet and Baeza-Yates [37] are useful references.

Brent's method (Section 9.3.6) is a collision resolution strategy for open addressing that reduces the expected search time for a successful search in a hash table with open addressing. Several other methods exist that either reduce the expected or worst-case search time. These include *binary tree hashing* [15,38], *optimal hashing* [15,39,40], Robin-Hood hashing (Section 9.3.10), and *min-max hashing* [13,23]. One interesting method, due to Celis [23], applies to any open addressing scheme. The idea is to study the distribution of the ages of elements in the hash table, that is, the distribution give by

$$D_i = \Pr\{x \text{ is stored at position } x_i\}$$

and start searching for x at the locations at which we are most likely to find it, rather than searching the table positions $x_0, x_1, x_2 \dots$ in order.

Perfect hash functions seem to have been first studied by Sprugnoli [41] who gave some heuristic number theoretic constructions of minimal perfect hash functions for small data sets. Sprugnoli is responsible for the terms “perfect hash function” and “minimal perfect hash function.” A number of other researchers have presented algorithms for discovering minimal and near-minimal perfect hash functions. Examples include Anderson and Anderson [42], Cichelli [43,44], Chang [45,46], Gori and Soda [47], and Sager [48]. Berman et al. [49] and Körner and Marton [50] discuss the theoretical limitations of perfect hash functions. A comprehensive, and recent, survey of perfect hashing and minimal perfect hashing is given by Czech et al. [51].

Tarjan and Yao [52] describe a set ADT implementation that gives $O(\log u / \log n)$ worst-case access time. It is obtained by combining a trie (Chapter 29) of degree n with a compression scheme for arrays of size n^2 that contain only n non-zero elements. (The trie has $O(n)$ nodes each of which has n pointers to children, but there are only a total of $O(n)$ children.) Although their result is superseded by the results of Fredman et al. [7] discussed in Section 9.2.4, they are the first theoretical results on worst-case search time for hash tables.

Dynamic perfect hashing (Section 9.2.5) and cuckoo hashing (Section 9.3.11) are methods of achieving $O(1)$ worst case search time in a dynamic setting. Several other methods have been proposed [53–55].

Yao [56] studies the *membership problem*. Given a set $S \subseteq U$, devise a data structure that can determine for any $x \in U$ whether x is contained in S . Yao shows how, under various conditions, this problem can be solved using a very small number of memory accesses per query. However, Yao's algorithms sometimes derive the fact that an element x is in S without actually finding x . Thus, they don't solve the set ADT problem discussed at the beginning of this chapter since they can not recover a pointer to x .

The “power of two random choices,” as used in multiple-choice hashing, (Section 9.3.7) has many applications in computer science. Karp, Luby and Meyer auf der Heide [57,58] were the first to use this paradigm for simulating PRAM computers on computers with fewer processors. The book chapter by Mitzenmacher et al. [59] surveys results and applications of this technique.

A number of table implementations have been proposed that are suitable for managing hash tables in external memory. Here, the goal is to reduce the number of disk blocks that must be accessed during an operation, where a disk block can typically hold a large number of elements. These schemes include *linear hashing* [60], *dynamic hashing* [61], *virtual hashing* [62], *extendible hashing* [63], *cascade hashing* [64], and *spiral storage* [65]. In terms of hashing, the main difference between internal memory and external memory is that, in internal memory, an array is allocated at a specific size and this can not be changed later. In contrast, an external memory file may be appended to or be truncated to increase or decrease its size, respectively. Thus, hash table implementations for external memory can avoid the periodic global rebuilding operations used in internal memory hash table implementations.

10.1 Introduction

The Bloom filter is a compact data structure for fast membership check against a data set. It was first proposed by Burton Howard Bloom in 1970 [1]. As illustrated in Figure 10.1, given an element, it answers such query: *is the element in the set?* The output is either “no” or “maybe.” In other words, it may give false positives, but false negatives are not possible.

The Bloom filter has wide applications in routing-table lookup [2–4], online traffic measurement [5,6], peer-to-peer systems [7,8], cooperative caching [9], firewall design [10], intrusion detection [11], bioinformatics [12], database query processing [13,14], stream computing [15], distributed storage system [16], and so on [17,18]. For example, a firewall may be configured with a large watch list of addresses that are collected by an intrusion detection system. If the requirement is to log all packets from those addresses, the firewall must check each arrival packet to see if the source address is a member of the list. Another example is routing-table lookup. The lengths of the prefixes in a routing table range from 8 to 32. A router can extract 25 prefixes of different lengths from the destination address of an incoming packet, and it needs to determine which prefixes are in the routing tables [2]. Some traffic measurement functions require the router to collect the flow labels [6,19], such as source/destination address pairs or address/port tuples that identify TCP flows. Each flow label should be collected only once. When a new packet arrives, the router must check whether the flow label extracted from the packet belongs to the set that has already been collected before. As a last example for the membership check problem, we consider the context-based access control (CBAC) function in Cisco routers [20]. When a router receives a packet, it may want to first determine whether the addresses/ports in the packet have a matching entry in the CBAC table before performing the CBAC lookup.

In all of the previous examples, we face the same fundamental problem. For a large data set, which may be an address list, an address prefix table, a flow label set, a CBAC table, or other types of data, we want to check whether a given element belongs to this set or not. If there is no performance requirement, this problem can be easily solved using conventional exact-checking data structures such as binary search [21] (which stores the set in a sorted array and uses binary search for membership check) or a traditional hash table [22] (which uses linked lists to resolve hash collision). However, these approaches are inadequate if there are stringent speed and memory requirements.

Modern high-end routers and firewalls implement their per-packet operations mostly in hardware. They are able to forward each packet in a couple of clock cycles. To keep up with such high throughput, many network functions that involve per-packet processing also have to be implemented in hardware. However, they cannot store the data structures for membership check in

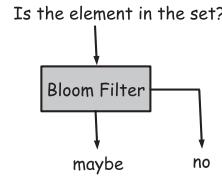

FIGURE 10.1 Black box view of a Bloom filter.

DRAM because the bandwidth and delay of DRAM access cannot match the packet throughput at the line speed. Consequently, the recent research trend is to implement membership check in the high-speed on-die cache memory, which is typically SRAM. The SRAM is however small and must be shared among many online functions. This prevents us from storing a large data set directly in the form of a sorted array or a hash table. On the other hand, a Bloom filter can provide compact membership checking with reasonable precision. For example, it has 1% false-positive probability with fewer than 10 bits per element and 0.1% false-positive probability with fewer than 15 bits per element.

10.2 Bloom Filter

10.2.1 Description of Bloom Filter

A Bloom filter is a space-efficient data structure to encode a set. It includes an array B of m bits, which are initialized to zeros. The array stores the membership information of a set as follows: each member e of the set is mapped to k bits that are randomly selected from B through k hash functions, $H_i(e)$, $1 \leq i \leq k$, whose range is $[0, m - 1]$.^{*} To encode the membership information of e , the bits, $B[H_1(e)], \dots, B[H_k(e)]$, are set to ones. These are called the “membership bits” in B for the element e . Figure 10.2 illustrates how a set $\{a, b, c\}$ is encoded to a Bloom filter with $m = 16$, $k = 3$.

To check the membership of an arbitrary element e' , if the k bits, $B[H_i(e')], 1 \leq i \leq k$, are all ones, e' is accepted to be a member of the set. Otherwise, it is denied. Continuing with the Bloom filter shown in Figure 10.2, we illustrate membership checking in the Bloom filter in Figure 10.3. As element a was previously encoded, the three bits $B[H_1(a)], B[H_2(a)], B[H_3(a)]$ were already set to ones. Therefore, a is accepted as a member. In the second example, as element d is not a member of the set $\{a, b, c\}$, chances are it will hit a zero in the array. Therefore, it is denied as a nonmember.

A Bloom filter doesn't have *false negative*, meaning that a member element will always be accepted. The filter however may incur *false positive*, meaning that if it answers that an element is in the set, it may not be really in the set. As illustrated in the third example of Figure 10.3, element e is not a member of set $\{a, b, c\}$, but $B[H_1(e)], B[H_2(e)], B[H_3(e)]$ all happen to be ones, which were individually set by real members.

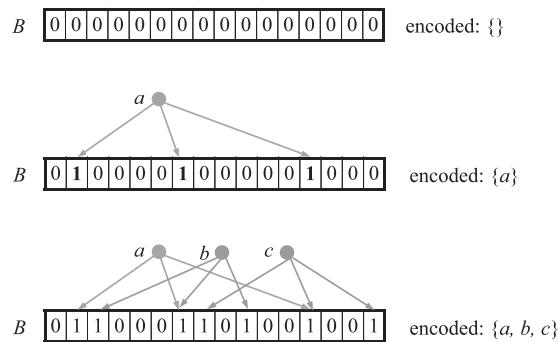

FIGURE 10.2 Encoding a set $\{a, b, c\}$ to a Bloom filter with $k = 3$.

* The hash functions can be any random functions as long as the k functions are different, that is, $H_i \neq H_j, i \neq j \in [1, k]$. However, hash function outputs are random and two hash results may happen to be the same, that is, $\exists i, j, e, i \neq j, H_i(e) = H_j(e)$.

TABLE 10.1 Performance Metrics of the Bloom Filter

Space	Memory Access	Hash Bits	False-Positive Ratio
m	k	$k \lceil \log_2 m \rceil$	$(1 - e^{-nk/m})^k$

m , the size of the bit array; k , the number of membership bits (a.k.a. the number of hash functions); n , the number of elements encoded.

10.2.2 Performance Metrics

The performance of the Bloom filter is judged based on three criteria. The first one is the processing overhead, which is k memory accesses and k hash operations for each membership query. The overhead[†] limits the highest throughput that the filter can support. For example, as both SRAM and the hash function circuit may be shared among different network functions, it is important for them to minimize their processing overhead in order to achieve good system performance. The second performance criterion is the space requirement, which is the size m of the array B . Minimizing the space requirement to encode each member allows a network function to fit a large set in the limited SRAM space for membership check. The third criterion is the *false-positive ratio* or *false-positive probability*, which is the probability for a Bloom filter to erroneously accept a nonmember. There is a trade-off between the space requirement and the false-positive ratio. We can reduce the latter by allocating more memory.

We can treat the k hash functions logically as a single one that produces $k \lceil \log_2 m \rceil$ hash bits. For example, suppose m is 2^{20} , $k=3$, and a hash routine outputs 64 bits. We can extract three 20-bit segments from the first 60 bits of a single hash output and use them to locate three bits in B . Hence, from now on, instead of specifying the number of hash functions required by a filter, we will state “the number of hash bits” that are needed, which is denoted as h . Table 10.1 summarizes the performance metrics of the Bloom filter. In the next subsection, we will show how the false-positive ratio in Table 10.1 is derived.

10.2.3 False-Positive Ratio and Optimal k

We denote the false-positive ratio as f_B . Assume that the hash functions generate fully random locations. The probability that a bit is not set to one by a hash function during the insertion of an element is $1 - (1/m)$, where m is the number of bits in the array. The probability that the bit remains zero after inserting n elements, each setting k bits to ones, is

$$\left(1 - \frac{1}{m}\right)^{kn}.$$

Therefore, the probability that it is one is

$$1 - \left(1 - \frac{1}{m}\right)^{kn}.$$

[†] In the rest of this chapter, we interchangeably use “processing overhead” and “overhead” without further notification.

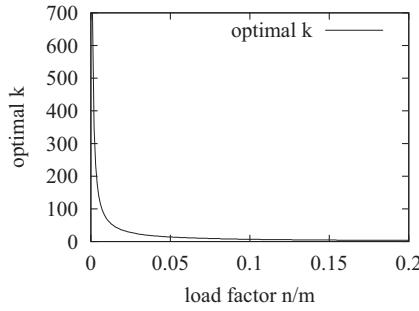

FIGURE 10.4 Optimal number of hash functions (k) with respect to the load factor (n/m).

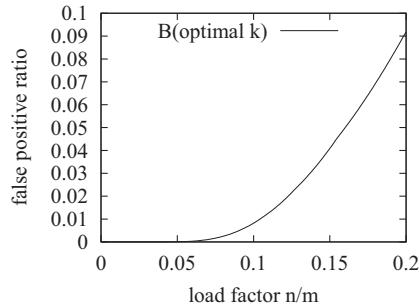

FIGURE 10.5 False-positive ratio of the Bloom filter when optimal k is used.

For an arbitrary nonmember element, each of the k mapped positions has the above probability to be one. The probability of all of them being one, that is, the false-positive ratio, is often given as[‡]

$$f_B = \left(1 - \left(1 - \frac{1}{m}\right)^{nk}\right)^k \approx (1 - e^{-nk/m})^k. \quad (10.1)$$

Obviously, the false-positive ratio decreases as the size m of the array increases, and increases as the number n of elements encoded increases. The optimal value of k (denoted as k^*) that minimizes the false-positive ratio can be derived by taking the first-order derivative on Equation 10.1 with respect to k , then letting the right side be zero, and solving the equation.

$$\frac{d}{dk} \left(1 - e^{-nk/m}\right)^k = 0.$$

The result is

$$k^* = \ln 2 \frac{m}{n} \approx 0.7 \frac{m}{n}. \quad (10.2)$$

Figure 10.4 shows the optimal k of the Bloom filter with respect to the load factor, which is defined as n/m . When the load factor is small, the optimal k can be very large. To avoid too many memory accesses, we may also set k as a small constant in practice. When the optimal k is used, the false-positive ratio becomes

$$f_B^* = \left(\frac{1}{2}\right)^k = \left(\frac{1}{2}\right)^{\ln 2 \times m/n} \approx 0.6185^{m/n}. \quad (10.3)$$

Figure 10.5 shows the false-positive ratio of the Bloom filter when the optimal k is used.

If the requirement is to bound the false-positive ratio by a predefined value f_{REQ} , that is, $f_B \leq f_{\text{REQ}}$, we can determine the length of the Bloom filter by letting $f_B^* \leq f_{\text{REQ}}$ in Equation 10.3, which gives us

$$m \geq -\frac{n \ln f_{\text{REQ}}}{(\ln 2)^2}. \quad (10.4)$$

[‡] Formula 10.1 is an approximation of the false-positive ratio as bits in the array are not strictly independent. More precise analysis can be found in Reference 23. However, when m is large enough (>1024), the approximation error can be neglected [23].

10.3 Counting Bloom Filter

Removing an element from the traditional Bloom filter is not possible. Each “1” bit in the Bloom filter may be shared by many elements, so we cannot simply reset the membership bits of the element to “0”, which may result in the removal of other elements. There are several ways to handle element deletion in the literature (see Section 10.5.5). In this section, we will discuss one of them in detail: the counting Bloom filter (CBF) [9].

10.3.1 Description of CBF

A CBF encodes a set and enables element deletion, which is essentially an array C of l counters. All the counters are initially 0. Similar to the Bloom filter, each member e of the set is mapped to k counters that are randomly selected from C through k hash functions, $H_i(e)$, $1 \leq i \leq k$, whose range is $[0, l - 1]$. To encode the membership information of e , the counters, $C[H_1(e)], \dots, C[H_k(e)]$, are incremented by one. To remove an element e from the set, the counters, $C[H_1(e)], \dots, C[H_k(e)]$, are decremented by one. To check the membership of an arbitrary element e' , if the k counters, $C[H_i(e')]$, $1 \leq i \leq k$, are all nonzero, e' is accepted to be a member of the set. Otherwise, it is denied.

Following the same analytical method in Section 10.2.3, we can see that the false-positive ratio of CBF is

$$f_C = \left(1 - \left(1 - \frac{1}{l}\right)^{nk}\right)^k \approx \left(1 - e^{-nk/l}\right)^k, \quad (10.5)$$

while the optimal k that minimize the false-positive ratio is

$$k_c^* = \ln 2 \frac{l}{n} \approx 0.7 \frac{l}{n}, \quad (10.6)$$

where n is the number of elements encoded. A CBF with l counters has the same false-positive ratio as a traditional Bloom filter with m bits.

10.3.2 Counter Size and Counter Overflow

As counters in CBF are preallocated, they have the same fixed size and hence counter overflow may happen. For example, suppose each counter consists of t bits. It can represent any count between 0 and $2^t - 1$. If a counter with value $2^t - 1$ is about to be incremented for encoding a new element, counter overflow will happen. A smaller value of t makes counter overflow more frequent. However, bigger t means more space: t times the space needed for a Bloom filter!

So our next question is, what is the best choice of t ? Or, how small can each counter be to make counter overflow sufficiently rare? To answer this question, we first need to know how big a count value may become. Let c be a random variable which represents the value of an arbitrary counter after inserting n elements, each randomly increments k out of l counters. Obviously, c follows Binomial distribution, $\text{Bino}(nk, 1/l)$.

$$\text{Prob}\{c = x\} = \binom{nk}{x} \left(\frac{1}{l}\right)^x \left(1 - \frac{1}{l}\right)^{nk-x}.$$

The probability that the counter is greater or equal to y is

$$\begin{aligned} \text{Prob}\{c \geq y\} &= \sum_{x=y}^{nk} \binom{nk}{x} \left(\frac{1}{l}\right)^x \left(1 - \frac{1}{l}\right)^{nk-x} \\ &= \binom{nk}{y} \frac{1}{l^y} \sum_{x=0}^{nk-y} \frac{(nk-y)^x}{(1+x)^x} \left(\frac{1}{l}\right)^x \left(1 - \frac{1}{l}\right)^{nk-y-x}, \end{aligned}$$

TABLE 10.2 Probability for Any Counter to Overflow
(Counter Value $\geq 2^t$) in a CBF with l Counters

$t = 2$	$t = 3$	$t = 4$	$t = 5$
$0.049 \times l$	$9.5 \times 10^{-6} \times l$	$1.4 \times 10^{-15} \times l$	$4.4 \times 10^{-40} \times l$

Each counter consists of t bits. The optimal k is used.

where i^j indicates the descending factorial $i^j = i(i-1)(i-2)\dots(i-j+1)$, $i \geq j$. Clearly, $(1+x)^x \geq x!$. As a result, we can bound $\text{Prob}\{c \geq y\}$ by

$$\begin{aligned} \text{Prob}\{c \geq y\} &\leq \binom{nk}{y} \frac{1}{l^y} \sum_{x=0}^{nk-y} \frac{(nk-y)^x}{x!} \left(\frac{1}{l}\right)^x \left(1 - \frac{1}{l}\right)^{nk-y-x} \\ &= \binom{nk}{y} \frac{1}{l^y} \sum_{x=0}^{nk-y} \binom{nk-y}{x} \left(\frac{1}{l}\right)^x \left(1 - \frac{1}{l}\right)^{nk-y-x} \\ &= \binom{nk}{y} \frac{1}{l^y}. \end{aligned} \quad (10.7)$$

The probability that any counter is greater or equal to y is (assuming counter values are independent)

$$\begin{aligned} \text{Prob}\{\max(c) \geq y\} &= 1 - (1 - \text{Prob}\{c \geq y\})^l \\ &\leq l \times \text{Prob}\{c \geq y\} \leq l \binom{nk}{y} \frac{1}{l^y} \leq l \left(\frac{enk}{yl}\right)^y, \end{aligned} \quad (10.8)$$

where e is Euler's number ($e = 2.71828 \dots$). If the optimal k is used, that is, $k = k_c^* = \ln 2(l/n)$, we can further bound

$$\text{Prob}\{\max(c) \geq y\} \leq l \left(\frac{e \ln 2}{y}\right)^y. \quad (10.9)$$

From Equation 10.9 and $y = 2^t$, we can calculate the overflow probability of CBF with t -bit counters. The results are shown in **Table 10.2**. For example, when $t = 4$ and $l = 2^{20}$, the overflow probability is 1.43×10^{-9} , which is extremely small. In other words, 4 bits per counter is enough for most practical values of l .

In practice, even if counter overflow ever happens, we can simply let it stay at the value. Although after many deletions this might lead to a situation where CBF allows a false negative (the count becomes 0 when it shouldn't be), the probability of such a chain of events is usually extremely low.

CBF is a natural extension to the traditional Bloom filter and it is very easy to implement. One issue with CBF is its limited scalability. Because the counter array cannot be expanded, the maximal number of keys to be stored simultaneously in the filter must be known before constructing the filter. Once the designed capacity of the table is exceeded, the false-positive ratio will grow rapidly as more keys are inserted. As a result, even though CBF is designed for dynamic set, it works best when element population has a preknown maximum point.

10.4 Blocked Bloom Filter

Given the fact that Bloom filters have been applied so extensively, any improvement to their performance can potentially have a broad impact. In this section, we study a variant of the Bloom filter, called Bloom-1, which makes just one memory access to perform membership check [24–26]. Therefore, it can be configured to outperform the commonly used Bloom filter with constant k . We will show that when the required false-positive ratio is extremely small, the optimal k of the Bloom filter will be too large to be practical. Next, we generalize Bloom-1 to Bloom- g , which allows g memory accesses. We show that they can achieve the low false-positive ratio of the Bloom filter with optimal k , without incurring the same kind of high overhead. This family of Bloom filter variants is called the *blocked Bloom filter*. We discuss how blocked Bloom filters can be applied for static or dynamic data sets.

10.4.1 Bloom-1 Filter

To check the membership of an element, a Bloom filter requires k memory accesses. We introduce the Bloom-1 filter, which requires one memory access for membership check. The basic idea is that, instead of mapping an element to k bits randomly

selected from the entire bit array, we map it to k bits in a word that is randomly selected from the bit array. A word is defined as a continuous block of bits that can be fetched from the memory to the processor in one memory access. In today's computer architectures, most general-purpose processors fetch words of 32 bits or 64 bits. Specifically designed hardware may access words of 72 bits or longer.

A Bloom-1 filter is an array $B1$ of l words, each of which is w bits long. The total number m of bits is $l \times w$. To encode a member e during the filter setup, we first obtain a number of hash bits from e , and use $\log_2 l$ hash bits to map e to a word in $B1$. It is called the "membership word" of e in the Bloom-1 filter. We then use $k \log_2 w$ hash bits to further map e to k membership bits in the word and set them to ones. The total number of hash bits that are needed is $\log_2 l + k \log_2 w$. Suppose $m = 2^{20}$, $k = 3$, $w = 2^6$, and $l = 2^{14}$. Only 32 hash bits are needed, which is smaller than the 60 hash bits required in the previous Bloom filter example under similar parameters.

To check if an element e' is a member in the set that is encoded in a Bloom-1 filter, we first perform hash operations on e' to obtain $\log_2 l + k \log_2 w$ hash bits. We use $\log_2 l$ bits to locate its membership word in $B1$, and then use $k \log_2 w$ bits to identify the membership bits in the word. If all membership bits are ones, it is considered to be a member. Otherwise, it is not.

The change from using k random bits in the array to using k random bits in a word may appear simple, but it is also fundamental. An important question is how it will affect the false-positive ratio and the processing overhead. A more interesting question is how it will open up new design space to configure various new filters with different performance properties. This is what we will investigate in depth.

The false-negative ratio of a Bloom-1 filter is also zero. The false-positive ratio f_{B1} of Bloom-1, which is the probability of mistakenly treating a nonmember as a member, is derived as follows: let F be the false-positive event that a nonmember e' is mistaken for a member. The element e' is hashed to a membership word. Let X be the random variable for the number of members that are mapped to the same membership word. Let x be a constant in the range of $[0, n]$, where n is the number of members in the set. Assume we use fully random hash functions. When $X = x$, the conditional probability for F to occur is

$$\text{Prob}\{F|X = x\} = \left(1 - \left(1 - \frac{1}{w}\right)^{xk}\right)^k. \quad (10.10)$$

Obviously, X follows the binomial distribution, $\text{Bino}(n, 1/l)$, because each of the n elements may be mapped to any of the l words with equal probabilities. Hence,

$$\text{Prob}\{X = x\} = \binom{n}{x} \left(\frac{1}{l}\right)^x \left(1 - \frac{1}{l}\right)^{n-x}, \quad \forall 0 \leq x \leq n. \quad (10.11)$$

Therefore, the false-positive ratio can be written as

$$\begin{aligned} f_{B1} &= \text{Prob}\{F\} = \sum_{x=0}^n \left(\text{Prob}\{X = x\} \cdot \text{Prob}\{F|X = x\} \right) \\ &= \sum_{x=0}^n \left(\binom{n}{x} \left(\frac{1}{l}\right)^x \left(1 - \frac{1}{l}\right)^{n-x} \left(1 - \left(1 - \frac{1}{w}\right)^{xk}\right)^k \right). \end{aligned} \quad (10.12)$$

10.4.2 Impact of Word Size

We first investigate the impact of word size w on the performance of a Bloom-1 filter. If n , l , and k are known, we can obtain the optimal word size that minimizes Equation 10.12. However, in reality, we can only decide the amount of memory (i.e., m) to be used for a filter, but cannot choose the word size once the hardware is installed. In the left plot of Figure 10.6, we compute the false-positive ratios of Bloom-1 under four word sizes: 32, 64, 72, and 256 bits, when the total amount of memory is fixed at $m = 2^{20}$ and k is set to 3. Note that the number of words, $l = m/w$, is inversely proportional to the word size.

The horizontal axis in the figure is the load factor, n/m , which is the number of members stored by the filter divided by the number of bits in the filter. Since most applications require relatively small false-positive ratios, we zoom in at the load factor range of $[0, 0.2]$ for a detailed look in the right plot of Figure 10.6. The computation results based on Equation 10.12 show that a larger word size helps to reduce the false-positive ratio. In that case, we should simply set $w = m$ for the lowest false-positive ratio. However, in practice, w is given by the hardware, not a configurable parameter. Without losing generality, we choose $w = 64$ in our computations and simulations for the rest of this chapter.

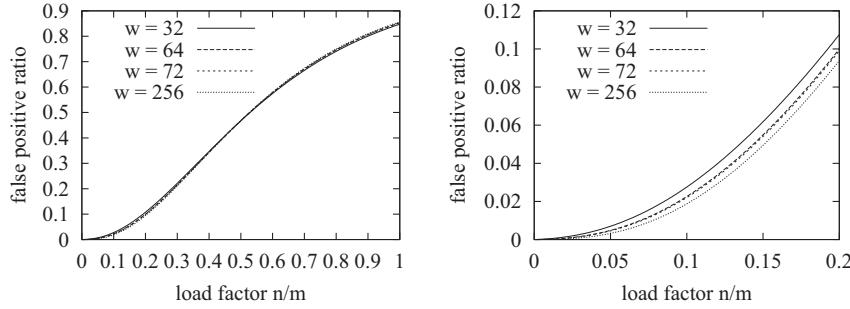

FIGURE 10.6 False-positive ratio with respect to word size w . Left plot: False-positive ratios for Bloom-1 under different word sizes. Right plot: Magnified false-positive ratios for Bloom-1 under different word sizes.

10.4.3 Bloom-1 Versus Bloom with Small k

Although the optimal k always yields the best false positive ratio of the Bloom filter, a small value of k is sometimes preferred to bound the processing overhead in terms of memory accesses and hash operations. We compare the performance of the Bloom-1 filter and the Bloom filter in both scenarios. In this section, we use the Bloom filter with $k = 3$ as the benchmark. Using $k = 4, 5, \dots$ produces quantitatively different results, but the qualitative conclusion will stay the same.

We compare the performance of three types of filters: (1) $B(k = 3)$, which represents a Bloom filter that uses three bits to encode each member; (2) $B1(k = 3)$, which represents a Bloom-1 filter that uses three bits to encode each member; (3) $B1(h = 3 \log_2 m)$, which represents a Bloom-1 filter that uses the same number of hash bits as $B(k = 3)$ does.

Let $k1^*$ be the optimal value of k that minimizes the false-positive ratio of the Bloom-1 filter in Equation 10.12. For $B1(h = 3 \log_2 m)$, we are allowed to use $3 \log_2 m$ hash bits, which can encode three or more membership bits in the filter. However, it is not necessary to use more than the optimal number $k1^*$ of membership bits. Hence, $B1(h = 3 \log_2 m)$ actually uses the k that is closest to $k1^*$ to encode each member.

Table 10.3 presents numerical results of the number of memory accesses and the number of hash bits needed by the three filters for each membership query. They together represent the query overhead and control the query throughput. First, we compare $B(k = 3)$ and $B1(k = 3)$. The Bloom-1 filter saves not only memory accesses but also hash bits. For example, in these examples, $B1(k = 3)$ requires about half of the hash bits needed by $B(k = 3)$. When the hash routine is implemented in hardware, such as CRC [27], the memory access may become the performance bottleneck, particularly when the filter's bit array is located off-chip or, even if it is on-chip, the bandwidth of the cache memory is shared by other system components. In this case, the query throughput of $B1(k = 3)$ will be three times of the throughput of $B(k = 3)$.

Next, we consider $B1(h = 3 \log_2 m)$. Even though it still makes one memory access to fetch a word, the processor may check more than 3 bits in the word for a membership query. If the operations of hashing, accessing memory, and checking membership bits are pipelined and the memory access is the performance bottleneck, the throughput of $B1(h = 3 \log_2 m)$ will also be three times of the throughput of $B(k = 3)$.

Finally, we compare the false-positive ratios of the three filters in [Figure 10.7](#). The figure shows that the overall performance of $B1(k = 3)$ is comparable to that of $B(k = 3)$, but its false-positive ratio is worse when the load factor is small. The reason is that concentrating the membership bits in one word reduces the randomness. $B1(h = 3 \log_2 m)$ is better than $B(k = 3)$ when the load factor is smaller than 0.1. This is because the Bloom-1 filter requires less number of hash bits on average to locate each membership bit than the Bloom filter does. Therefore, when available hash bits are the same, $B1(h = 3 \log_2 m)$ is able to use a larger k than $B(k = 3)$, as shown in [Figure 10.8](#).

TABLE 10.3 Query Overhead Comparison of Bloom-1 Filters and Bloom Filter with $k = 3$

Data Structure	Number of Memory Access	Number of Hash Bits		
		$m = 2^{16}$	$m = 2^{20}$	$m = 2^{24}$
$B(k = 3)$	3	48	60	72
$B1(k = 3)$	1	28	32	36
$B1(h = 3 \log_2 m)$	1	16–46	20–56	24–72

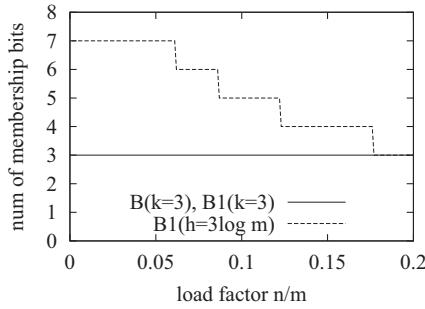

FIGURE 10.8 Number of membership bits used by the filters.

10.4.4 Bloom-1 versus Bloom with Optimal k

We can reduce the false-positive ratio of a Bloom filter or a Bloom-1 filter by choosing the optimal number of membership bits. From Equation 10.2, we find the optimal value k^* that minimizes the false-positive ratio of a Bloom filter. From Equation 10.12, we can find the optimal value $k1^*$ that minimizes the false-positive ratio of a Bloom-1 filter. The values of k^* and $k1^*$ with respect to the load factor are shown in Figure 10.9. When the load factor is less than 0.1, $k1^*$ is significantly smaller than k^* .

We use $B(\text{optimal } k)$ to denote a Bloom filter that uses the optimal number k^* of membership bits and $B1(\text{optimal } k)$ to denote a Bloom-1 filter that uses the optimal number $k1^*$ of membership bits.

To make the comparison more concrete, we present the numerical results of memory access overhead and hashing overhead with respect to the load factor in Table 10.4. For example, when the load factor is 0.04, the Bloom filter requires 17 memory accesses and 340 hash bits to minimize its false-positive ratio, whereas the Bloom-1 filter requires only 1 memory access and 62 hash bits. In practice, the load factor is determined by the application requirement on the false-positive ratio. If an application requires a very small false-positive ratio, it has to choose a small load factor.

Next, we compare the false-positive ratios of $B(\text{optimal } k)$ and $B1(\text{optimal } k)$ with respect to the load factor in Figure 10.10. The Bloom filter has a much lower false-positive ratio than the Bloom-1 filter. On one hand, we must recognize the fact that, as

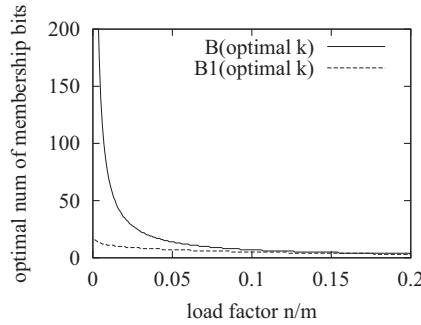

FIGURE 10.9 Optimal number of membership bits with respect to the load factor.

TABLE 10.4 Query Overhead Comparison of Bloom-1 Filter and Bloom Filter with Optimal Number of Membership Bits

	Load Factor n/m				
	0.01	0.02	0.04	0.08	0.16

$B(\text{optimal } k)$	69	35	17	9	4
$B1(\text{optimal } k)$	1	1	1	1	1
<i>Hash bits per query</i>					
$B(\text{optimal } k)$	1380	700	340	180	80
$B1(\text{optimal } k)$	80	74	62	50	38

Parameters: $m = 2^{20}$ and $w = 64$.

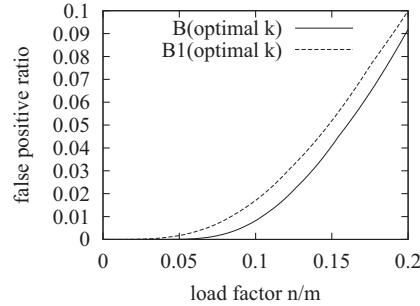

FIGURE 10.10 False-positive ratios of the Bloom filter and the Bloom-1 filter with optimal k .

shown in Table 10.4, the overhead for the Bloom filter to achieve its low false-positive ratio is simply too high to be practical. On the other hand, it raises a challenge for us to improve the design of the Bloom-1 filter so that it can match the performance of the Bloom filter at much lower overhead. In the next section, we generalize the Bloom-1 filter to allow performance-overhead trade-off, which provides flexibility for practitioners to achieve a lower false-positive ratio at the expense of modestly higher query overhead.

10.4.5 Bloom-g: A Generalization of Bloom-1

As a generalization of Bloom-1 filter, a Bloom- g filter maps each member e to g words instead of one and spreads its k membership bits evenly in the g words. More specifically, we use $g \log_2 l$ hash bits derived from e to locate g membership words, and then use $k \log_2 w$ hash bits to locate k membership bits. The first one or multiple words are each assigned $\lceil k/g \rceil$ membership bits, and the remaining words are each assigned $\lfloor k/g \rfloor$ bits, so that the total number of membership bits is k .

To check the membership of an element e' , we have to access g words. Hence the query overhead includes g memory accesses and $g \log_2 l + k \log_2 w$ hash bits.

The false-negative ratio of a Bloom- g filter is zero and the false-positive ratio f_{Bg} of the Bloom- g filter is derived as follows: each member encoded in the filter randomly selects g membership words. There are n members. Together they select gn membership words (with replacement). These words are called the “encoded words.” In each encoded word, k/g bits are randomly selected to be set as ones during the filter setup. To simplify the analysis, we use k/g instead of taking the ceiling or floor.

Now consider an arbitrary word D in the array. Let X be the number of times this word is selected as an encoded word during the filter setup. Assume we use fully random hash functions. When any member randomly selects a word to encode its membership, the word D has a probability of $1/l$ to be selected. Hence, X is a random number that follows the binomial distribution $\text{Bino}(gn, 1/l)$. Let x be a constant in the range $[0, gn]$.

$$\text{Prob}\{X = x\} = \binom{gn}{x} \left(\frac{1}{l}\right)^x \left(1 - \frac{1}{l}\right)^{gn-x}. \quad (10.13)$$

Consider an arbitrary nonmember e' . It is hashed to g membership words. A false positive happens when its membership bits in each of the g words are ones. Consider an arbitrary membership word of e' . Let F be the event that the k/g membership bits

of e' in this word are all ones. Suppose this word is selected for x times as an encoded word during the filter setup. We have the following conditional probability:

$$\text{Prob}\{F|X = x\} = \left(1 - \left(1 - \frac{1}{w}\right)^{x(k/g)}\right)^{k/g}. \quad (10.14)$$

The probability for F to happen is

$$\begin{aligned} \text{Prob}\{F\} &= \sum_{x=0}^{gn} \left(\text{Prob}\{X = x\} \cdot \text{Prob}\{F|X = x\} \right) \\ &= \sum_{x=0}^{gn} \left(\binom{gn}{x} \cdot \left(\frac{1}{l}\right)^x \cdot \left(1 - \frac{1}{l}\right)^{gn-x} \cdot \left(1 - \left(1 - \frac{1}{w}\right)^{x(k/g)}\right)^{k/g} \right). \end{aligned} \quad (10.15)$$

Element e' has g membership words. Hence, the false-positive ratio is

$$f_{Bg} = (\text{Prob}\{F\})^g = \left[\sum_{x=0}^{gn} \left(\binom{gn}{x} \cdot \left(\frac{1}{l}\right)^x \cdot \left(1 - \frac{1}{l}\right)^{gn-x} \cdot \left(1 - \left(1 - \frac{1}{w}\right)^{x(k/g)}\right)^{k/g} \right) \right]^g. \quad (10.16)$$

When $g = k$, exactly one bit is set in each membership word. This special Bloom- k is identical to a Bloom filter with k membership bits. (Note that Bloom- k may happen to pick the same membership word more than once. Hence, just like a Bloom filter, Bloom- k allows more than one membership bit in a word.) To prove this, we first let $g = k$, and Equation 10.16 becomes

$$\begin{aligned} f_{Bk} &= \left[\sum_{x=0}^{kn} \left(\binom{kn}{x} \cdot \left(\frac{1}{l}\right)^x \cdot \left(1 - \frac{1}{l}\right)^{kn-x} \cdot \left(1 - \left(1 - \frac{1}{w}\right)^x\right) \right) \right]^k \\ &= \left[1 - \sum_{x=0}^{kn} \left(\binom{kn}{x} \cdot \left(\frac{1}{l} \cdot \left(1 - \frac{1}{w}\right)\right)^x \cdot \left(1 - \frac{1}{l}\right)^{kn-x} \right) \right]^k \\ &= \left(1 - \left(1 - \frac{1}{lw}\right)^{kn} \right)^k. \end{aligned} \quad (10.17)$$

As $m = lw$, we have $f_{Bk} = f_B$. In other words, a Bloom- k filter is identical to a Bloom filter.

10.4.6 Bloom- g versus Bloom with Small k

We compare the performance and overhead of the Bloom- g filters and the Bloom filter with $k = 3$. Because the overhead of Bloom- g increases with g , it is highly desirable to use a small value for g . Hence, we focus on Bloom-2 and Bloom-3 filters as typical examples in the Bloom- g family.

We compare the following filters:

1. $B(k = 3)$, the Bloom filter with $k = 3$;
2. $B2(k = 3)$, the Bloom-2 filter with $k = 3$;
3. $B2(h = 3 \log_2 m)$, the Bloom-2 filter that is allowed to use the same number of hash bits as $B(k = 3)$ does.

In this section, we do not consider Bloom-3 because it is equivalent to $B(k = 3)$, as we have discussed in Section 10.4.5.

From Equation 10.16, when $g = 2$, we can find the optimal value of k , denoted as $k2^*$, that minimizes the false-positive ratio. Similar to $B1(h = 3 \log_2 m)$, the filter $B2(h = 3 \log_2 m)$ uses the k that is closest to $k2^*$ under the constraint that the number of required hash bits is less than or equal to $3 \log_2 m$.

Table 10.5 compares the query overhead of three filters. The Bloom filter, $B(k = 3)$, needs three memory accesses and $3 \log_2 m$ hash bits for each membership query. The Bloom-2 filter, $B2(k = 3)$, requires two memory accesses and $2 \log_2 l + 3 \log_2 w$ hash bits. It is easy to see $2 \log_2 l + 3 \log_2 w = 3 \log_2 m - \log_2 l < 3 \log_2 m$. Hence, $B2(k = 3)$ incurs fewer memory accesses and fewer hash bits than $B(k = 3)$. On the other hand, $B2(h = 3 \log_2 m)$ uses the same number of hash bits as $B(k = 3)$ does, but makes fewer memory accesses.

TABLE 10.5 Query Overhead Comparison of Bloom-2 Filter and Bloom Filter with $k=3$

Data Structure	Number of Memory Access	Number of Hash Bits		
		$m = 2^{16}$	$m = 2^{20}$	$m = 2^{24}$
$B(k=3)$	3	48	60	72
$B2(k=3)$	2	38	46	54
$B2(h=3\log_2 m)$	2	32–44	40–58	48–72

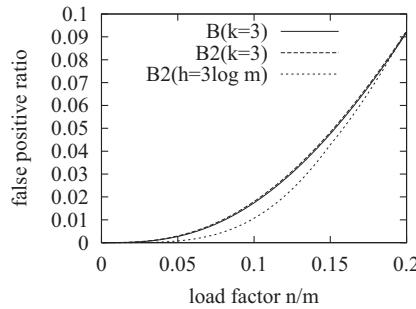

FIGURE 10.11 False-positive ratios of Bloom filter and Bloom-2 filter.

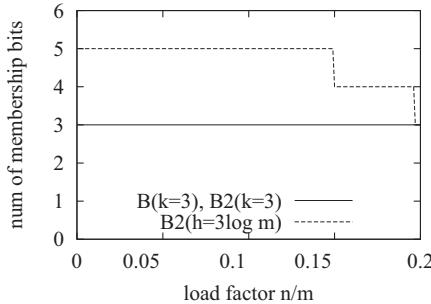

FIGURE 10.12 Number of membership bits used by the filters.

Figure 10.11 presents the false-positive ratios of $B(k=3)$, $B2(k=3)$, and $B2(h=3 \log_2 m)$. Figure 10.12 shows the number of membership bits used by the filters. The figures show that $B(k=3)$ and $B2(k=3)$ have comparable false-positive ratios in load factor range of $[0.1, 1]$, whereas $B2(h=3 \log_2 m)$ performs better in load factor range of $[0.00005, 1]$. For example, when the load factor is 0.04, the false-positive ratio of $B(k=3)$ is 1.5×10^{-3} and that of $B2(k=3)$ is 1.6×10^{-3} , while the false-positive ratio of $B2(h=3 \log_2 m)$ is 3.1×10^{-4} , about one-fifth of the other two. Considering that $B2(h=3 \log_2 m)$ uses the same number of hash bits as $B(k=3)$ but only two memory accesses per query, it is a very useful substitute of the Bloom filter to build fast and accurate data structures for membership check.

10.4.7 Bloom-g versus Bloom with Optimal k

We now compare the Bloom-g filters and the Bloom filter when they use the optimal numbers of membership bits determined from Equations 10.1 and 10.16, respectively. We use $B(\text{optimal } k)$ to denote a Bloom filter that uses the optimal number k^* of membership bits to minimize the false-positive ratio. We use $B_g(\text{optimal } k)$ to denote a Bloom-g filter that uses the optimal number k_g^* of membership bits, where $g = 1, 2$, or 3 . Figure 10.13 compares their numbers of membership bits (i.e., k^* , $k1^*$, $k2^*$, and $k3^*$). It shows that the Bloom filter uses many more membership bits when the load factor is small.

Next, we compare the filters in terms of query overhead. For $1 \leq g \leq 3$, $B_g(\text{optimal } k)$ makes g memory accesses and uses $g \log_2 l + k g^* \log_2 w$ hash bits per membership query. Numerical comparison is provided in Table 10.6. In order to achieve a small false-positive ratio, one has to keep the load factor small, which means that $B(\text{optimal } k)$ will have to make a large number of memory accesses and use a large number of hash bits. For example, when the load factor is 0.08, it makes 9 memory accesses

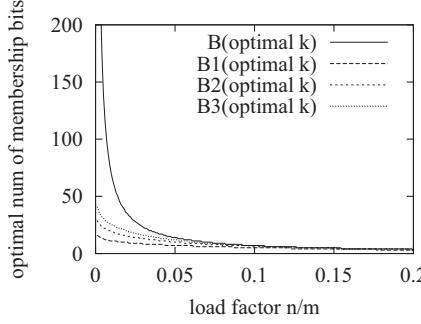

FIGURE 10.13 Optimal number of membership bits with respect to the load factor.

TABLE 10.6 Query Overhead Comparison of Bloom Filter and Bloom-g Filter with Optimal k

	Load Factor n/m				
	0.01	0.02	0.04	0.08	0.16
<i>Memory accesses per query</i>					
$B(\text{optimal } k)$	69	35	17	9	4
$B1(\text{optimal } k)$	1	1	1	1	1
$B2(\text{optimal } k)$	2	2	2	2	2
$B3(\text{optimal } k)$	3	3	3	3	3
<i>Hash bits per query</i>					
$B(\text{optimal } k)$	1380	700	340	180	80
$B1(\text{optimal } k)$	80	74	62	50	38
$B2(\text{optimal } k)$	142	118	94	70	52
$B3(\text{optimal } k)$	198	162	126	90	66

Parameters: $m = 2^{20}$ and $w = 64$.

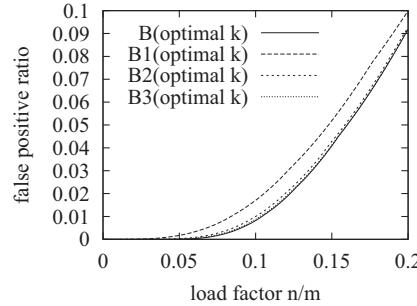

FIGURE 10.14 False-positive ratios of Bloom and Bloom-g with optimal k .

with 180 hash bits per query, whereas the Bloom-1, Bloom-2, and Bloom-3 filters make 1, 2, and 3 memory accesses with 50, 70, and 90 hash bits, respectively. When the load factor is 0.02, it makes 35 memory accesses with 700 hash bits, whereas the Bloom-1, Bloom-2, and Bloom-3 filters make just 1, 2, and 3 memory accesses with 74, 118 and 162 hash bits, respectively.

Figure 10.14 presents the false-positive ratios of the Bloom and Bloom-g filters. As we already showed in Section 10.4.4, $B1(\text{optimal } k)$ performs worse than $B(\text{optimal } k)$. However, the false-positive ratio of $B2(\text{optimal } k)$ is very close to that of $B(\text{optimal } k)$. Furthermore, the curve of $B3(\text{optimal } k)$ is almost entirely overlapped with that of $B(\text{optimal } k)$ for the whole load-factor range. The results indicate that with just two memory accesses per query, $B2(\text{optimal } k)$ works almost as good as $B(\text{optimal } k)$, even though the latter makes many more memory accesses.

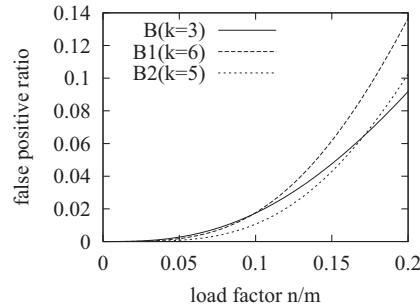

FIGURE 10.15 False-positive ratios of the Bloom filter with $k = 3$, the Bloom-1 filter with $k = 6$, and the Bloom-2 filter with $k = 5$.

10.4.8 Discussion

The mathematical and numerical results demonstrate that Bloom-2 and Bloom-3 have smaller false-positive ratios than Bloom-1 at the expense of larger query overhead. Below we give an intuitive explanation: Bloom-1 uses a single hash to map each member to a word before encoding. It is well known that a single hash cannot achieve an evenly distributed load; some words will have to encode much more members than others, and some words may be empty as no members are mapped to them. This uneven distribution of members to the words is the reason for larger false positives. Bloom-2 maps each member to two words and splits the membership bits among the words. Bloom-3 maps each member to three words. They achieve better load balance such that most words will each encode about the same number of membership bits. This helps them improve their false-positive ratios.

10.4.9 Using Bloom-g in a Dynamic Environment

In order to compute the optimal number of membership bits, we must know the values of n , m , w , and l . The values of m , w , and l are known once the amount of memory for the filter is allocated. The value of n is known only when the filter is used to encode a static set of members. In practice, however, the filter may be used for a dynamic set of members. For example, a router may use a Bloom filter to store a watch list of IP addresses, which are identified by the intrusion detection system as potential attackers. The router inspects the arrival packets and logs those packets whose source addresses belong to the list. If the watch list is updated once a week or at the midnight of each day, we can consider it as a static set of addresses during most of the time. However, if the system is allowed to add new addresses to the list continuously during the day, the watch list becomes a dynamic set. In this case, we do not have a fixed optimal value of k^* for the Bloom filter. One approach is to set the number of membership bits to a small constant, such as three, which limits the query overhead. In addition, we should also set the maximum load factor to bound the false-positive ratio. If the actual load factor exceeds the maximum value, we allocate more memory and set up the filter again in a larger bit array.

The same thing is true for the Bloom-g filter. For a dynamic set of members, we do not have a fixed optimal number of membership bits, and the Bloom-g filter will also have to choose a fixed number of membership bits. The good news for the Bloom-g filter is that its number of membership bits is unrelated to its number of memory accesses. The flexible design allows it to use more membership bits while keeping the number of memory accesses small or even a constant one.

Comparing with the Bloom filter, we may configure a Bloom-g filter with more membership bits for a smaller false-positive ratio, while in the mean time keeping both the number of memory accesses and the number of hash bits smaller. Imagine a filter of 2^{20} bits is used for a dynamic set of members. Suppose the maximum load factor is set to be 0.1 to ensure a small false-positive ratio. Figure 10.15 compares the Bloom filter with $k = 3$, the Bloom-1 filter with $k = 6$, and the Bloom-2 filter with $k = 5$. As new members are added over time, the load factor increases from 0 to 0.1. In this range of load factors, the Bloom-2 filter has significantly smaller false-positive ratios than the Bloom filter. When the load factor is 0.04, the false-positive ratio of Bloom-2 is just one-fourth of the false positive ratio of Bloom. Moreover, it makes fewer memory accesses per membership query. The Bloom-2 filter uses 58 hash bits per query, and the Bloom filter uses 60 bits. The false-positive ratios of the Bloom-1 filter are close to or slightly better than those of the Bloom filter. It achieves such performance by making just one memory access per query and uses 50 hash bits.

10.5 Other Bloom Filter Variants

Since the Bloom filter was first proposed in 1970 [1], many variants have emerged to meet different requirements, such as supporting set updates, improving the space efficiency, memory access efficiency, false-positive ratio, and hash complexity of the

Bloom filter. A comprehensive survey on Bloom filter variants and their applications can be found in Reference 18. Other Bloom filter variants were proposed to solve specific problems, for example, representing multisets [6,28–34] or sets with multiattribute members [35,36].

We will briefly introduce five categories of Bloom filter variants: the methods that aim to improve the space, hash, accuracy, and memory access efficiency of traditional Bloom filters, and the algorithms to support dynamic set.

10.5.1 Improving Space Efficiency

Some Bloom filter variants aim to improve the space efficiency [37–39]. It has been proven that the Bloom filter is not space-optimal [17,39,40]. Pagh et al. [39] designed a new RAM data structure whose space usage is within a lower order term of the optimal value. Porat [38] designed a dictionary data structure that maps keys to values with optimal space. Mitzenmacher [37] proposed the compressed Bloom filters, which is suitable for message passing, for example, when the filters are transmitted through the Internet. The idea is to use a large, sparse Bloom filter at the sender/receiver, and compress/decompress the filter before/after transmission.

10.5.2 Reducing False-Positive Ratio

Reducing the false-positive ratio of the Bloom filter is another subject of research. Lumetta and Mitzenmacher [41] proposed to use two choices (i.e., two sets of hash functions) for each element encoded in the Bloom filter. The idea is to pick the set of hash functions that produce the least number of ones, so as to reduce the false-positive ratio. This approach generates fewer false positives than the Bloom filter when the load factor is small, but it requires twice the number of hash bits and twice the number of memory access than the Bloom filter does.

Hao et al. [27] use partitioned hashing to divide members into several groups, each group with a different set of hash functions. Heuristic algorithms are used to find the “best” partition. However, this scheme requires the keys of member elements known as a prior to compute the final partition. Therefore, it only works well when members are inserted all at once and membership queries are performed afterwards.

Tabataba and Hashemi [42] proposed the Dual Bloom Filter to improve the false-positive ratio of a single Bloom filter. The idea is to use two equal sized Bloom filters to encode the set with different sets of hash functions. An element is considered a member only when both filters produce positives. In order to reduce the space usage for storing random numbers for different hash functions, the second Bloom filter encodes ones complemented values of the elements.

Lim et al. [43] use two cross-checking Bloom filters together with traditional Bloom filter to reduce the false positives. It first divides the set S to be encoded to two disjoint subsets A and B ($S = A \cup B$, $A \cap B = \emptyset$). Then they use three Bloom filters to encode S , A , B , respectively, denoted as $F(S)$, $F(A)$, $F(B)$. Different hash functions are used to provide cross-checking. All three filters are checked during membership lookup. Only when $F(S)$ gives positive result, while $F(A)$ and $F(B)$ do not both give negative results, it claims the element as a member. Their evaluation shows that it improves the false positive of Bloom filters with the same size by magnitudes.

10.5.3 Improving Read/Write Efficiency

Other works try to improve the read/write efficiency of the Bloom filter. Zhu et al. [44] proposed the hierarchical Bloom filter, which builds a small, less accurate Bloom filter over the large, accurate filter to reduce the number of queries to the large filter. As the small filter has better locality, the total number of memory accesses is reduced. Their method is suitable for the scenarios where large filter access is costive, and element queries are not uniformly distributed [44].

The Partitioned Bloom filter [13,45] can also improve the read/write efficiency. It divides the memory into k segments. k hash functions are used to map an element to one bit in each segment. If the segments reside in different memory banks, reads/writes of the membership bits can proceed in parallel, so that the overall read/write efficiency is improved.

Kim et al. [46] proposed a parallelized Bloom filter design to reduce the power consumption and increase the computation throughput of Bloom filters. The idea is to transform multiple hash functions of Bloom filters into the multiple stages. When the membership bit from earlier hash function is “0,” the query string is not progressed to the next stage.

Chen et al. [47] proposed a new Bloom filter variant that allocates two membership bits to each memory block. This reduces the total number of memory accesses by half. Blocked Bloom filters [24–26] generalized [47] and further pushed the problem to extremes: they allocate the membership bits to arbitrary number of blocks. Qiao et al. [26] thoroughly studied the trade-offs between block sizes, number of hash bits, and false-positive ratio.

Canim et al. [48] proposed a two-layer buffered Bloom filter to represent a large set stored in flash memory (a.k.a. solid-state storage, SSD). The design considers several important characteristics of flash memory: (1) data can be read/write by pages. (2) A page write is slower than a page read and data blocks are erased first before they are updated (in-place update problem). (3)

Each cell allows a limited number of erase operations in flash memory life cycle. Therefore, it is important to reduce the number of writes to flash memory. In the design proposed by Canim et al. [48], the filter layer in flash consists of several subfilters, each with the size of a page; while the buffer layer in RAM buffers the read and write operations to each subfilter and applies them in bulk when a buffer is full. The buffered Bloom filter adopts an off-line model, where element insertions and queries are deferred and handled in batch.

Debnath et al. [49] adopted an online model in their design of the BloomFlash, which is also a set representative stored in flash memory. The idea is to reduce random write operations as much as possible. First, bit updates are buffered in RAM so that updates to the same page are handled at once. Second, the Bloom filter is segmented to many subfilters, with each subfilter occupying one flash page. For each element insertion/query, an additional hash function is evoked to choose which subfilter to access. In their design, the size of each subfilter is fixed to the size of a flash page, typically 2 kB or 4 kB [49].

Lu et al. [50] proposed a Forest-structured Bloom filter for dynamic set in flash storage. The proposed data structure resides partially in flash and partially in RAM. It partitions flash space into a collection of flash-page sized subfilters and organizes them into a forest structure. As the set size is increasing, new subfilters are added to the forest.

10.5.4 Reducing Hash Complexity

There are also works that aim to reduce the hash complexity of the Bloom filter. Kirsch and Mitzenmacher [45] have shown that for the Bloom filter, only two hash functions are necessary. Additional hash functions can be produced by a simple linear combination of the output of two hash functions. This gives us an efficient way to produce many hash bits, but it does not reduce the number of hash bits required by the Bloom filter or its variants. There are also other works that design efficient yet well-randomized hash functions that are suitable for Bloom filter-like data structures.

10.5.5 Bloom Filter for Dynamic Set

The Bloom filter does not support element deletion or update well, and it requires the number of elements as a prior to optimize the number of hash functions. Almeida et al. [51] proposed the Scalable Bloom filters for dynamic sets, which create a new Bloom filter when current Bloom filters are “full.” Membership query checks all the filters. Each successive bloom filter has a tighter maximum false-positive probability on a geometric progression, so that the compounded probability over the whole series converges to some wanted value. However, this approach uses a lot of space and does not support deletion.

Rottenstreich et al. proposed the Variable-Increment Counting Bloom Filter (VI-CBF) [52] to improve the space efficiency of CBF. For each element insertion, counters are updated by a hashed variable increment instead of a unit increment. Then, during a query, the exact value of a counter is considered, not just its positiveness. Due to possible counter overflow, CBF and VI-CBF both introduce false negatives [53].

The Bloom filter with variable length signatures (VBF) proposed by Lu et al. [34] also enables element deletion. Instead of setting k membership bits, a VBF sets $t(t \leq k)$ bits to one to encode an element. To check the membership of an element, if $q(q \leq t \leq k)$ membership bits are ones, it claims that the element is a member. Deletion is done by setting several membership bits to zero such that remaining ones are less than q . VBF also has false negatives.

Bonomi et al. [54] introduced a data structure based on d -left hashing that is functionally equivalent but uses approximately half as much space as CBF. It has much better scalability than CBF. Once the designed capacity is exceeded, the keys could be reinserted in a new hash table of double size. However, it requires random permutation, which introduces more computational complexity.

Rothenberg et al. [55] achieved false-negative-free deletions by deleting element probabilistically. Their proposed Deletable Bloom filter divides the standard Bloom filter into r regions. It uses a bit map of size r to indicate if there is any “bit collision” (i.e., two members setting the same bit to “1” among member elements in each region. When trying to delete an element, it only resets the bits that are located in collision-free regions. There is a probability that an element can be successfully deleted: when there is at least one membership bit located in a collision-free region. As the load factor increases, the probability of successful deletion decreases. Also, as elements are inserted and deleted, even if the load factor remains the same, the deletion probability still drops. This is because bits the bitmap does not reflect the “real” bit collision when elements previously causing the collision were already deleted. But there is no way to reset bits in the bit map back to “0”s.

In same applications, new data is more meaningful than old data, so some data structure deletes old data in first-in-first-out manner. For example, Chang et al. [28] proposed an aging scheme called double buffering where two large buffers are used alternatively. In this scheme, the memory space is divided into two equal-sized Bloom filters called active filter and warm-up filter. The warm-up filter is a subset of the active filter, which consists only elements that appeared after the active filter is more than half full. When the active filter is full, it is cleared out, and the two filters exchange roles. Each time the active filter is cleared out, a number of old data are deleted, the size of which is half the capacity of the Bloom filter.

Yoon [56] proposed an active-active scheme to better utilize the memory space of double buffering. The idea is to insert new elements to one filter (instead of possibly two in double buffering) and query both filters. When active filter becomes full, the other filter is cleared out and the filters switch roles. It can store more data with the same memory size and tolerable false-positive rate compared to double buffering.

Deng and Rafiei [57] proposed the Stable Bloom filter to detect duplicates in infinite input data stream. Similar to the CBF, a Stable Bloom filter is an array of counters. When an element is inserted, the corresponding counters are set to the maximum value. The false-positive ratio depends on the ratio of zeros, which is a fixed value for a Stable Bloom filter. It achieves this by decrementing some random counters by one whenever a new element is inserted.

Bonomi et al. [58] proposed time-based deletion with a flag associated with each bit in the filter. If a member is accessed, the flags of its corresponding bits are set to “1.” At the end of each period, bits with unset flags are reset to zeros, and then all flags are unset to “0”s to prepare for the next period. Elements that are not accessed during a period are deleted consequently. However, it has to wait a time period for the deletion to take effect.

10.6 Summary

This chapter presents the Bloom filters, including many variants designed to realize different performance objectives. We describe the basic form of the Bloom filter that encodes a set for membership lookup, with discussion on performance metrics and minimization of false-positive ratio. We move on to CBFs which allow member deletion. We then discuss a group of blocked Bloom filters which achieve much better performance in terms of memory access overhead at the cost of modestly higher false-positive ratio. Finally, we give a brief overview on many other Bloom filter variants with consideration of space efficiency, false-positive ratio, read/write efficiency, hash complexity, and dynamic sets.

11.1 Introduction

Balanced binary search trees are among the most important data structures in Computer Science. This is because they are efficient, versatile, and extensible in many ways. They are used as a black-box in numerous algorithms and even other data structures.

The main virtue of balanced binary search trees is their ability to maintain a dynamic set in sorted order, while supporting a large range of operations in time logarithmic in the size of the set. The operations include search, insertion, deletion, predecessor/successor search, range search, rank search, batch update, split, meld, and merge. These operations are described in more detail in Section 11.2 below.

Data structures supporting the operations search, insertion, deletion, and predecessor (and/or successor) search are often denoted *ordered dictionaries*. In the comparison based model, the logarithmic performance of balanced binary search trees is optimal for ordered dictionaries, whereas in the RAM model, faster operations are possible [1,2]. If one considers *unordered dictionaries*, that is, only the operations search, insertion, and deletion, expected constant time is possible by hashing.

11.2 Basic Definitions

11.2.1 Trees

There are many ways to define trees. In this section, we define a tree as a hierarchical organization of a collection of nodes. For alternatives to our exposition, see the chapter on trees.

A *tree* can be empty. If it is not empty, it consists of one node, which is referred to as the *root* of the tree, and a collection of trees, referred to as *subtrees*. Thus, a tree consists of many smaller trees, each with their own root. We use r to denote the single node which is the root of the entire tree.

We only consider *finite* trees, that is, every collection of subtrees is finite, and there are no infinite chains of nonempty subtrees. Furthermore, we only consider *ordered* trees, meaning that the collection of subtrees of a node is an ordered sequence rather than

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

just a set. If every nonempty tree has exactly two subtrees, then the tree is called *binary*. In this case, we refer to the two subtrees as the *left* and *right* subtrees.

We use u , v , w , etc. to denote nodes and T to denote trees, applying apostrophes, index, etc. to increase the name space. For a node u , we use $u.l$ and $u.r$ to denote the left and right subtree, respectively, of the tree rooted by u . However, when no confusion can occur, we do not necessarily distinguish between nodes and subtrees. Thus, by the subtree v , we mean the subtree rooted at the node v and by T we mean the entire tree or the root of the tree.

We use the standard genealogical terminology to denote nodes in the vicinity of a designated node. Thus, if u is the root of a tree and v is the root of a subtree of u , then v is referred to as a *child* of u . By analogy, this defines *grandchildren*, *parent*, *grandparent*, and *sibling*.

The set of nodes *belonging* to a nonempty tree is its root, along with all the nodes belonging to its subtrees. For an empty tree, this set is of course empty. If a node v belongs to the subtree of u , then v is a *descendant* of u , and u is an *ancestor* of v . An ancestor or descendant v of a node u is *proper* if $u \neq v$.

Quite often, it is convenient to refer to empty subtrees as real nodes, in which case they are referred to as *external* nodes (or leaves). The remaining nodes are then referred to as *internal* nodes. It is easy to prove by induction that the number of external nodes is always one larger than the number of internal nodes.

The number of nodes belonging to a tree is referred to as its *size* (or its *weight*). In some applications, we define the size of the tree to be the number of internal nodes in the tree, but more often it is convenient to define the size of the tree to be the number of external nodes. We use n to denote the size of the tree rooted by r , and $|u|$ to denote the size of the subtree rooted by u .

A *path* in a tree is a sequence of nodes u_1, u_2, \dots, u_k , $k \geq 1$, such that for $i \in \{1, \dots, k-1\}$, u_{i+1} is a child of u_i . Note that the length of such a path is $k-1$. The *depth* of a node u in the tree T is the length of the path from the root of T to u , and the *height* of a tree T is the maximal depth of any external node.

11.2.2 Binary Trees as Dictionaries

When trees are used to implement the abstract data type *dictionary*, nodes have associated values. A dictionary basically organizes a set of *keys*, which must be elements drawn from a total ordering, and must usually supply at least the operations search, insertion, and deletion. There may be additional information associated with each key, but this does not lead to any conceptual complications, so here we simply focus on the keys.

When a tree is used as a dictionary, each node stores one key, and we impose the following ordering invariant (the *in-order* invariant): for each node u in the tree, every key in $u.l$ is strictly smaller than $u.k$, and every key in $u.r$ is strictly larger than $u.k$. A tree organized according to this invariant is referred to as a binary *search* tree.

An important implication of this ordering invariant is that a sorted list of all the keys in the tree can be produced in linear time using an *in-order traversal* defined recursively as follows. On an empty tree, do nothing. Otherwise, recurs on the left subtree, report the root key, and then recurs on the right subtree.

Many different operations can be supported by binary search tree implementations. Here, we discuss the most common. Using the ordering invariant, we can devise a searching procedure of asymptotic time complexity proportional to the height of the tree. Since searching turns out to be at the heart of most of the operations of interest to us, unless we stipulate otherwise, all the operations in the following inherit the same complexity.

1. *Simple Searching:* To search for x in a tree rooted by u , we first compare x to $u.k$. If they are equal, a positive response is given. Otherwise, if x is smaller than $u.k$, we search recursively in $u.l$, and if x is larger, we search in $u.r$. If we arrive at an empty tree, a negative response is given. In this description, we have used *ternary* comparisons, in that our decisions regarding how to proceed depend on whether the search key is less than, equal to, or greater than the root key. For implementation purposes, it is possible to use the more efficient *binary* comparisons [3].

A characteristic feature of search trees is that when a searching fails, a nearest neighbor can be provided efficiently. Dictionaries supporting predecessor/successor queries are referred to as *ordered*. This is in contrast to hashing (described in a chapter of their own) which represents a class of unordered dictionaries. A *predecessor* search for x must return the largest key less than or equal to x . This operation as well as the similar *successor* search are simple generalizations of the search strategy outlined above. The case where x is found on the way is simple, so assume that x is not in the tree. Then the crucial observation is that if the last node encountered during the search is smaller than x , then this node is the predecessor. Otherwise, the predecessor key is the largest key in the left subtree of the last node on the search path containing a key smaller than x . A successor search is similar.

2. *Simple Updates:* An *insertion* takes a tree T and a key x not belonging to T as arguments and adds a node containing x and two empty subtrees to T . The node replaces the empty subtree in T where the search for x terminates.

A *deletion* takes a tree T and a key x belonging to T as arguments and removes the node u containing x from the tree. If u 's children are empty trees, u is simply replaced by an empty tree. If u has exactly one child which is an internal node,

then this child is replacing u . Finally, if u has two internal nodes as children, u 's predecessor node v is used. First, the key in u is overwritten by the key of v , after which v is deleted. Note that because of the choice of v , the ordering invariant is not violated. Note also that v has at most one child which is an internal node, so one of the simpler replacing strategies described above can be used to remove v .

3. *More Searching Procedures:* A *range* search takes a tree T and two key values $k_1 \leq k_2$ as arguments and returns all keys x for which $k_1 \leq x \leq k_2$. A range search can be viewed as an in-order traversal, where we do not recurs down the left subtree and do not report the root key if k_1 should be in the right subtree; similarly, we do not recurs down the right subtree and do not report the root key if k_2 should be in the left subtree. The complexity is proportional to the height of the tree plus the size of the output.

A useful technique for providing more complex operations efficiently is to equip the nodes in the tree with additional information which can be exploited in more advanced searching, and which can also be maintained efficiently. A *rank* search takes a tree T and an integer d between one and n as arguments, and returns the d th smallest key in T . In order to provide this functionality efficiently, we store in each node the size of the subtree in which it is the root. Using this information during a search down the tree, we can at each node determine in which subtree the node must be located and we can appropriately adjust the rank that we search for recursively. If the only modifications made to the tree are small local changes, this extra information can be kept up-to-date efficiently, since it can always be recomputed from the information in the children.

4. *Operations Involving More Trees:* The operation *split* takes a key value x and tree T as arguments and returns two trees; one containing all keys from T less than or equal to x and one with the remaining keys. The operations is destructive, meaning that the argument tree T will not be available after the operation. The operation *meld* takes two trees as arguments, where all keys in one tree are smaller than all keys in the other, and combines the trees into one containing all the keys. This operation is also destructive. Finally, *merge* combines the keys from two argument trees, with no restrictions on keys, into one. Also this operation is destructive.

11.2.3 Implementation of Binary Search Trees

In our discussion of time and space complexities, we assume that some standard implementation of trees are used. Thus, in analogy with the recursive definition, we assume that a tree is represented by information associated with its root, primarily the key, along with pointers (references) to its left and right subtrees, and that this information can be accessed in constant time.

In some situations, we may assume that additional pointers are present, such as *parent-pointers*, giving a reference from a node to its parent. We also sometimes use *level-pointers*. A *level* consists of all nodes of the same depth, and a level-pointer to the right from a node with key k points to the node at the same level with the smallest key larger than k . Similar for level-pointers to the left.

11.3 Generic Discussion of Balancing

As seen in Section 11.2, the worst case complexity of almost all operations on a binary search tree is proportional to its height, making the height its most important single characteristic.

Since a binary tree of height h contains at most $2^h - 1$ nodes, a binary tree of n nodes has a height of at least $\lceil \log(n+1) \rceil$. For static trees, this lower bound is achieved by a tree where all but one level is completely filled. Building such a tree can be done in linear time (assuming that the sorted order of the keys is known), as discussed in Section 11.5 below. In the dynamic case, however, insertions and deletions may produce a very unbalanced tree—for instance, inserting elements in sorted order will produce a tree of height linear in the number of elements.

The solution is to rearrange the tree after an insertion or deletion of an element, if the operation has made the tree unbalanced. For this, one needs a *definition of balance* and a *rebalancing algorithm* describing the rearrangement leading to balance after updates. The combined balance definition and rebalancing algorithm we denote a *rebalancing scheme*. In this section, we discuss rebalancing schemes at a generic level.

The trivial rebalancing scheme consists of defining a balanced tree as one having the optimal height $\lceil \log(n+1) \rceil$, and letting the rebalancing algorithm be the rebuilding of the entire tree after each update. This costs linear time per update, which is exponentially larger than the search time of the tree. It is one of the basic results of Computer Science, first proved by Adel'son-Vel'skiĭ and Landis in 1962 [4], that logarithmic update cost can be achieved simultaneously with logarithmic search cost in binary search trees.

Since the appearance of [4], many other rebalancing schemes have been proposed. Almost all reproduce the result of [4] in the sense that they, too, guarantee a height of $c \cdot \log(n)$ for some constant $c > 1$, while handling updates in $O(\log n)$ time. The schemes can be grouped according to the ideas used for definition of balance, the ideas used for rebalancing, and the exact complexity results achieved.

11.3.1 Balance Definitions

The balance definition is a structural constraint on the tree ensuring logarithmic height. Many schemes can be viewed as belonging to one of the following three categories: schemes with a constraint based on the *heights of subtrees*, schemes with a constraint based on the *sizes of subtrees*, and schemes which can be seen as *binarizations of multi-way search tree schemes* and which have a constraint inherited from these. The next section will give examples of each.

For most schemes, balance information is stored in the nodes of the tree in the form of single bits or numbers. The structural constraint is often expressed as an invariant on this information, and the task of the rebalancing algorithm is to reestablish this invariant after an update.

11.3.2 Rebalancing Algorithms

The rebalancing algorithm restores the structural constraint of the scheme if it is violated by an update. It uses the balance information stored in the nodes to guide its actions.

The general form of the algorithm is the same in almost all rebalancing schemes—balance violations are removed by working towards the root along the search path from the leaf where the update took place. When removing a violation at one node, another may be introduced at its parent, which is then handled, and so forth. The process stops at the root at the latest.

The violation at a node is removed in $O(1)$ time by a local restructuring of the tree and/or a change of balance information, giving a total worst case update time proportional to the height of the tree. The fundamental restructuring operation is the *rotation*, shown in [Figure 11.1](#). It was introduced in Reference 4. The crucial feature of a rotation is that it preserves the in-order invariant of the search tree while allowing one subtree to be moved upwards in the tree at the expense of another.

A rotation may be seen as substituting a connected subgraph T consisting of two nodes with a new connected subgraph T' on the same number of nodes, redistributing the keys (here x and y) in T' according to in-order, and redistributing the subtrees rooted at leaves of T by attaching them as leaves of T' according to in-order. Described in this manner, it is clear that in-order will be preserved for *any* two subgraphs T and T' having an equal number of nodes. One particular case is the *double rotation* shown in [Figure 11.2](#), so named because it is equivalent to two consecutive rotations.

Actually, any such transformation of a connected subgraph T to another T' on the same number of nodes can be executed through a series of rotations. This can be seen by noting that any connected subgraph can be converted into a right-path, that is, a tree where all left children are empty trees, by repeated rotations (in [Figure 11.1](#), if y but not x is on the rightmost path in the tree, the rotation will enlarge the rightmost path by one node). Using the right-path as an intermediate state and running one of the conversions backwards will transform T into T' . The double rotation is a simple case of this. In a large number of rebalancing schemes, the rebalancing algorithm performs at most one rotation or double rotation per node on the search path.

We note that rebalancing schemes exist [5] where the rebalancing along the search path is done in a top-down fashion instead of the bottom-up fashion described above. This is useful when several processes concurrently access the tree, as discussed in Section 11.8.

In another type of rebalancing schemes, the restructuring primitive used is the rebuilding of an entire subtree to perfect balance, where perfect balance means that any node is the median among the nodes in its subtree. This primitive is illustrated in

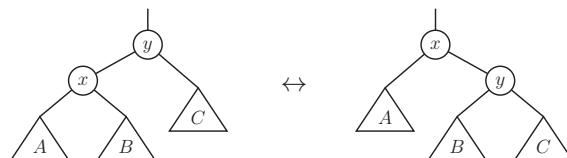

FIGURE 11.1 Rotation.

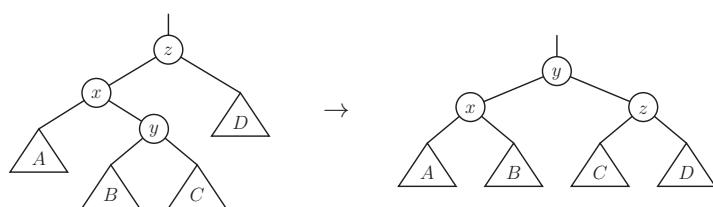

FIGURE 11.2 Double rotation.

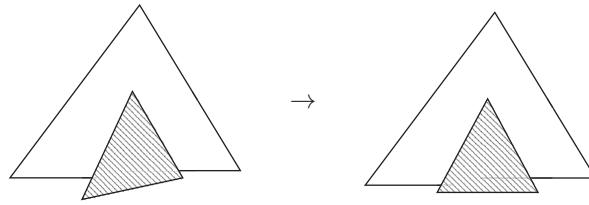

FIGURE 11.3 Rebuilding a subtree.

Figure 11.3. In these rebalancing schemes, the restructuring is only applied to one node on the search path for the update, and this resolves all violations of the balance invariant.

The use of this rebalancing technique is sometimes termed *local* or *partial rebuilding* (in contrast to global rebuilding of data structures, which designates a periodically rebuilding of the entire structure). In Section 11.5, we discuss linear time algorithms for rebalancing a (sub-)tree to perfect balance.

11.3.3 Complexity Results

Rebalancing schemes can be graded according to several complexity measures. One such measure is how much rebalancing work is needed after an update. For this measure, typical values include amortized $O(\log n)$, worst case $O(\log n)$, amortized $O(1)$, and worst case $O(1)$. Values below logarithmic may at first sight seem useless due to the logarithmic search time of balanced search trees, but they are relevant in a number of settings. One setting is finger search trees (described in a chapter of their own in this book), where the search for the update point in the tree does not start at the root and hence may take sub-logarithmic time. Another setting is situations where the nodes of the tree are annotated with information which is expensive to update during restructuring of the tree, such that rotations may take non-constant time. This occurs in Computational Geometry, for instance. A third setting is concurrent access to the tree by several processes. Searching the tree concurrently is not a problem, whereas concurrent updates and restructuring may necessitate lockings of nodes in order to avoid inconsistencies. This makes restructuring more expensive than searches.

Another complexity measure is the exact height maintained. The majority of schemes maintain a height bounded by $c \cdot \log n$ for some constant $c > 1$. Of other results, splay trees [6] have no sub-linear bound on the height, but still perform searches in amortized $O(\log n)$ time. Splay trees are described in a chapter of their own in this book. In the other direction, a series of papers investigate how close c can get to the optimal value one, and at what rebalancing cost. We discuss these results in Section 11.7.

One may also consider the exact amount of balance information stored in each node. Some schemes store an integer, while some only need one or two bits. This may effect the space consumption of nodes, as a single bit may be stored implicitly, for example, as the sign bit of a pointer, or by storing subtrees out of order when the bit is set. Schemes even exist which do not need to store any information at all in nodes. We discuss these schemes in Section 11.6.

Finally, measures such as complexity of implementation and performance in practice can also be considered. However, we will not discuss these here, mainly because these measures are harder to quantify.

11.4 Classic Balancing Schemes

11.4.1 AVL-Trees

AVL-trees were introduced in 1962 in Reference 4, and are named after their inventors Adel'son-Vel'ski and Landis. They proposed the first dictionary structure with logarithmic search and update times, and also introduced the rebalancing technique using rotations.

The balance definition in AVL-trees is based on the height of subtrees. The invariant is that for any node, the heights of its two subtrees differ by at most one. Traditionally, the balance information maintained at each node is $+1$, 0 , or -1 , giving the difference in heights between the right subtree and the left subtree. This information can be represented by two bits. Another method is to mark a node when its height is larger than its siblings. This requires only one bit per node, but reading the balance of a node now involves visiting its children. In the other direction, storing the height of each node requires $\log \log n$ bits of information per node, but makes the rebalancing algorithms simpler to describe and analyze.

By induction on h , it is easily proved that for an AVL-tree of height h , the minimum number of nodes is $F_{h+2} - 1$, where F_i denotes the i 'th Fibonacci number, defined by $F_1 = F_2 = 1$ and $F_{j+2} = F_{j+1} + F_j$. A well-known fact for Fibonacci numbers is that

$F_i \geq \Phi^{i-2}$, where Φ is the golden ratio $(\sqrt{5} + 1)/2 \approx 1.618$. This shows that the height of an AVL-tree with n nodes is at most $\log_{\Phi}(n+1)$, that is, AVL-trees have a height bound of the type $c \cdot \log n$ with $c = 1/\log \Phi \approx 1.440$.

After an update, violations of the balance invariant can only occur at nodes on the search path from the root to the update point, as only these nodes have subtrees changed. The rebalancing algorithm resolves these in a bottom-up fashion. At each node, it either performs a rotation, performs a double rotation, or just updates balance information, with the choice depending on the balance of its child and grandchild on the search path. The algorithm stops when it can guarantee that no ancestor has a balance problem, or when the root is reached.

In AVL-trees, the rebalancing algorithm has the following properties: After an insertion, change of balance information may take place any number of steps towards the root, but as soon as a rotation or double rotation takes place, no further balance problems remain. Hence, only $O(1)$ structural change is made. In contrast, after a deletion it may happen that rotations are performed at all nodes on the search path. If only insertions take place, the amortized amount of rebalancing work, including updating of balance information, can be shown [7] to be $O(1)$. The same is true if only deletions take place [8]. It is not true in the fully dynamic case, as it is easy to find an AVL-tree where alternating insertions and deletions of the same key require rebalancing along the entire search path after each update.

11.4.2 Weight-Balanced Trees

Weight-balanced trees were proposed in 1973 by Nievergelt and Reingold [9], and have a balance definition based on the sizes of subtrees. Here, the size of a subtree is most conveniently defined as the number of external nodes (empty trees) in the subtree, and the size, also denoted the *weight*, of a node is the size of its subtree. The balance invariant of weight-balanced trees states that for any node, the ratio between its own weight and the weight of its right child (or left) is in the interval $[\alpha, 1 - \alpha]$ for some fixed value $\alpha > 0$. This ratio is denoted the *balance* of the node. Since a node of weight three must have subtrees of weight two and one, we must have $\alpha \leq 1/3$. Weight-balanced trees are also called BB $[\alpha]$ -trees, which stands for trees of bounded balance with parameter α .

By the balance criterion, for any node v the weight of the parent of v is at least a factor $1/(1 - \alpha)$ larger than the weight of v . A tree of height k therefore has a root of weight at least $1/(1 - \alpha)^k$, which shows that the height of a weight-balanced tree with n nodes is at most $\log_{1/(1-\alpha)}(n+1)$, that is, weight-balanced trees have a height bound of the type $c \cdot \log n$ with $c = -1/\log(1 - \alpha) > 1.709$.

The balance information stored in each node is its weight, for which $\log n$ bits are needed. After an update, this information must be updated for all nodes on the search path from the root to the update point. Some of these nodes may now violate the balance criterion. The rebalancing algorithm proposed in Reference 9 resolves this unbalance in a bottom-up fashion along the search path using either a rotation or a double rotation at each violating node. The choice of rotation depends on the weight of the children and the grandchildren of the node.

In Reference 9, the rebalancing algorithm was claimed to work for α in the interval $[0, 1 - 1/\sqrt{2}]$, but Blum and Mehlhorn [10] later observed that the correct interval is $(2/11, 1 - 1/\sqrt{2}]$. They also showed that for α strictly inside this interval, the rebalancing of an unbalanced node restores its balance to a value in $[(1 + \delta)\alpha, 1 - (1 + \delta)\alpha]$, where δ depends on the choice of α . This implies that when the node becomes unbalanced again, the number of updates which have taken place below it since it was last rebalanced is at least a fraction (depending on α) of its current weight. This feature, unique to weight-balanced trees, has important applications, for example, for data structures in Computational Geometry. A number of these structures are binary search trees where each node has an associated secondary structure built on the elements in the subtree of the node. When a rotation takes place, the structures of the nodes taking part in the rotation will have to be rebuilt. If we attribute the cost of this rebuilding evenly to the updates which have taken place below the node since it was last involved in a rotation, then, as an example, a linear rebuilding cost of the secondary structure will amount to a constant attribution to each of these updates. As the search path for an update contains $O(\log n)$ nodes, any single update can at most receive this many attributions, which implies an amortized $O(\log n)$ update complexity for the entire data structure.

The same analysis allows BB $[\alpha]$ -trees to be maintained by local rebuilding instead of rotations in amortized $O(\log n)$ time, as first noted by Overmars and van Leeuwen [11]: After an update, the subtree rooted at the highest unbalanced node (if any) on the search path is rebuilt to perfect balance. Since a rebuilding of a subtree leaves all nodes in it with balance close to $1/2$, the number of updates which must have taken place below the node since it was last part of a rebuilding is a constant fraction of its current weight. The rebuilding uses work linear in this weight, which can be covered by attributing a constant amount of work to each of these updates. Again, each update is attributed $O(\log n)$ work. This scheme will work for any $\alpha \leq 1/3$.

For the original rebalancing algorithm using rotations, a better analysis can be made for α chosen strictly inside the interval $(2/11, 1 - 1/\sqrt{2}]$: The total work per rebalancing operation is now $O(1)$, so the work to be attributed to each update below a node is $O(1/w)$, where w is the weight of the node. As noted above in the proof of the height bound of weight-balanced trees, w is exponentially increasing along the search path from the update point to the root. This implies that each update is attributed only $O(1)$ work in total, and also that the number of rotations taking place at a given height decreases exponentially with the

height. This result from [10] seems to be the first on $O(1)$ amortized rebalancing in binary search trees. The actual time spent after an update is still logarithmic in weight-balanced trees, though, as the balance information needs to be updated along the entire search path, but this entails no structural changes.

Recently, the idea of balancing by weight has been applied to multi-way search trees [12], leading to trees efficient in external memory which posses the same feature as weight-balanced binary trees, namely that between each rebalancing at a node, the number of updates which have taken place below the node is proportional to the weight of the node.

11.4.3 Balanced Binary Trees Based on Multi-Way Trees

The B-tree [13], which is treated in another chapter of this book, is originally designed to handle data stored on external memory. The basic idea is to associate a physical block with a high-degree node in a multi-way tree. A B-tree is maintained by merging and splitting nodes, and by increasing and decreasing the number of layers of multi-way nodes. The smallest example of a B-tree is the 2-3-tree [14], where the nodes have degree 2 or 3. In a typical B-tree implementation, the degree of a node is much larger, and it varies roughly within a factor of 2.

The concept of multi-way nodes, splitting, and merging, has also proven to be very fruitful in the design of balancing schemes for binary trees. The first such example is the binary B-tree [15], a binary implementation of 2-3-trees. Here, the idea is to organize binary nodes into larger chunks of nodes, here called *pseudo-nodes*. In the binary version of a 2-3-tree, a node of degree 2 is represented by one binary node, while a node of degree 3 is represented as two binary nodes (with the additional constraint that one of the two nodes is the right child of the other). In the terms of binary nodes grouped into pseudo-nodes, it is convenient to say that edges within a pseudo-node are *horizontal* while edges between pseudo-nodes are *vertical*.

As a natural extension of binary B-trees, Bayer invented *Symmetric Binary Trees*, or SBB-trees [16]. The idea was that, instead of only allowing a binary node to have one horizontal outgoing edge to its right child, we can allow both left- and right-edges to be horizontal. For both binary B-trees and Symmetric Binary B-trees, Bayer designed maintenance algorithms, where the original B-tree operations split, merge, and increase/decrease number of levels were implemented for the pseudo-nodes.

Today, SBB-trees mostly appear under the name *red-black trees* [5]. Here, the horizontal and vertical edges are represented by one “color” per node. (Both notations can be represented by one bit per node.) SBB/red-black trees are binary implementations of B-trees where each node has degree between 2 and 4.

One advantage with SBB-trees/red-black trees is that a tree can be updated with only a constant number of rotations per insertion or deletion. This property is important for example when maintaining priority search trees [17] where each rotation requires $\Theta(\log n)$ time.

The first binary search tree with $O(1)$ rotations per update was the half-balanced trees by Olivie [18]. Olivie’s idea was to use *path-balancing*, where the quotient between the shortest and longest path from each node is restricted to be at most $1/2$, and he showed that this path-balance could be maintained with $O(1)$ rotations per update. It turns out to be the case that half-balanced trees and SBB/red-black trees are structurally equivalent, although their maintenance algorithms are different. It has also been proven by Tarjan [19] that SBB/red-black trees can be maintained by $O(1)$ rotations. These algorithms can also be generalized to maintain pseudo-nodes of higher degree, resulting in binary B-tree implementations with lower height [20], still requiring $O(1)$ rotations per update.

The mechanism behind the constant number of rotations per update can be explained in a simple way by examining three cases of what can happen during insertion and deletion in a binary B-tree representation.

- When a pseudo-node becomes too large, it can be split into two pseudo-nodes without any rotation; we just need to change the balance information.
- Also, when a pseudo-node becomes too small and its sibling has minimal size, these two nodes can be merged without any rotation; we just change balance information.
- In all other cases, when a pseudo-node becomes too small or too large, this will be resolved by moving nodes between the pseudo-node and its sibling and no splitting or merging will take place.

From these three basic facts, it can be shown that as soon as the third case above occurs, no more rebalancing will be done during the same update. Hence, the third case, requiring rotations, will only occur once per update. For details, we refer to the literature [19,20].

Binary B-trees can also be used to design very simple maintenance algorithms that are easy to code. This is illustrated by AA-trees [21,22]. AA-trees are actually the same as Bayer’s binary version of 2-3-trees, but with design focused on simplicity. Compared with normal red-black tree implementations, AA-trees require very few different cases in the algorithm and much less code for implementation.

While binary B-trees and SBB/red-black trees deal with small pseudo-nodes, the stratified trees by van Leeuwen and Overmars [23] use large pseudo-nodes arranged in few layers. The concept of stratification does not imply that all pseudo-nodes have similar size; it is mainly a way to conceptually divide the tree into layers, using the notion of merging and splitting.

11.5 Rebalancing a Tree to Perfect Balance

A basic operation is the rebalancing operation, which takes a binary tree as input and produces a balanced tree. This operation is important in itself, but it is also used as a subroutine in balancing schemes (see Section 11.6).

It is quite obvious that one can construct a perfectly balanced tree from an ordered tree, or a sorted list, in linear time. The most straightforward way is to put the elements in sorted order into an array, take the median as the root of the tree, and construct the left and right subtrees recursively from the upper and lower halves of the array. However, this is unnecessarily cumbersome in terms of time, space, and elegance.

A number of restructuring algorithms, from the type mentioned above to more elegant and efficient ones based on rotations, can be found in the literature [24–28]. Of these, the one by Stout and Warren [28] seems to be most efficient. It uses the following principle:

1. *Skew*. Make right rotations at the root until no left child remains. Continue down the right path making right rotations until the entire tree becomes one long rightmost path (a “vine”).
2. *Split*. Traverse down the vine a number of times, each time reducing the length of the vine by left rotations.

If we start with a vine of length $2^p - 1$, for some integer p , and make one rotation per visited node, the resulting vine will be of length $2^{p-1} - 1$ after the first pass, $2^{p-2} - 1$ after the second pass, etc., until the vine is reduced to a single node; the resulting tree is a perfectly balanced tree. If the size of the tree is $2^p - 1$, this will work without any problem. If, however, the size is not a power of two, we have to make some special arrangements during the first pass of left rotations. Stout and Warren solved the problem of how to make evenly distributed rotations along the vine in a rather complicated way, but there is a simpler one. It has never before been published in itself, but has been included in demo software and in published code [29,30].

The central operation is a split operation that takes as parameters two numbers p_1 and p_2 and compresses a right-skewed path of p_1 nodes into a path of p_2 nodes ($2p_2 \geq p_1$). The simple idea is to use a counter stepping from $p_1 - p_2$ to $p_2(p_1 - p_2)$ with increment $p_1 - p_2$. Every time this counter reaches or exceeds a multiple of p_2 , a rotation is performed. In effect, the operation will make $p_1 - p_2$ evenly distributed left rotations.

With this split operation available, we can do as follows to rebalance a tree of size n (n internal nodes): First, skew the tree. Next, find the largest integer b such that b is an even power of 2 and $b - 1 \leq n$. Then, if $b - 1 < n$, call Split with parameters n and $b - 1$. Now, the vine will have proper length and we can traverse it repeatedly, making a left rotation at each visited node, until only one node remains.

In contrast to the Stout-Warren algorithm, this algorithm is straightforward to implement. We illustrate it in [Figure 11.4](#). We describe the five trees, starting with the topmost:

1. A tree with 12 internal nodes to be balanced.
2. After Skew.
3. With $n = 12$ and $b = 8$, we call split with parameters 12 and 7, which implies that five evenly distributed rotations will be made. As the result, the vine will be of length 7, which fulfills the property of being $2^p - 1$.
4. The next split can be done by traversing the vine, making one left rotation at each node. As a result, we get a vine of length 3 (nodes 3, 6, and 10).
5. After the final split, the tree is perfectly balanced.

11.6 Schemes with no Balance Information

As discussed above, a balanced binary search tree is typically maintained by local constraints on the structure of the tree. By keeping structure information in the nodes, these constraints can be maintained during updates.

In this section, we show that a plain vanilla tree, without any local balance information, can be maintained efficiently. This can be done by coding the balance information implicitly (Section 11.6.1) or by using global instead of local balance criteria, hereby avoiding the need for balance information (Section 11.6.2). Splay trees [6] also have no balance information. They do not have a sub-linear bound on their height, but still perform searches in amortized $O(\log n)$ time. Splay trees are described in a chapter of their own in this book.

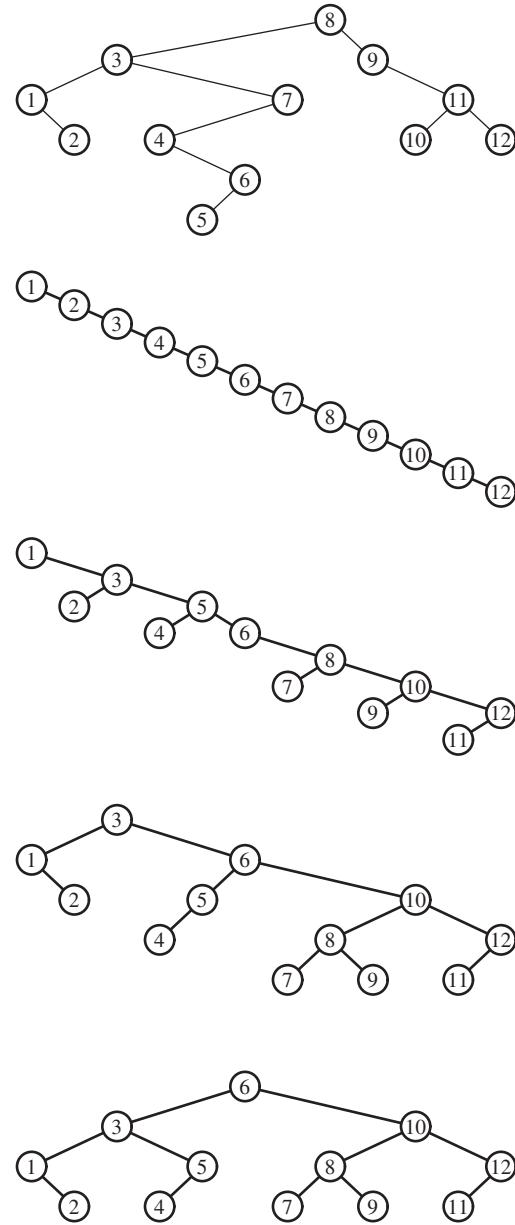

FIGURE 11.4 Rebalancing a binary search tree.

11.6.1 Implicit Representation of Balance Information

One idea of how to remove the need for local balance information is to store the information implicitly. There are two main techniques for this: coding information in the way empty pointers are located or coding information by changing the order between left and right children.

In both cases, we can easily code one bit implicitly at each internal node, but not at external nodes. Therefore, we need to use balance schemes that can do with only one bit per internal node and no balance information at external nodes.

As an example, we may use the AVL-tree. At each node, we need to keep track of whether the two subtrees have the same height or if one of them is one unit higher than its sibling. We can do this with one bit per internal node by letting the bit be 1 if and only if the node is higher than its sibling. For external nodes we know the height, so no balance information is needed there.

The assumption that we only need one bit per internal node is used in the two constructions below.

1. *Using Empty Pointers:* As pointed out by Brown [31,32], the explicitly stored balance information may in some classes of balanced trees be eliminated by coding the information through the location of empty pointers. We use a tree of pseudo-nodes, where a pseudo-node contains two consecutive elements, stored in two binary nodes. The pseudo-node will have three outgoing pointers, and since the two binary nodes are consecutive, one of the three pointers will be empty. By varying which of the two nodes become parent, we can arrange the pseudo-node in two ways. These two different structures are used to represent bit values 0 and 1, respectively; by checking the position of the empty pointer, we can compute the bit value. In order for this to work, we allow the pseudo-nodes at the bottom of the tree to contain one or two binary nodes.

During insertion, we traverse down the tree. If the inserted element lies between the two keys in a visited pseudo-node, we replace it by one of the elements in the pseudo-node and continue down the tree with that element instead. At the bottom of the tree, if we find a pseudo-node with only one key, we just add the new key. If, on the other hand, we find a pseudo-node with two keys, we split it into two pseudo-nodes which will cause an insertion in the tree of pseudo-nodes. Rotations etc. can be done with pseudo-nodes instead of ordinary binary nodes. (If a rotation involves the lowest level of the tree of pseudo-nodes, some care has to be taken in order to maintain the invariant that only the lowest pseudo-nodes may contain a single node.)

Deletions are handled correspondingly. If the deleted element is contained in an internal pseudo-node, we replace it by its predecessor or successor, which resides at the bottom of the tree; in this way we ensure that the deletion occurs at the bottom. If the deletion occurs at a pseudo-node with two binary nodes, we just remove the node, if the pseudo-node contains only one node, a deletion occurs in the tree of pseudo-nodes.

Despite the pseudo-nodes, the tree is really just a binary search tree where no balance information is explicitly stored. Since each pseudo-node has internal height 2, and the number of pseudo-nodes is less than n , the height of the binary tree is $O(\log n)$. A drawback is that the height of the underlying binary tree will become higher by the use of pseudo-nodes. Instead of n internal nodes we will have roughly $n/2$ pseudo-nodes, each of height 2. In the worst case, the height of the binary tree will be doubled.

2. *Swapping Pointers:* Another possibility for coding information into a structure is to use the ordering of nodes. If we redefine binary search trees, such that the left and right subtree of a node are allowed to change place, we can use this possibility to encode one bit per node implicitly. By comparing the keys of the two children of a node, the one-bit information can be extracted. During search, we have to make one comparison extra at each node. This idea has been used by Munro and Suwanda [33–35] to achieve implicit implementation of binary search trees, but it can of course also be used for traditional pointer-based tree structures.

11.6.2 General Balanced Trees

In the following, we use $|T|$ to denote the weight (number of leaves) in a tree T . We also use $|v|$ to denote the weight of a subtree rooted at node v . It should be noted that for a tree T storing n keys in internal nodes, $|T| = n + 1$.

Instead of coding balance information into the structure of the tree, we can let the tree take any shape, as long as its height is logarithmic. Then, there is no local balance criterion to maintain, and we need no balance information in the nodes, not even implicitly coded. As we show below, the tree can still be maintained efficiently.

When maintaining trees this way, we use the technique of *partial rebuilding*. This technique was first introduced by Overmars and van Leeuwen [11,36] for maintaining weight-balanced trees. By making a partial rebuilding at node v , we mean that the subtree rooted at v is rebuilt into a perfectly balanced tree. The cost of such rebalancing is $\Theta(|v|)$. In Section 11.5, we discuss linear time algorithms for rebalancing a (sub-)tree to perfect balance.

Apart from the advantage of requiring no balance information in the nodes, it can be shown [37] that the constant factor for general balanced trees is lower than what has been shown for the maintenance of weight-balanced trees by partial rebuilding.

The main idea in maintaining a general balanced tree is to let the tree take *any* shape as long as its height does not exceed $\log |T|$ by more than a specified constant factor. The key observation is that whenever the tree gets too high by an insertion, we can find a node where partial rebuilding can be made at a low amortized cost. (Since deletions do not increase the height of the tree, we can handle deletions efficiently by rebuilding the entire tree after a large number of elements have been deleted.)

We use two constants $c > 1$, and $b > 0$, and we maintain a balanced tree T with maximum height $\lceil c \log |T| + b \rceil$.

No balance information is used, except two global integers, containing $|T|$, the number of leaves in T , and $d(T)$, the number of deletions made since the last time the entire tree T was rebalanced.

Updates are performed in the following way:

1. *Insertion:* If the depth of the new leaf exceeds $\lceil c \log(|T| + d(T)) \rceil$, we back up along the insertion path until we find the lowest node v , such that $h(v) > \lceil c \log |v| \rceil$. The subtree v is then rebuilt to perfect balance. The node v is found by explicitly

traversing the subtrees below the nodes on the path from the inserted leaf to v , while counting the number of leaves. The cost for this equals the cost for traversing the subtree below v once, which is $O(|v|)$.

2. *Deletion:* $d(T)$ increases by one. If $d(T) \geq (2^{b/c} - 1)|T|$, we rebuild T to perfect balance and set $d(T) = 0$.

First, we show that the height is low enough. Since deletions do not increase the height of T , we only need to show that the height is not increased too much by an insertion. We prove this by induction. Assume that

$$h(T) \leq \lceil c \log(|T| + d(T)) \rceil \quad (11.1)$$

holds before an insertion. (Note that the height of an empty tree is zero.) During the insertion, the height condition can only be violated by the new node. However, if such a violation occurs, the partial rebuilding will ensure that Inequality (11.1) holds after the insertion. Hence, Inequality (11.1) holds by induction. Combining this with the fact that $d(T) < (2^{b/c} - 1)|T|$, we get that $h(T) \leq \lceil c \log |T| + b \rceil$.

Next, we show that the maintenance cost is low enough. Since the amortized cost for the rebuilding of the entire tree caused by deletions is obviously $O(1)$ per deletion, we only need to consider insertions.

In fact, by the way we choose where to perform rebuilding, we can guarantee that *when a partial rebuilding occurs at node v , $\Omega(v)$ updates have been made below v since the last time v was involved in a partial rebuilding*. Indeed, this observation is the key observation behind general balanced trees.

Let v_H be v 's child on the path to the inserted node. By the way v is selected by the algorithm, we know the following about v and v_h :

$$h(v) > \lceil c \log |v| \rceil \quad (11.2)$$

$$h(v_H) \leq \lceil c \log |v_H| \rceil \quad (11.3)$$

$$h(v) = h(v_h) + 1 \quad (11.4)$$

Combining these, we get

$$\lceil c \log |v| \rceil < h(v) = h(v_H) + 1 \leq \lceil c \log |v_H| \rceil + 1 \quad (11.5)$$

and, thus

$$\begin{aligned} \log |v| &< \log |v_H| + 1/c \\ |v_H| &> 2^{-1/c} |v| \end{aligned} \quad (11.6)$$

Since $2^{-1/c} > 1/2$, we conclude that the weight of v_H is $\Theta(v)$ larger than the weight of v 's other child. The only way this difference in weight between the two children can occur is by insertions or deletion below v . Hence, $\Omega(v)$ updates must have been made below v since the last time v was involved in a partial rebuilding. In order for the amortized analysis to hold, we need to reserve a constant cost at v for each update below v . At each update, updates are made below $O(\log n)$ nodes, so the total reservation per update is $O(\log n)$.

Since the tree is allowed to take any shape as long as its height is low enough, we call this type of balanced tree *general balanced trees* [37]. We use the notation GB-trees or $GB(c)$ -trees, where c is the height constant above. (The constant b is omitted in this notation.) (The idea of general balanced trees have also been rediscovered under the name scapegoat trees [26].)

Example. The upper tree in [Figure 11.5](#) illustrates a $GB(1.2)$ -tree where five deletions and some insertions have been made since the last global rebuilding. When inserting 10, the height becomes 7, which is too high, since $7 > \lceil c \log(|T| + d(T)) \rceil = \lceil 1.2 \log(20 + 5) \rceil = 6$. We back up along the path until we find the node 14. The height of this node is 5 and the weight is 8. Since $5 > \lceil 1.2 \log 8 \rceil$, we can make a partial rebuilding at that node. The resulting tree is shown as the lower tree in [Figure 11.5](#).

11.6.3 Application to Multi-Dimensional Search Trees

The technique of partial rebuilding is an attractive method in the sense that it is useful not only for ordinary binary search trees, but also for more complicated data structures, such as multi-dimensional search trees, where rotations cannot be used efficiently. For example, partial rebuilding can be used to maintain logarithmic height in k - d trees [38] under updates [11, 36, 39]. A detailed study of the use of partial rebuilding can be found in Mark Overmars' Ph.D. thesis [36]. For the sake of completeness, we just mention that if the cost of rebalancing a subtree v is $O(P(|v|))$, the amortized cost of an update will be $O\left(\frac{P(n)}{n} \log n\right)$. For example, applied to k - d trees, we get an amortized update cost of $O(\log^2 n)$.

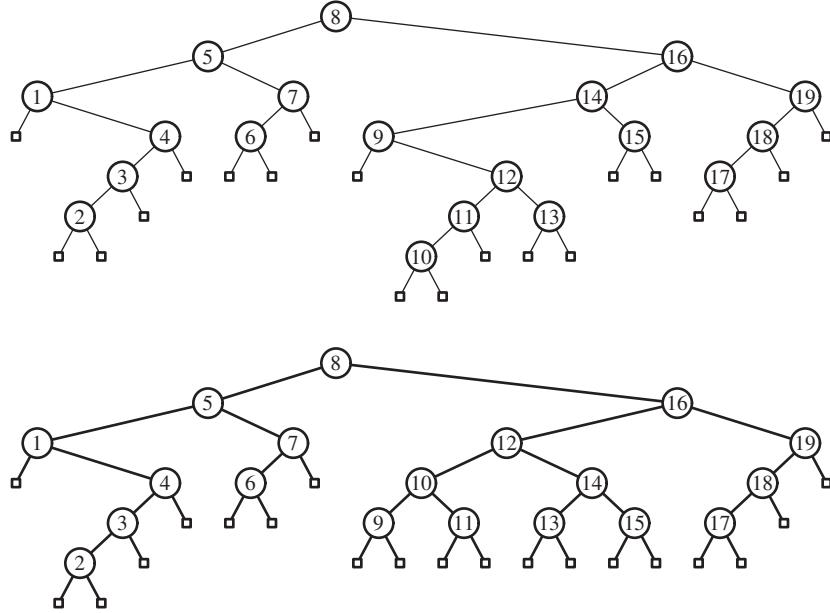

FIGURE 11.5 Upper tree: A GB(1,2)-tree which requires rebalancing. Lower tree: After partial rebuilding.

11.7 Low Height Schemes

Most rebalancing schemes reproduce the result of AVL-trees [4] in the sense that they guarantee a height of $c \cdot \log(n)$ for some constant $c > 1$, while doing updates in $O(\log n)$ time. Since the height determines the worst-case complexity of almost all operations, it may be reasonable to ask exactly how close to the best possible height $\lceil \log(n+1) \rceil$ a tree can be maintained during updates. Presumably, the answer depends on the amount of rebalancing work we are willing to do, so more generally the question is: given a function f , what is the best possible height maintainable with $O(f(n))$ rebalancing work per update?

This question is of practical interest—in situations where many more searches than updates are performed, lowering the height by factor of (say) two will improve overall performance, even if it is obtained at the cost of a larger update time. It is also of theoretical interest, since we are asking about the inherent complexity of maintaining a given height in binary search trees. In this section, we review the existing answers to the question.

Already in 1976, Maurer et al. [40] proposed the k -neighbor trees, which guarantee a height of $c \cdot \log(n)$, where c can be chosen arbitrarily close to one. These are unary-binary trees, with all leaves having the same depth and with the requirement that between any two unary nodes on the same level, at least $k - 1$ binary nodes appear. They may be viewed as a type of $(1, 2)$ -trees where the rebalancing operations exchange children, not only with neighboring nodes (as in standard (a, b) -tree or B -tree rebalancing), but with nodes a horizontal distance k away. Since at each level, at most one out of k nodes is unary, the number of nodes increases by a factor of $(2(k-1)+1)/k = 2 - 1/k$ for each level. This implies a height bound of $\log_{2-1/k} n = \log(n)/\log(2-1/k)$. By first order approximation, $\log(1+x) = \Theta(x)$ and $1/(1+x) = 1 - \Theta(x)$ for x close to zero, so $1/\log(2-1/k) = 1/(1 + \log(1-1/2k)) = 1 + \Theta(1/k)$. Hence, k -trees maintain a height of $(1 + \Theta(1/k)) \log n$ in time $O(k \log n)$ per update.

Another proposal [20] generalizes the red-black method of implementing $(2, 4)$ -trees as binary trees, and uses it to implement (a, b) -trees as binary trees for $a = 2^k$ and $b = 2^{k+1}$. Each (a, b) -tree node is implemented as a binary tree of perfect balance. If the underlying (a, b) -tree has t levels, the binary tree has height at most $t(k+1)$ and has at least $(2^k)^t = 2^{kt}$ nodes. Hence, $\log n \geq tk$, so the height is at most $(k+1)/k \log n = (1 + 1/k) \log n$. As in red-black trees, a node splitting or fusion in the (a, b) -tree corresponds to a constant amount of recoloring. These operations may propagate along the search path, while the remaining rebalancing necessary takes place at a constant number of (a, b) -tree nodes. In the binary formulation, these operations involve rebuilding subtrees of size $\Theta(2^k)$ to perfect balance. Hence, the rebalancing cost is $O(\log(n)/k + 2^k)$ per update.

Choosing $k = \lfloor \log \log n \rfloor$ gives a tree with height bound $\log n + \log(n)/\log \log n$ and update time $O(\log n)$. Note that the constant for the leading term of the height bound is now one. To accommodate a non-constant k , the entire tree is rebuilt when $\lfloor \log \log n \rfloor$ changes. Amortized this is $O(1)$ work, which can be made a worst case bound by using incremental rebuilding [36].

Returning to k -trees, we may use the method of non-constant k also there. One possibility is $k = \Theta(\log n)$, which implies a height bound as low as $\log n + O(1)$, maintained with $O(\log^2 n)$ rebalancing work per update. This height is $O(1)$ from the best

possible. A similar result can be achieved using the general balanced trees described in Section 11.6: In the proof of complexity in that section, the main point is that the cost $|v|$ of a rebuilding at a node v can be attributed to at least $(2^{-1/c} - 1/2)|v|$ updates, implying that each update is attributed at most $(1/(2^{-1/c}) - 1/2)$ cost at each of the at most $O(\log n)$ nodes on the search path. The rebalancing cost is therefore $O(1/(2^{-1/c} - 1/2) \log n)$ for maintaining height $c \cdot \log n$. Choosing $c = 1 + 1/\log n$ gives a height bound of $\log n + O(1)$, maintained in $O(\log^2 n)$ amortized rebalancing work per update, since $(2^{-1/(1+(1/\log n))} - 1/2)$ can be shown to be $\Theta(1/\log n)$ using the first order approximations $1/(1+x) = 1 - \Theta(x)$ and $2^x = 1 + \Theta(x)$ for x close to zero.

We note that a binary tree with a height bound of $\log n + O(1)$ in a natural way can be embedded in an array of length $O(n)$: Consider a tree T with a height bound of $\log n + k$ for an integer k , and consider n ranging over the interval $[2^i; 2^{i+1}]$ for an integer i . For n in this interval, the height of T never exceeds $i+k$, so we can think of T as embedded in a virtual binary tree T' with $i+k$ completely full levels. Numbering nodes in T' by an in-order traversal and using these numbers as indexes in an array A of size $2^{i+k} - 1$ gives an embedding of T into A . The keys of T will appear in sorted order in A , but empty array entries may exist between keys. An insertion into T which violates the height bound corresponds to an insertion into the sorted array A at a non-empty position. If T is maintained by the algorithm based on general balanced trees, rebalancing due to the insertion consists of rebuilding some subtree in T to perfect balance, which in A corresponds to an even redistribution of the elements in some consecutive segment of the array. In particular, the redistribution ensures an empty position at the insertion point.

In short, the tree rebalancing algorithm can be used as a maintenance algorithm for a sorted array of keys supporting insertions and deletions in amortized $O(\log^2 n)$ time. The requirement is that the array is never filled to more than some fixed fraction of its capacity (the fraction is $1/2^{k-1}$ in the example above). Such an amortized $O(\log^2 n)$ solution, phrased directly as a maintenance algorithm for sorted arrays, first appeared in Reference 41. By the converse of the embedding just described, [41] implies a rebalancing algorithm for low height trees with bounds as above. This algorithm is similar, but not identical, to the one arising from general balanced trees (the criteria for when to rebuild/redistribute are similar, but differ in the details). A solution to the sorted array maintenance problem with worst case $O(\log^2 n)$ update time was given in Reference 42. Lower bounds for the problem appear in References 43 and 44, with one of the bounds stating that for algorithms using even redistribution of the elements in some consecutive segment of the array, $O(\log^2 n)$ time is best possible when the array is filled up to some constant fraction of its capacity.

We note that the correspondence between the tree formulation and the array formulation only holds when using partial rebuilding to rebalance the tree—only then is the cost of the redistribution the same in the two versions. In contrast, a rotation in the tree will shift entire subtrees up and down at constant cost, which in the array version entails cost proportional to the size of the subtrees. Thus, for pointer based implementation of trees, the above $\Omega(\log^2 n)$ lower bound does not hold, and better complexities can be hoped for.

Indeed, for trees, the rebalancing cost can be reduced further. One method is by applying the idea of *bucketing*: The subtrees on the lowest $\Theta(\log K)$ levels of the tree are changed into buckets holding $\Theta(K)$ keys. This size bound is maintained by treating the buckets as (a, b) -tree nodes, that is, by bucket splitting, fusion, and sharing. Updates in the top tree only happen when a bucket is split or fused, which only happens for every $\Theta(K)$ updates in the bucket. Hence, the amortized update time for the top tree drops by a factor K . The buckets themselves can be implemented as well-balanced binary trees—using the schemes above based on k -trees or general balanced trees for both top tree and buckets, we arrive at a height bound of $\log n + O(1)$, maintained with $O(\log \log^2 n)$ amortized rebalancing work. Applying the idea recursively inside the buckets will improve the time even further. This line of rebalancing schemes was developed in References 45–50, ending in a scheme [48] maintaining height $\lceil \log(n+1) \rceil + 1$ with $O(1)$ amortized rebalancing work per update.

This rather positive result is in contrast to an observation made in Reference 49 about the cost of maintaining exact optimal height $\lceil \log(n+1) \rceil$: When $n = 2^i - 1$ for an integer i , there is only one possible tree of height $\lceil \log(n+1) \rceil$, namely a tree of i completely full levels. By the ordering of keys in a search tree, the keys of even rank are in the lowest level, and the keys of odd rank are in the remaining levels (where the rank of a key k is defined as the number of keys in the tree that are smaller than k). Inserting a new smallest key and removing the largest key leads to a tree of same size, but where all elements previously of odd rank now have even rank, and vice versa. If optimal height is maintained, all keys previously in the lowest level must now reside in the remaining levels, and vice versa—in other words, the entire tree must be rebuilt. Since the process can be repeated, we obtain a lower bound of $\Omega(n)$, even with respect to amortized complexity. Thus, we have the intriguing situation that a height bound of $\lceil \log(n+1) \rceil$ has amortized complexity $\Theta(n)$ per update, while raising the height bound a trifle to $\lceil \log(n+1) \rceil + 1$ reduces the complexity to $\Theta(1)$.

Actually, the papers [45–50] consider a more detailed height bound of the form $\lceil \log(n+1) + \varepsilon \rceil$, where ε is any real number greater than zero. For ε less than one, this expression is optimal for the first integers n above $2^i - 1$ for any i , and optimal plus one for the last integers before $2^{i+1} - 1$. In other words, the smaller an ε , the closer to the next power of two is the height guaranteed to be optimal. Considering tangents to the graph of the logarithm function, it is easily seen that ε is proportional to the fraction of integers n for which the height is non-optimal.

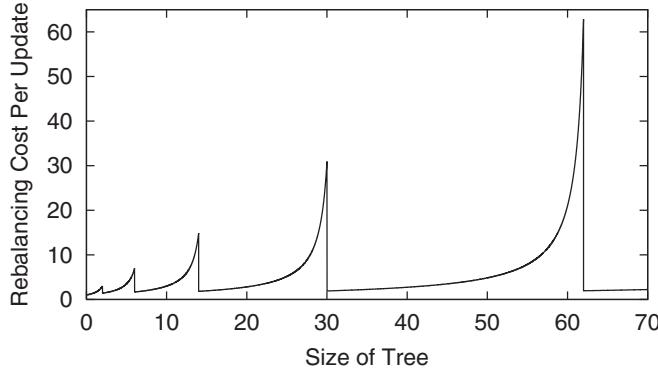

FIGURE 11.6 The cost of maintaining optimal height as a function of tree size.

Hence, an even more detailed formulation of the question about height bound versus rebalancing work is the following: Given a function f , what is the smallest possible ε such that the height bound $\lceil \log(n+1) + \varepsilon \rceil$ is maintainable with $O(f(n))$ rebalancing work per update?

In the case of amortized complexity, the answer is known. In Reference 51, a lower bound is given, stating that no algorithm using $o(f(n))$ amortized rebuilding work per update can guarantee a height of $\lceil \log(n+1) + 1/f(n) \rceil$ for all n . The lower bound is proved by mapping trees to arrays and exploiting a fundamental lemma on density from [43]. In Reference 52, a balancing scheme was given which maintains height $\lceil \log(n+1) + 1/f(n) \rceil$ in amortized $O(f(n))$ time per update, thereby matching the lower bound. The basic idea of the balancing scheme is similar to k -trees, but a more intricate distribution of unary nodes is used. Combined, these results show that for amortized complexity, the answer to the question above is

$$\varepsilon(n) \in \Theta(1/f(n)).$$

We may view this expression as describing the inherent amortized complexity of rebalancing a binary search tree, seen as a function of the height bound maintained. Using the observation above that for any i , $\lceil \log(n+1) + \varepsilon \rceil$ is equal to $\lceil \log(n+1) \rceil$ for n from $2^i - 1$ to $(1 - \Theta(\varepsilon))2^{i+1}$, the result may alternatively be viewed as the cost of maintaining optimal height when n approaches the next power of two: for $n = (1 - \varepsilon)2^{i+1}$, the cost is $\Theta(1/\varepsilon)$. A graph depicting this cost appears in Figure 11.6.

This result holds for the fully dynamic case, where one may keep the size at $(1 - \varepsilon)2^{i+1}$ by alternating between insertions and deletions. In the semi-dynamic case where only insertions take place, the amortized cost is smaller—essentially, it is the integral of the function in Figure 11.6, which gives $\Theta(n \log n)$ for n insertions, or $\Theta(\log n)$ per insertion. More concretely, we may divide the insertions causing n to grow from 2^i to 2^{i+1} into i segments, where segment one is the first 2^{i-1} insertions, segment two is the next 2^{i-2} insertions, and so forth. In segment j , we employ the rebalancing scheme from [52] with $f(n) = \Theta(2^j)$, which will keep optimal height in that segment. The total cost of insertions is $O(2^i)$ inside each of the i segments, for a combined cost of $O(i2^i)$, which is $O(\log n)$ amortized per insertion. By the same reasoning, the lower bound from [51] implies that this is best possible for maintaining optimal height in the semi-dynamic case.

Considering worst case complexity for the fully dynamic case, the amortized lower bound stated above of course still applies. The best existing upper bound is height $\lceil \log(n+1) + \min\{1/\sqrt{f(n)}, \log(n)/f(n)\} \rceil$, maintained in $O(f(n))$ worst case time, by a combination of results in References 46 and 51. For the semi-dynamic case, a worst case cost of $\Theta(n)$ can be enforced when n reaches a power of two, as can be seen by the argument above on odd and even ranks of nodes in a completely full tree.

11.8 Relaxed Balance

In the classic search trees, including AVL-trees [4] and red-black trees [5], balancing is tightly coupled to updating. After an insertion or deletion, the updating procedure checks to see if the structural invariant is violated, and if it is, the problem is handled using the balancing operations before the next operation may be applied to the tree. This work is carried out in a bottom-up fashion by either solving the problem at its current location using rotations and/or adjustments of balance variables, or by carrying out a similar operation which moves the problem closer to the root, where, by design, all problems can be solved.

In relaxed balancing, the tight coupling between updating and balancing is removed. Basically, any restriction on when rebalancing is carried out and how much is done at a time is removed, except that the smallest unit of rebalancing is typically one single or double rotation. The immediate disadvantage is of course that the logarithmic height guarantee disappears, unless other methods are used to monitor the tree height.

FIGURE 11.7 Update operations.

The advantage gained is flexibility in the form of extra control over the combined process of updating and balancing. Balancing can be “turned off” during periods with frequent searching and updating (possibly from an external source). If there is not too much correlation between updates, the tree would likely remain fairly balanced during that time. When the frequency drops, more time can be spent on balancing. Furthermore, in multi-processor environments, balancing immediately after an update is a problem because of the locking strategies which must be employed. Basically, the entire search path must be locked because it may be necessary to rebalance all the way back up to the root. This problem is discussed as early as in Reference 5, where top-down balancing is suggested as a means of avoiding having to traverse the path again bottom-up after an update. However, this method generally leads to much more restructuring than necessary, up to $\Theta(\log n)$ instead of $O(1)$. Additionally, restructuring, especially in the form of a sequence of rotations, is generally significantly more time-consuming than adjustment of balance variables. Thus, it is worth considering alternative solutions to this concurrency control problem.

The advantages outlined above are only fully obtained if balancing is still efficient. That is the challenge: to define balancing constraints which are flexible enough that updating without immediate rebalancing can be allowed, yet at the same time sufficiently constrained that balancing can be handled efficiently at any later time, even if path lengths are constantly super-logarithmic.

The first partial result, dealing with insertions only, is from [53]. Below, we discuss the results which support insertion as well as deletion.

11.8.1 Red-Black Trees

In standard red-black trees, the balance constraints require that no two consecutive nodes are red and that for any node, every path to a leaf has the same number of black nodes. In the relaxed version, the first constraint is abandoned and the second is weakened in the following manner: Instead of a color variable, we use an integer variable, referred to as the *weight* of a node, in such a way that zero can be interpreted as red and one as black. The second constraint is then changed to saying that for any node, every path to a leaf has the same sum of weights. Thus, a standard red-black tree is also a relaxed tree; in fact, it is the ideal state of a relaxed tree. The work on red-black trees with relaxed balance was initiated in References 54 and 55.

Now, the updating operations must be defined so that an update can be performed in such a way that updating will leave the tree in a well-defined state, that is, it must be a relaxed tree, without any subsequent rebalancing. This can be done as shown in Figure 11.7. The operations are from [56].

The trees used here, and depicted in the figure, are assumed to be leaf-oriented. This terminology stems from applications where it is convenient to treat the external nodes differently from the remaining nodes. Thus, in these applications, the external nodes are not empty trees, but real nodes, possibly of another type than the internal nodes. In database applications, for instance, if a sequence of sorted data in the form of a linked list is already present, it is often desirable to build a tree on top of this data to facilitate faster searching. In such cases, it is often convenient to allow copies of keys from the leaves to also appear in the tree structure. To distinguish, we then refer to the key values in the leaves as keys, and refer to the key values in the tree structure as *routers*, since they merely guide the searching procedure. The ordering invariant is then relaxed, allowing keys in the left subtree of a tree rooted by u to be smaller than or equal to $u.k$, and the size of the tree is often defined as the number of leaves. When using the terminology outlined here, we refer to the trees as *leaf-oriented* trees.

The balance problems in a relaxed tree can now be specified as the relations between balance variables which prevent the tree from being a standard red-black tree, that is, consecutive red nodes (nodes of weight zero) and weights greater than one. Thus, the balancing scheme must be targeted at removing these problems. It is an important feature of the design that the global constraint on a standard red-black tree involving the number of black nodes is not lost after an update. Instead, the information is captured in the second requirement and as soon as all weight greater than one has been removed, the standard constraint holds again.

The strategy for the design of balancing operations is the same as for the classical search trees. Problems are removed if this is possible, and otherwise, the problem is moved closer to the root, where all problems can be resolved. In Figure 11.8, examples are shown of how consecutive red nodes and weight greater than one can be eliminated, and in Figure 11.9, examples are given of how these problems may be moved closer to the root, in the case where they cannot be eliminated immediately.

It is possible to show complexity results for relaxed trees which are similar to the ones which can be obtained in the classical case. A logarithmic bound on the number of balancing operations required to balance the tree in response to an update was established in Reference 57. Since balancing operations can be delayed any amount of time, the usual notion of n as the number

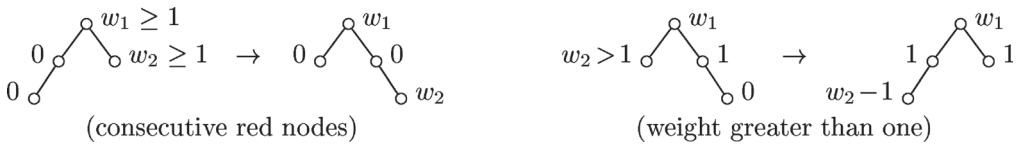

FIGURE 11.8 Example operations eliminating balance problems.

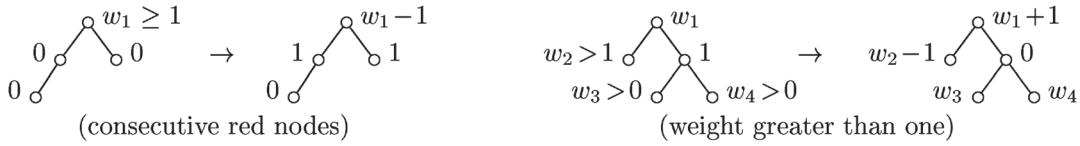

FIGURE 11.9 Example operations moving balance problems closer to the root.

of elements in the tree at the time of balancing after an update is not really meaningful, so the bound is logarithmic in N , which is the maximum number of elements in the tree since it was last in balance. In Reference 58, amortized constant bounds were obtained and in References 59, a version is presented which has fewer and smaller operations, but meets the same bounds. Also, restructuring of the tree is worst-case constant per update. Finally, [56] extends the set of operations with a group insertion, such that an entire search tree can be inserted in between two consecutive keys in amortized time $O(\log m)$, where m is the size of the subtree.

The amortized bounds as well as the worst case bounds are obtained using potential function techniques [60]. For group insertion, the results further depend on the fact that trees with low total potential can build [61], such that the inserted subtree does not increase the potential too dramatically.

11.8.2 AVL-Trees

The first relaxed version of AVL-trees [4] is from [62]. Here, the standard balance constraint of requiring that the heights of any two subtrees differ by at most one is relaxed by introducing a slack parameter, referred to as a *tag* value. The tag value, t_u , of any node u must be an integer greater than or equal to -1 , except that the tag value of a leaf must be greater than or equal to zero. The constraint that heights may differ by at most one is then imposed on the *relaxed height* instead. The relaxed height $rh(u)$ of a node u is defined as

$$rh(u) = \begin{cases} t_u, & \text{if } u \text{ is a leaf} \\ \max(rh(u.l), rh(u.r)) + 1 + t_u, & \text{otherwise} \end{cases}$$

As for red-black trees, enough flexibility is introduced by this definition that updates can be made without immediate rebalancing while leaving the tree in a well-defined state. This can be done by adjusting tag values appropriately in the vicinity of the update location. A standard AVL-tree is the ideal state of a relaxed AVL-tree, which is obtained when all tag values are zero. Thus, a balancing scheme aiming at this is designed.

In Reference 63, it is shown that a scheme can be designed such that the complexities from the sequential case are met. Thus, only a logarithmic number of balancing operations must be carried out in response to an update before the tree is again in balance. As opposed to red-black trees, the amortized constant rebalancing result does not hold in full generality for AVL-trees, but only for the semi-dynamic case [7]. This result is matched in Reference 64.

A different AVL-based version was treated in Reference 65. Here, rotations are only performed if the subtrees are balanced. Thus, violations of the balance constraints must be dealt with bottom-up. This is a minimalistic approach to relaxed balance. When a rebalancing operation is carried out at a given node, the children do not violate the balance constraints. This limits the possible cases, and is asymptotically as efficient as the structure described above [66,67].

11.8.3 Multi-Way Trees

Multi-way trees are usually described either as (a, b) -trees or B -trees, which are treated in another chapter of this book. An (a, b) -tree [39,68] consists of nodes with at least a and at most b children. Usually, it is required that $a \geq 2$ to ensure logarithmic height, and in order to make the rebalancing scheme work, b must be at least $2a - 1$. Searching and updating including rebalancing is $O(\log_a n)$. If $b \geq 2a$, then rebalancing becomes amortized $O(1)$. The term B -trees [13] is often used synonymously, but sometimes refers to the variant where $b = 2a - 1$ or the variant where $b = 2a$.

For (a, b) -trees, the standard balance constraints for requiring that the number of children of each node is between a and b and that every leaf is at the same depth are relaxed as follows. First, nodes are allowed to have fewer than a children. This makes it possible to perform a deletion without immediate rebalancing. Second, nodes are equipped with a tag value, which is a non-positive integer value, and leaves are only required to have the same *relaxed depth*, which is the usual depth, except that all tag values encountered from the root to the node in question are added. With this relaxation, it becomes possible to perform an insertion locally and leave the tree in a well-defined state.

Relaxed multi-way trees were first considered in Reference 62, and complexity results matching the standard case were established in Reference 69. Variations with other properties can be found in Reference 70. Finally, a group insertion operation with a complexity of amortized $O(\log_a m)$, where m is the size of the group, can be added while maintaining the already achieved complexities for the other operations [71,72]. The amortized result is a little stronger than usual, where it is normally assumed that the initial structure is empty. Here, except for very small values of a and b , zero-potential trees of any size can be constructed such the amortized results starting from such a tree hold immediately [61].

11.8.4 Other Results

Even though there are significant differences between the results outlined above, it is possible to establish a more general result giving the requirements for when a balanced search tree scheme can be modified to give a relaxed version with corresponding complexity properties [73]. The main requirements are that rebalancing operations in the standard scheme must be local constant-sized operations which are applied bottom-up, but in addition, balancing operation must also move the problems of imbalance towards the root. See [74] for an example of how these general ideas are expressed in the concrete setting of red-black trees.

In Reference 75, it is demonstrated how the ideas of relaxed balance can be combined with methods from search trees of near-optimal height, and [70] contains complexity results made specifically for the reformulation of red-black trees in terms of layers based on black height from [76].

Finally, performance results from experiments with relaxed structures can be found in References [77,78].

12.1 Finger Searching

One of the most studied problems in computer science is the problem of maintaining a sorted sequence of elements to facilitate efficient searches. The prominent solution to the problem is to organize the sorted sequence as a balanced search tree, enabling insertions, deletions and searches in logarithmic time. Many different search trees have been developed and studied intensively in the literature. A discussion of balanced binary search trees can be found in [Chapter 11](#).

This chapter is devoted to *finger search trees*, which are search trees supporting *fingers*, that is, pointers to elements in the search trees and supporting efficient updates and searches in the vicinity of the fingers.

If the sorted sequence is a *static* set of n elements then a simple and space efficient representation is a sorted array. Searches can be performed by binary search using $1 + \lfloor \log n \rfloor$ comparisons (we throughout this chapter let $\log x$ to denote $\log_2 \max\{2, x\}$). A finger search starting at a particular element of the array can be performed by an *exponential search* by inspecting elements at distance $2^i - 1$ from the finger for increasing i followed by a binary search in a range of $2^{\lfloor \log d \rfloor} - 1$ elements, where d is the rank difference in the sequence between the finger and the search element. In [Figure 12.1](#) is shown an exponential search for the element 42 starting at 5. In the example $d = 20$. An exponential search requires $2 + 2 \lfloor \log d \rfloor$ comparisons.

Bentley and Yao [\[1\]](#) gave a close to optimal static finger search algorithm which performs $\sum_{i=1}^{\log^* d - 1} \log^{(i)} d + \mathcal{O}(\log^* d)$ comparisons, where $\log^{(1)} x = \log x$, $\log^{(i+1)} x = \log(\log^{(i)} x)$, and $\log^* x = \min\{i \mid \log^{(i)} x \leq 1\}$.

12.2 Dynamic Finger Search Trees

A dynamic finger search data structure should in addition to finger searches also support the insertion and deletion of elements at a position given by a finger. This section is devoted to an overview of existing dynamic finger search data structures. Sections 12.3 and 12.4 give details concerning how three constructions support efficient finger searches: The level linked (2,4)-trees of Huddleston and Mehlhorn [\[2\]](#), the randomized skip lists of Pugh [\[3,4\]](#) and the randomized binary search trees, treaps, of Seidel and Aragon [\[5\]](#).

Guibas et al. [\[6\]](#) introduced finger search trees as a variant of B-trees [\[7\]](#), supporting finger searches in $\mathcal{O}(\log d)$ time and updates in $\mathcal{O}(1)$ time, assuming that only $\mathcal{O}(1)$ movable fingers are maintained. Moving a finger d positions requires $\mathcal{O}(\log d)$ time. This work was refined by Huddleston and Mehlhorn [\[2\]](#). Tsakalidis [\[8\]](#) presented a solution based on AVL-trees, and Kosaraju [\[9\]](#) presented a generalized solution. Tarjan and van Wyk [\[10\]](#) presented a solution based on red-black trees.

[★] This chapter has been reprinted from first edition of this Handbook, without any content updates.

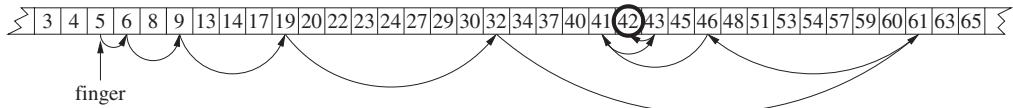

FIGURE 12.1 Exponential search for 42.

The above finger search tree constructions either assume a fixed constant number of fingers or only support updates in amortized constant time. Constructions supporting an arbitrary number of fingers and with worst case update have been developed. Levcopoulos and Overmars [11] presented a search tree that supported updates at an arbitrary position in worst case $\mathcal{O}(1)$ time, but only supports searches in $\mathcal{O}(\log n)$ time. Constructions supporting $\mathcal{O}(\log d)$ time searches and $\mathcal{O}(\log^* n)$ time insertions and deletions were developed by Harel [12,13] and Fleischer [14]. Finger search trees with worst-case constant time insertions and $\mathcal{O}(\log^* n)$ time deletions were presented by Brodal [15], and a construction achieving optimal worst-case constant time insertions and deletions were presented by Brodal et al. [16].

Belloch et al. [17] developed a space efficient alternative solution to the level linked (2,4)-trees of Huddleston and Mehlhorn, see Section 12.3. Their solution allows a single finger, that can be moved by the same performance cost as (2,4)-trees. In the solution no level links and parent pointers are required, instead a special $\mathcal{O}(\log n)$ space data structure, *hand*, is created for the finger that allows the finger to be moved efficiently.

Sleator and Tarjan introduced *splay trees* as a class of self-adjusting binary search trees supporting searches, insertions and deletions in amortized $\mathcal{O}(\log n)$ time [18]. That splay trees can be used as efficient finger search trees was later proved by Cole [19,20]: Given an $\mathcal{O}(n)$ initialization cost, the amortized cost of an access at distance d from the preceding access in a splay tree is $\mathcal{O}(\log d)$ where accesses include searches, insertions, and deletions. Notice that the statement only applies in the presence of one finger, which always points to the last accessed element.

All the above mentioned constructions can be implemented on a pointer machine where the only operation allowed on elements is the comparison of two elements. For the Random Access Machine model of computation (RAM), Dietz and Raman [21,22] developed a finger search tree with constant update time and $\mathcal{O}(\log d)$ search time. This result is achieved by tabulating small tree structures, but only performs the comparison of elements. In the same model of computation, Andersson and Thorup [23] have surpassed the logarithmic bound in the search procedure by achieving $\mathcal{O}\left(\sqrt{\frac{\log d}{\log \log d}}\right)$ query time. This result is achieved by considering elements as bit-patterns/machine words and applying techniques developed for the RAM to surpass lower bounds for comparison based data structures. A survey on RAM dictionaries can be found in Chapter 40.

12.3 Level Linked (2,4)-Trees

In this section we discuss how (2,4)-trees can support efficient finger searches by the introduction of *level links*. The ideas discussed in this section also applies to the more general class of height-balanced trees denoted (a, b) -trees, for $b \geq 2a$. A general discussion of height balanced search trees can be found in Chapter 11. A throughout treatment of level linked (a, b) -trees can be found in the work of Huddleston and Mehlhorn [2,24].

A (2,4)-tree is a height-balanced search tree where all leaves have the same depth and all internal nodes have degree two, three or four. Elements are stored at the leaves, and internal nodes only store search keys to guide searches. Since each internal node has degree at least two, it follows that a (2,4)-tree has height $\mathcal{O}(\log n)$ and supports searches in $\mathcal{O}(\log n)$ time.

An important property of (2,4)-trees is that insertions and deletions given by a finger take amortized $\mathcal{O}(1)$ time (this property is not shared by (2,3)-trees, where there exist sequences of n insertions and deletions requiring $\Theta(n \log n)$ time). Furthermore a (2,4)-tree with n leaves can be split into two trees of size n_1 and n_2 in amortized $\mathcal{O}(\log \min(n_1, n_2))$ time. Similarly two (2,4)-trees of size n_1 and n_2 can be joined (concatenated) in amortized $\mathcal{O}(\log \min(n_1, n_2))$ time.

To support finger searches (2,4)-trees are augmented with level links, such that all nodes with equal depth are linked together in a double linked list. Figure 12.2 shows a (2,4)-tree augmented with level links. Note that all edges represent bidirected links. The additional level links are straightforward to maintain during insertions, deletions, splits and joins of (2,4)-trees.

To perform a finger search from x to y we first check whether y is to the left or right of x . Assume without loss of generality that y is to the right of x . We then traverse the path from x towards the root while examining the nodes v on the path and their right neighbors until it has been established that y is contained within the subtree rooted at v or v 's right neighbor. The upwards search is then terminated and at most two downwards searches for y is started at respectively v and/or v 's right neighbor. In Figure 12.2 the pointers followed during a finger search from J to T are depicted by thick lines.

The $\mathcal{O}(\log d)$ search time follows from the observation that if we advance the upwards search to the parent of node v then y is to the right of the leftmost subtree of v 's right neighbor, that is, d is at least exponential in the height reached so far. In Figure 12.2

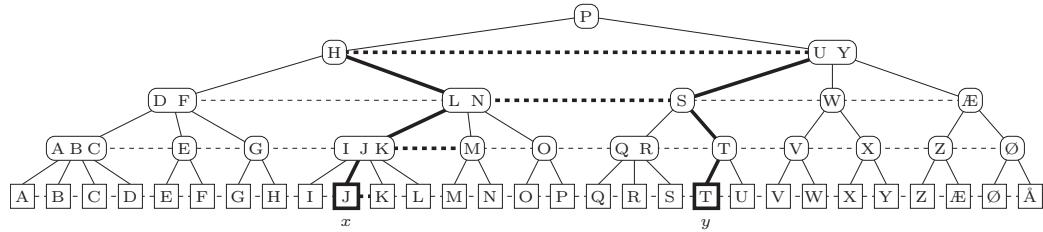

FIGURE 12.2 Level linked (2,4)-trees.

we advance from the internal node labeled “L N” to the node labeled “H” because from “S” we know that y is to the right of the subtree rooted at the node “Q R.”

The construction for level linked (2,4)-trees generalizes directly to level linked (a, b) -trees that can be used in external memory. By choosing $a = 2b$ and b such that an internal node fits in a block in external memory, we achieve *external memory* finger search trees supporting insertions and deletions in $\mathcal{O}(1)$ memory transfers, and finger searches with $\mathcal{O}(\log_b n)$ memory transfers.

12.4 Randomized Finger Search Trees

Two randomized alternatives to deterministic search trees are the randomized binary search trees, *treaps*, of Seidel and Aragon [5] and the *skip lists* of Pugh [3,4]. Both treaps and skip lists are elegant data structures, where the randomization facilitates simple and efficient update operations.

In this section we describe how both treaps and skip lists can be used as efficient finger search trees without altering the data structures. Both data structures support finger searches in *expected* $\mathcal{O}(\log d)$ time, where the expectations are taken over the random choices made by the algorithm during the construction of the data structure. For a general introduction to randomized dictionary data structures see Chapter 14.

12.4.1 Treaps

A treap is a rooted binary tree where each node stores an element and where each element has an associated random priority. A treap satisfies that the elements are sorted with respect to an inorder traversal of tree, and that the priorities of the elements satisfy heap order, that is, the priority stored at a node is always smaller than or equal to the priority stored at the parent node. Provided that the priorities are distinct, the shape of a treap is uniquely determined by its set of elements and the associated priorities. Figure 12.3 shows a treap storing the elements A,B, …,T and with random integer priorities between one and hundred.

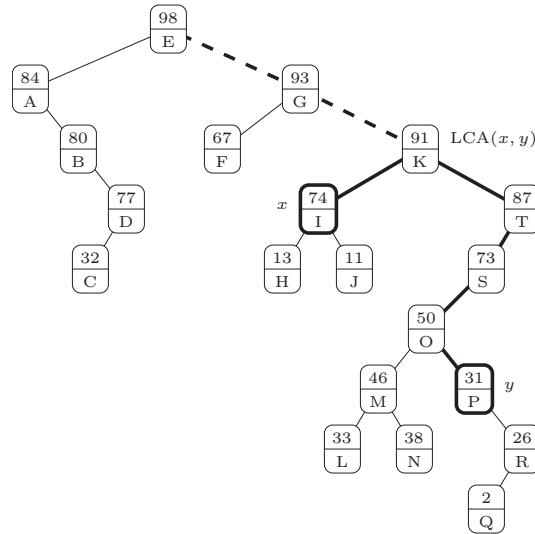

FIGURE 12.3 Performing finger searches on treaps.

The most prominent properties of treaps are that they have expected $\mathcal{O}(\log n)$ height, implying that they provide searches in expected $\mathcal{O}(\log n)$ time. Insertions and deletions of elements can be performed in expected at most two rotations and expected $\mathcal{O}(1)$ time, provided that the position of insertion or deletion is known, that is, insertions and deletions given by a finger take expected $\mathcal{O}(1)$ time [5].

The essential property of treaps enabling expected $\mathcal{O}(\log d)$ finger searches is that for two elements x and y whose ranks differ by d in the set stored, the expected length of the path between x and y in the treap is $\mathcal{O}(\log d)$. To perform a finger search for y starting with a finger at x , we ideally start at x and traverse the ancestor path of x until we reach the *least common ancestor* of x and y , $\text{LCA}(x, y)$, and start a downward tree search for y . If we can decide if a node is $\text{LCA}(x, y)$, this will traverse exactly the path from x to y . Unfortunately, it is nontrivial to decide if a node is $\text{LCA}(x, y)$. In [5] it is assumed that a treap is extended with additional pointers to facilitate finger searches in expected $\mathcal{O}(\log d)$ time. Below an alternative solution is described not requiring any additional pointers than the standard left, right and parent pointers.

Assume without loss of generality that we have a finger at x and have to perform a finger search for $y \geq x$ present in the tree. We start at x and start traversing the ancestor path of x . During this traversal we keep a pointer ℓ to the last visited node that can potentially be $\text{LCA}(x, y)$. Whenever we visit a node v on the path from x to the root there are three cases:

1. $v \leq x$, then x is in the right subtree of v and cannot be $\text{LCA}(x, y)$; we advance to the parent of v .
2. $x < v \leq y$, then x is in the left subtree of v and $\text{LCA}(x, y)$ is either y or an ancestor of y ; we reset $\ell = v$ and advance to the parent of v .
3. $x < y < v$, then $\text{LCA}(x, y)$ is in the left subtree of v and equals ℓ .

Unfortunately, after $\text{LCA}(x, y)$ has been visited case (1) can happen $\omega(\log d)$ times before the search is terminated at the root or by case (3). Seidel and Aragon [5] denote these extra nodes visited above $\text{LCA}(x, y)$ the *excess path* of the search, and circumvent this problem by extending treaps with special pointers for this.

To avoid visiting long excess paths we extend the above upward search with a concurrent downward search for y in the subtree rooted at the current candidate ℓ for $\text{LCA}(x, y)$. In case (1) we always advance the tree search for y one level down, in case (2) we restart the search at the new ℓ , and in (3) we finalize the search. The concurrent search for y guarantees that the distance between $\text{LCA}(x, y)$ and y in the tree is also an upper bound on the nodes visited on the excess path, that is, we visit at most twice the number of nodes as is on the path between x and y , which is expected $\mathcal{O}(\log d)$. It follows that treaps support finger searches in $\mathcal{O}(\log d)$ time. In Figure 12.3 is shown the search for $x = I$, $y = P$, $\text{LCA}(x, y) = K$, the path from x to y is drawn with thick lines, and the excess path is drawn with dashed lines.

12.4.2 Skip Lists

A skip list is a randomized dictionary data structure, which can be considered to consists of expected $\mathcal{O}(\log n)$ levels. The lowest level being a single linked list containing the elements in sorted order, and each succeeding level is a random sample of the elements of the previous level, where each element is included in the next level with a fixed probability, for example, 1/2. The pointer representation of a skip is illustrated in Figure 12.4.

The most prominent properties of skip lists are that they require expected linear space, consist of expected $\mathcal{O}(\log n)$ levels, support searches in expected $\mathcal{O}(\log n)$ time, and support insertions and deletions at a given position in expected $\mathcal{O}(1)$ time [3,4].

Pugh in Reference 3 elaborates on the various properties and extensions of skip lists, including pseudo-code for how skip lists support finger searches in expected $\mathcal{O}(\log d)$ time. To facilitate backward finger searches, a finger to a node v is stored as an expected $\mathcal{O}(\log n)$ space finger data structure that for each level i stores a pointer to the node to the left of v where the level i pointer either points to v or a node to the right of v . Moving a finger requires this list of pointers to be updated correspondingly.

A backward finger search is performed by first identifying the lowest node in the finger data structure that is to the left of the search key y , where the nodes in the finger data structure are considered in order of increasing levels. Thereafter the search proceeds downward from the identified node as in a standard skip list search.

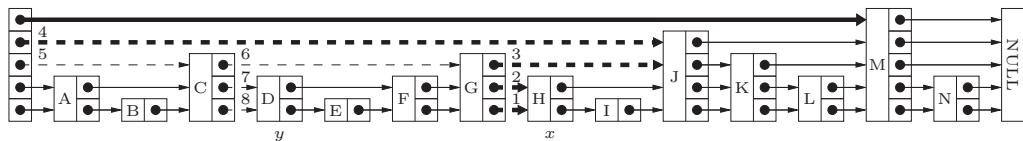

FIGURE 12.4 Performing finger searches on skip list.

[Figure 12.4](#) shows the situation where we have a finger to H, represented by the thick (solid or dashed) lines, and perform a finger search for the element D to the left of H. Dashed (thick and thin) lines are the pointers followed during the finger search. The numbering indicate the other in which the pointers are traversed.

If the level links of a skip list are maintained as double-linked lists, then finger searches can be performed in expected $\mathcal{O}(\log d)$ time by traversing the existing links, without having a separate $\mathcal{O}(\log n)$ space finger data structure.

12.5 Applications

Finger search trees have, for example, been used in algorithms within computational geometry [10,25–29] and string algorithms [30,31]. In the rest of this chapter we give examples of the efficiency that can be obtained by applying finger search trees. These examples typically allow one to save a factor of $\mathcal{O}(\log n)$ in the running time of algorithms compared to using standard balanced search trees supporting $\mathcal{O}(\log n)$ time searches.

12.5.1 Optimal Merging and Set Operations

Consider the problem of merging two sorted sequences X and Y of length respectively n and m , where $n \leq m$, into one sorted sequence of length $n + m$. The canonical solution is to repeatedly insert each $x \in X$ in Y . This requires that Y is searchable and that there can be inserted new elements, that is, a suitable representation of Y is a balanced search tree. This immediately implies an $\mathcal{O}(n \log m)$ time bound for merging. In the following we discuss how finger search trees allow this bound to be improved to $\mathcal{O}(n \log \frac{m}{n})$.

Hwang and Lin [32] presented an algorithm for merging two sorted sequence using optimal $\mathcal{O}(n \log \frac{m}{n})$ comparisons, but did not discuss how to represent the sets. Brown and Tarjan [33] described how to achieve the same bound for merging two AVL trees [34]. Brown and Tarjan subsequently introduced *level linked* (2,3)-trees and described how to achieve the same merging bound for level linked (2,3)-trees [35].

Optimal merging of two sets also follows as an application of finger search trees [2]. Assume that the two sequences are represented as finger search trees, and that we repeatedly insert the n elements from the shorter sequence into the larger sequence using a finger that moves monotonically from left to right. If the i th insertion advances the finger d_i positions, we have that the total work of performing the n finger searches and insertions is $\mathcal{O}(\sum_{i=1}^n \log d_i)$, where $\sum_{i=1}^n d_i \leq m$. By convexity of the logarithm the total work becomes bounded by $\mathcal{O}(n \log \frac{m}{n})$.

Since sets can be represented as sorted sequences, the above merging algorithm gives immediately raise to optimal, that is, $\mathcal{O}(\log \binom{n+m}{n}) = \mathcal{O}(n \log \frac{m}{n})$ time, algorithms for set union, intersection, and difference operations [2]. For a survey of data structures for set representations see [Chapter 34](#).

12.5.2 Arbitrary Merging Order

A classical $\mathcal{O}(n \log n)$ time sorting algorithm is binary merge sort. The algorithm can be viewed as the merging process described by a balanced binary tree: Each leaf corresponds to an input element and each internal node corresponds to the merging of the two sorted sequences containing respectively the elements in the left and right subtree of the node. If the tree is balanced then each element participates in $\mathcal{O}(\log n)$ merging steps, that is, the $\mathcal{O}(n \log n)$ sorting time follows.

Many divide-and-conquer algorithms proceed as binary merge sort, in the sense that the work performed by the algorithm can be characterized by a treewise merging process. For some of these algorithms the tree determining the merges is unfortunately fixed by the input instance, and the running time using linear merges becomes $\mathcal{O}(n \cdot h)$, where h is the height of the tree. In the following we discuss how finger search trees allow us to achieve $\mathcal{O}(n \log n)$ for unbalanced merging orders to.

Consider an arbitrary binary tree T with n leaves, where each leaf stores an element. We allow T to be arbitrarily unbalanced and that elements are allowed to appear at the leaves in any arbitrary order. Associate to each node v of T the set S_v of elements stored at the leaves of the subtree rooted at v . If we for each node v of T compute S_v by merging the two sets of the children of v using finger search trees, cf. Section 12.5.1, then the total time to compute all the sets S_v is $\mathcal{O}(n \log n)$.

The proof of the total $\mathcal{O}(n \log n)$ bound is by structural induction where we show that in a tree of size n , the total merging cost is $\mathcal{O}(\log(n!)) = \mathcal{O}(n \log n)$. Recall that two sets of size n_1 and n_2 can be merged in $\mathcal{O}\left(\log \binom{n_1+n_2}{n_1}\right)$ time. By induction we get that

the total merging in a subtree with a root with two children of size respectively n_1 and n_2 becomes:

$$\begin{aligned} & \log(n_1!) + \log(n_2!) + \log \binom{n_1 + n_2}{n_1} \\ &= \log(n_1!) + \log(n_2!) + \log((n_1 + n_2)!) - \log(n_1!) - \log(n_2!) \\ &= \log((n_1 + n_2)!). \end{aligned}$$

The above approach of arbitrary merging order was applied in [30,31] to achieve $\mathcal{O}(n \log n)$ time algorithms for finding repeats with gaps and quasiperiodicities in strings. In both these algorithms \mathcal{T} is determined by the suffix-tree of the input string, and the S_v sets denote the set of occurrences (positions) of the substring corresponding to the path label of v .

12.5.3 List Splitting

Hoffmann et al. [36] considered how finger search trees can be used for solving the following *list splitting* problem, that, for example, also is applied in References 26 and 29. Assume we initially have a sorted list of n elements that is repeatedly split into two sequences until we end up with n sequences each containing one element. If the splitting of a list of length k into two lists of length k_1 and k_2 is performed by performing a simultaneous finger search from each end of the list, followed by a split, the searching and splitting can be performed in $\mathcal{O}(\log \min(k_1, k_2))$ time. Here we assume that the splitting order is unknown in advance.

By assigning a list of k elements a potential of $k - \log k \geq 0$, the splitting into two lists of size k_1 and k_2 releases the following amount of potential:

$$\begin{aligned} & (k - \log k) - (k_1 - \log k_1) - (k_2 - \log k_2) \\ &= -\log k + \log \min(k_1, k_2) + \log \max(k_1, k_2) \\ &\geq -1 + \log \min(k_1, k_2), \end{aligned}$$

since $\max(k_1, k_2) \geq k/2$. The released potential allows each list splitting to be performed in amortized $\mathcal{O}(1)$ time. The initial list is charged $n - \log n$ potential. We conclude that starting with a list of n elements, followed by a sequence of at most $n - 1$ splits requires total $\mathcal{O}(n)$ time.

12.5.4 Adaptive Merging and Sorting

The area of *adaptive sorting* addresses the problem of developing sorting algorithms which perform $\mathcal{O}(n \log n)$ comparisons for inputs with a limited amount of disorder for various definitions of measures of disorder, for example, the measure Inv counts the number of pairwise insertions in the input. For a survey of adaptive sorting algorithms see [37].

An adaptive sorting algorithm that is optimal with respect to the disorder measure Inv has running time $\mathcal{O}(n \log \frac{\text{Inv}}{n})$. A simple adaptive sorting algorithm optimal with respect to Inv is the *insertion sort* algorithm, where we insert the elements of the input sequence from left to right into a finger search tree. Insertions always start at a finger on the last element inserted. Details on applying finger search trees in insertion sort can be found in References [24,35,38].

Another adaptive sorting algorithm based on applying finger search trees is obtained by replacing the linear merging in binary merge sort by an *adaptive merging* algorithm [39–42]. The classical binary merge sort algorithm always performs $\Omega(n \log n)$ comparisons, since in each merging step where two lists each of size k are merged the number of comparisons performed is between k and $2k - 1$.

The idea of the adaptive merging algorithm is to identify consecutive blocks from the input sequences which are also consecutive in the output sequence, as illustrated in Figure 12.5. This is done by repeatedly performing a finger search for the smallest element of the two input sequences in the other sequence and deleting the identified block in the other sequence by a split operation. If the blocks in the output sequence are denoted Z_1, \dots, Z_k , it follows from the time bounds of finger search trees that the total time for this adaptive merging operation becomes $\mathcal{O}(\sum_{i=1}^k \log |Z_i|)$. From this merging bound it can be argued that

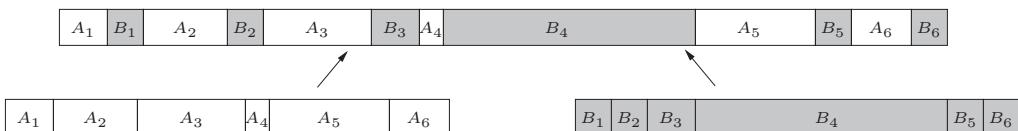

FIGURE 12.5 Adaptive merging.

merge sort with adaptive merging is adaptive with respect to the disorder measure INV (and several other disorder measures). See [39–41] for further details.

13.1 Introduction

In this chapter, we discuss the following topics:

1. Introduction to splay trees and their applications
2. Splay trees—description, analysis, algorithms, and optimality of splay trees
3. Linking and cutting trees
4. Case study: application to network flows
5. Variants of splay trees.

There are various data structures such as AVL-trees, red-black trees, and 2-3-trees (see [Chapter 11](#)), which support operations such as insert, delete (including deleting the minimum item), and search (or membership) in $O(\log n)$ time (for each operation). Splay trees introduced by Sleator and Tarjan [\[1,2\]](#) support all these operations in $O(\log n)$ amortized time, which roughly means that starting from an empty tree, a sequence of m of these operations will take $O(m \log n)$ time (deterministic), an individual operation may take either more time or less time (see Theorem 13.1). We discuss some applications in the rest of this section.

Assume that we are searching for an item in a “large” sorted file, and if the item is in the k th position, then we can search the item in $O(\log k)$ time by exponential and binary search. Similarly, finger search trees (see [Chapter 12](#)) can be used to search any item at distance f from a finger in $O(\log f)$ time. Splay trees can search (again in amortized sense) an item from any finger (which need not even be specified) in $O(\log f)$ time, where f is the distance from the finger (see Section 13.4.2). Since the finger is not required to be specified, the time taken will be minimum over all possible fingers (time, again in amortized sense).

If we know the frequency or probability of access of each item, then we can construct an optimum binary search tree (see [Chapter 11](#)) for these items; total time for all access will be the smallest for optimal binary search trees. If we do not know the probability (or access frequency), and if we use splay trees, even then the total time taken for all accesses will still be the same as that for a binary search tree, up to a multiplicative constant (see Section 13.4.1).

In addition, splay trees can be used almost as a “black box” in linking and cutting trees (see Section 13.5). Here we need the ability to add (or subtract) a number to key values of all ancestors of a node x .

Moreover, in practice, the rebalancing operations (rotations) are very much simpler than those in height balanced trees. Hence, in practice, we can also use splay trees as an alternative to height balanced trees (such as AVL-trees, red-black trees, and 2-3-trees), if we are interested only in the total time. However, some experimental studies [3] suggest that for random data, splay trees outperform balanced binary trees only for highly skewed data; and for applications like “vocabulary accumulation” of English text [4], even standard binary search trees, which do not have good worst-case performance, outperform both balanced binary trees (AVL-trees) and splay trees. In any case, the constant factor and the algorithms are not simpler than those for the usual heap, hence it will not be practical to use splay trees for sorting (say as in heap sort), even though the resulting algorithm will take $O(n \log n)$ time for sorting, unless the data has some degree of presortedness, in which case splay sort is a practical alternative (see Chapter 11) [5]. Splay trees, however, cannot be used in real-time applications.

Splay trees can also be used for data compression. As splay trees are binary search trees, they can be used directly [6] with guaranteed worst-case performance. They are also used in data compression with some modifications [7]. Routines for data compression can be shown to run in time proportional to the entropy of input sequence [8] for usual splay trees and their variants.

13.2 Splay Trees

Let us assume that for each node x , we store a real number $\text{key}(x)$.

In any binary search tree, left subtree of any node x contains items having “key” values less than the value of $\text{key}(x)$ and right subtree of the node x contains items with “key” values larger than the value of $\text{key}(x)$.

In splay trees, we first search the query item, say x as in the usual binary search trees (see Chapter 3)—compare the query item with the value in the root, if smaller then recursively search in the left subtree else if larger then, recursively search in the right subtree, and if it is equal then we are done. Then, informally speaking, we look at every disjoint pair of consecutive ancestors of x , say $y = \text{parent}(x)$ and $z = \text{parent}(y)$, and perform certain pair of rotations. As a result of these rotations, x comes in place of z .

In case x has an odd number of proper ancestors, then the ancestor of x (which is child of the root) will also have to be dealt separately, in terminal case—we rotate the edge between x and the root. This step is called zig step (see Figure 13.1).

If x and y are both left or are both right children of their respective parents, then we first rotate the edge between y and its parent z and then the edge between x and its parent y . This step is called zig-zig step (see Figure 13.2).

If x is a left (respectively right) child and y is a right (respectively left) child, then we first rotate the edge between x and y and then between x and z , this step is called zig-zag step (see Figure 13.3).

These rotations (together) not only make x the new root but also roughly speaking halve the depth (length of path to root) of all ancestors of x in the tree. If the node x is at depth “ d ,” $\text{splay}(x)$ will take $O(d)$ time, that is, time proportional to access the item in node x .

Formally, $\text{splay}(x)$ is a sequence of rotations which are performed (as follows) until x becomes a root:

- If $\text{parent}(x)$ is root, then we carry out usual rotation (see Figure 13.1).
- If x and $\text{parent}(x)$ are both left (or are both right) children of their parents, then we first rotate at $y = \text{parent}(x)$ (i.e., the edge between y and its parent) and then rotate at x (see Figure 13.2).

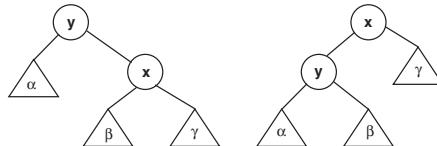

FIGURE 13.1 $\text{parent}(x)$ is the root—edge xy is rotated (zig case).

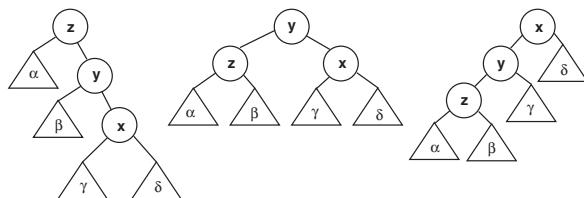

FIGURE 13.2 x and $\text{parent}(x)$ are both right children (zig-zig case)—first edge yz is rotated then edge xy .

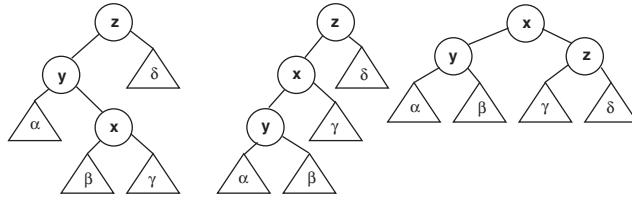

FIGURE 13.3 x is a right child while $\text{parent}(x)$ is a left child (zig-zag case)—first edge xy is rotated then edge xz .

- If x is left (or respectively right) child but $\text{parent}(x)$ is right (respectively left) child of its parent, then first rotate at x and then again rotate at x (see Figure 13.3).

13.3 Analysis

We will next like to look at the “amortized” time taken by splay operations. Amortized time is the average time taken over a worst-case sequence of operations.

For the purpose of analysis, we give a positive weight $w(x)$ to (any) item x in the tree. The weight function can be chosen completely arbitrarily (as long it is strictly positive). For analysis of splay trees, we need some definitions (or nomenclature) and have to fix some parameters.

Weight of item x : For each item x , an arbitrary positive weight $w(x)$ is associated (see Section 13.4 for some examples of function $w(x)$).

Size of node x : $\text{Size}(x)$ is the sum of the individual weights of all items in the subtree rooted at the node x .

Rank of node x : Rank of a node x is $\log_2(\text{size}(x))$.

Potential of a tree: Let α be some positive constant (we will discuss choice of α later), then the potential of a tree T is taken to be

$$\alpha(\text{Sum of rank}(x) \text{ for all nodes } x \in T) = \alpha \sum_{x \in T} \text{rank}(x).$$

Amortized time: As always,

$$\text{Amortized time} = \text{Actual Time} + \text{New Potential} - \text{Old Potential}.$$

Running time of splaying: Let β be some positive constant, choice of β is also discussed later

but $\beta \leq \alpha$, then the running time for splaying is

$$\beta \times \text{Number of rotations}.$$

If there are no rotations, then we charge one unit for splaying.

We also need a simple result from algebra. Observe that $4xy = (x+y)^2 - (x-y)^2$. Now if $x+y \leq 1$, then $4xy \leq 1 - (x-y)^2 \leq 1$ or taking logarithms,^{*} $\log x + \log y \leq -2$. Note that the maximum value occurs when $x=y=1/2$.

Fact 13.1

[Result from Algebra] If $x+y \leq 1$, then $\log x + \log y \leq -2$. The maximum value occurs when $x=y=1/2$.

Lemma 13.1

[Access Lemma] The amortized time to splay a tree (with root “ t ”) at a node “ x ” is at most

$$3\alpha(\text{rank}(t) - \text{rank}(x)) + \beta = O\left(\log\left(\frac{\text{Size}(t)}{\text{Size}(x)}\right)\right)$$

Proof. We will calculate the change in potential, and hence the amortized time taken in each of the three cases.

Let $s(\cdot)$ denote the sizes before rotation(s) and $s'(\cdot)$ be the sizes after rotation(s). Let $r(\cdot)$ denote the ranks before rotation(s) and $r'(\cdot)$ be the ranks after rotation(s).

Case 1: x and $\text{parent}(x)$ are both left (or both right) children

Please refer to Figure 13.2. Here, $s(x) + s'(z) \leq s'(x)$ or $(s(x)/s'(x)) + (s'(z)/s'(x)) \leq 1$.

^{*} All logarithms in this chapter are to base 2.

Thus, by Fact 13.1,

$$-2 \geq \log \frac{s(x)}{s'(x)} + \log \frac{s'(z)}{s'(x)} = r(x) + r'(z) - 2r'(x)$$

or

$$r'(z) \leq 2r'(x) - r(x) - 2.$$

Observe that two rotations are performed and only the ranks of x, y , and z are changed.

Further, as $r'(x) = r(z)$, the amortized time is

$$\begin{aligned} &= 2\beta + \alpha((r'(x) + r'(y) + r'(z)) - (r(x) + r(y) + r(z))) \\ &= 2\beta + \alpha((r'(y) + r'(z)) - (r(x) + r(y))) \\ &\leq 2\beta + \alpha((r'(y) + r'(z)) - 2r(x)), (\text{as } r(y) \geq r(x)). \end{aligned}$$

As $r'(x) \geq r'(y)$, amortized time

$$\begin{aligned} &\leq 2\beta + \alpha((r'(x) + r'(z)) - 2r(x)) \\ &\leq 2\beta + \alpha((r'(x) + (2r'(x) - r(x) - 2) - 2r(x))) \\ &\leq 3\alpha(r'(x) - r(x)) - 2\alpha + 2\beta \\ &\leq 3\alpha(r'(x) - r(x)) (\text{as } \alpha \geq \beta). \end{aligned}$$

Case 2: x is a left child, $\text{parent}(x)$ is a right child

Please refer to [Figure 13.3](#). $s'(y) + s'(z) \leq s'(x)$ or $(s'(y)/s'(x)) + (s'(z)/s'(x)) \leq 1$.

Thus, by Fact 13.1,

$$\begin{aligned} -2 &\geq \log(s'(y)/s'(x)) + \log(s'(z)/s'(x)) = r'(y) + r'(z) - 2r'(x) \text{ or} \\ r'(y) + r'(z) &\leq 2r'(x) - 2. \end{aligned}$$

Now Amortized time $= 2\beta + \alpha((r'(x) + r'(y) + r'(z)) - (r(x) + r(y) + r(z)))$. But, as $r'(x) = r(z)$, Amortized time $= 2\beta + \alpha((r'(y) + r'(z)) - (r(x) + r(y)))$. Using $r(y) \geq r(x)$, Amortized time $\leq 2\beta + \alpha((r'(y) + r'(z)) - 2r(x)) \leq 2\alpha(r'(x) - r(x)) - 2\alpha + 2\beta \leq 3\alpha(r'(x) - r(x)) - 2(\alpha - \beta) \leq 3\alpha(r'(x) - r(x))$.

Case 3: $\text{parent}(x)$ is a root

Please refer to [Figure 13.1](#). There is only one rotation, Amortized time

$$= \beta + \alpha((r'(x) + r'(y)) - (r(x) + r(y))).$$

But as $r'(x) = r(y)$, Amortized time is

$$\begin{aligned} &\beta + \alpha(r'(y) - r(x)) \\ &\leq \beta + \alpha(r'(x) - r(x)) \\ &\leq \beta + 3\alpha(r'(x) - r(x)). \end{aligned}$$

As case 3, occurs only once, and other terms vanish by telescopic cancellation, the lemma follows. ■

Theorem 13.1

Time for m accesses on a tree having at most n nodes is $O((m + n) \log n)$

Proof. Let the weight of each node x be fixed as $1/n$. As there are n nodes in the entire tree, the total weight of all nodes in the tree is 1.

If t is the root of the tree, then $\text{size}(t) = 1$ and as each node x has at least one node (x itself) present in the subtree rooted at x (when x is a leaf, exactly one node will be present), for any node x , $\text{size}(x) \geq (1/n)$. Thus we have following bounds for the ranks— $r(t) \leq 0$ and $r(x) \geq -\log n$.

Or, from Lemma 13.1, amortized time per splay is at most $1 + 3 \log n$. As maximum possible value of the potential is $n \log n$, maximum possible potential change is also $O(n \log n)$, the theorem follows. ■

We will generalize the result of Theorem 13.1, where we will be choosing some other weight functions, to discuss other optimality properties of Splay trees.

13.3.1 Access and Update Operations

We are interested in performing the following operations:

1. Access(x): x is a key value which is to be searched.
2. Insert(x): a node with key value x is to be inserted, if a node with this key value is not already present.
3. Delete(x): node containing key value x is to be deleted.

4. **Join(t_1, t_2):** t_1 and t_2 are two trees. We assume that all items in tree t_1 have smaller key values than the key value of any item in the tree t_2 . The two trees are to be combined or joined into a single tree, as a result, the original trees t_1 and t_2 get “destroyed.”
5. **Split(x, t):** the tree t is split into two trees (say) t_1 and t_2 (the original tree is “lost”). The tree t_1 should contain all nodes having key values less than (or equal to) x and tree t_2 should contain all nodes having key values strictly larger than x .

We next discuss implementation of these operations, using a single primitive operation—splay. We will show that each of these operations for splay trees can be implemented using $O(1)$ time and with one or two “splay” operations.

Access(x, t): Search the tree t for key value x , using the routines for searching in a “binary search tree” and splay at the last node—the node containing value x , in case the search is successful, or the parent of “failure” node in case the search is unsuccessful.

Join(t_1, t_2): Here we assume that all items in splay tree t_1 have key values which are smaller than key values of items in splay tree t_2 , and we are required to combine these two splay trees into a single splay tree.

Access largest item in t_1 , formally, by searching for “ $+\infty$,” that is, a call to Access($+\infty, t_1$). As a result, the node containing the largest item (say r) will become the root of the tree t_1 . Clearly, now the root r of the splay tree t_1 will not have any right child. Make the root of the splay tree t_2 the right child of r , the root of t_1 , as a result, t_2 will become the right subtree of the root r and r will be the root of the resulting tree.

Split(x, t): We are required to split the tree t into two trees: t_1 containing all items with key values less than (or equal to) x and t_2 containing items with key values greater than x .

If we carry out Access(x, t), and if a node with key value x is present, then the node containing the value x will become the root. We then remove the link from node containing the value x to its right child (say node containing value y); the resulting tree with root, containing the value x , will be t_1 , and the tree with root, containing the value y , will be the required tree t_2 .

And if the item with key value x is not present, then the search will end at a node (say) containing key value z . Again, as a result of splay, the node with value z will become the root. If $z > x$, then t_1 will be the left subtree of the root and the tree t_2 will be obtained by removing the edge between the root and its left child.

Otherwise, $z < x$, and t_2 will be the right subtree of the root and t_1 will be the resulting tree obtained by removing the edge between the root and its right child.

Insert(x, t): We are required to insert a new node with key value x in a splay tree t . We can implement insert by searching for x , the key value of the item to be inserted in tree t using the usual routine for searching in a binary search tree. If the item containing the value x is already present, then we splay at the node containing x and return. Otherwise, assume that we reach a leaf (say) containing key y , $y \neq x$. Then if $x < y$, then add the new node containing value x as a left child of node containing value y , and if $x > y$, then the new node containing the value x is made the right child of the node containing the value y , in either case we splay at the new node (containing the value x) and return.

Delete(x, t): We are required to delete the node containing the key value x from the splay tree t . We first access the node containing the key value x in the tree t —Access(x, t). If there is a node in the tree containing the key value x , then that node becomes the root, otherwise, after the access the root will be containing a value different from x and we return(-1)—value not found. If the root contains value x , then let t_1 be the left subtree and t_2 be the right subtree of the root. Clearly, all items in t_1 will have key values less than x and all items in t_2 will have key values greater than x . We delete the links from roots of t_1 and t_2 to their parents (the root of t , the node containing the value x). Then, we join these two subtrees—Join(t_1, t_2) and return.

Observe that in both “Access” and “Insert,” after searching, a splay is carried out. Clearly, the time for splay will dominate the time for searching. Moreover, except for splay, everything else in “Insert” can be easily done in $O(1)$ time. Hence the time taken for “Access” and “Insert” will be of the same order as the time for a splay. Again, in “Join,” “Split,” and “Delete,” the time for “Access” will dominate, and everything else in these operations can again be done in $O(1)$ time, hence “Join,” “Split,” and “Delete” can also be implemented in same order of time as for an “Access” operation, which we just saw is, in turn, of same order as the time for a splay. Thus each of above operations will take same order of time as for a splay. Hence, from Theorem 13.1, we have

Theorem 13.2

Time for m update or access operations on a tree having at most n nodes is $O((m + n) \log n)$.

Observe that, at least in amortized sense, the time taken for first m operations on a tree which never has more than n nodes is the same as the time taken for balanced binary search trees (see [Chapter 11](#)) such as AVL-trees, 2-3-trees, and so on.

13.4 Optimality of Splay Trees

If $w(i)$ the weight of node i is independent of the number of descendants of node i , then the maximum value of $\text{size}(i)$ will be $W = \sum w(i)$ and minimum value of $\text{size}(i)$ will be $w(i)$.

As size of the root t will be W , and hence rank $\log W$, so by Lemma 13.1, the amortized time to splay at a node “ x ” will be $O(\log(\text{Size}(t)/\text{Size}(x))) = O(\log(W/\text{Size}(x))) = O(\log W/w(x))$.

Also observe that the maximum possible change in the rank (for just node i) will be $\log W - \log w(i) = \log(W/w(i))$ or the total maximum change in all ranks (the potential of the tree, with $\alpha = 1$) will be bounded by $\sum \log(W/w(i))$.

Note that, as $\sum w(i)/W = 1$, $\sum |\log(W/w(i))| \leq n \log n$ (the maximum occurs when all $(w(i)/W)$ are equal to $1/n$), hence maximum change in potential is always bounded by $O(n \log n)$.

As a special case, in Theorem 13.1, we had fixed $w(i) = 1/n$, and as a result, the amortized time per operation is bounded by $O(\log n)$ or time for m operations become $O((m+n) \log n)$. We next fix $w(i)$'s in some other cases.

13.4.1 Static Optimality

On any sequence of accesses, a splay tree is as efficient as the optimum binary search tree, up to a constant multiplicative factor. This can be very easily shown.

Let $q(i)$ be the number of times the i th node is accessed, we assume that each item is accessed at least once or $q(i) \geq 1$. Let $m = \sum q(i)$ be the total number of times we access any item in the splay tree. Assign a weight of $q(i)/m$ to item i . We call $q(i)/m$ the *access frequency* of the i th item. Observe that the total (or maximum) weight is 1 and hence the rank of the root $r(t) = 0$.

Thus,

$$r(t) - r(x) = 0 - r(x) = -\log \left(\sum_{i \in T_x} \frac{q(i)}{m} \right) \leq -\log \left(\frac{q(x)}{m} \right).$$

Hence, from Lemma 13.1, with $\alpha = \beta = 1$, the amortized time per splay (say at node “ x ”) is at most

$$\begin{aligned} & 3\alpha(r(t) - r(x)) + \beta \\ &= 1 + 3(-\log(q(x)/m)) \\ &= 1 + 3 \log(m/q(x)). \end{aligned}$$

As i th item is accessed $q(i)$ times, amortized total time for all accesses of the i th item is $O(q(i) + q(i) \log(m/q(i)))$, hence total amortized time will be $O(m + \sum q(i) \log(m/q(i)))$. Moreover, as the maximum value of potential of the tree is $\sum \max\{r(x)\} \leq \sum \log(m/q(i)) = O(\sum \log(m/q(i)))$, the total time will be $O(m + \sum q(i) \log(m/q(i)))$.

Theorem 13.3

Time for m update or access operations on an n -node tree is $O(m + \sum q(i) \log(m/q(i)))$, where $q(i)$ is the total number of times item i is accessed, here $m = \sum q(i)$.

Remark 13.1

The total time for this analysis is the same as that for the (static) optimal binary search tree.

13.4.2 Static Finger Theorem

We first need a result from mathematics. Observe that, in the interval $k-1 \leq x \leq k$, $1/x \geq (1/k)$ or $(1/x^2) \geq (1/k^2)$. Hence, in this interval, we have $1/k^2 \leq \int_{k-1}^k (dx/x^2)$ summing from $k=2$ to n , $\sum_2^n (1/k^2) \leq \int_1^n (dx/x^2) = 1 - 1/n$ or $\sum_{k=1}^n (1/k^2) < 2$.

If f is an integer between 0 and n , then we assign a weight of $1/(|i_j - f| + 1)^2$ to item i_j . Then $W \leq 2 \sum_{k=1}^{\infty} (1/k^2) < 4 = O(1)$.

Consider a particular access pattern (i.e., a snapshot or history or a run). Let the sequence of accessed items be i_1, \dots, i_m , some i_j 's may occur more than once.

Then, by the discussion at the beginning of this section, amortized time for the j th access is $O(\log(|i_j - f| + 1))$. Or the total amortized time for all access will be $O(m + \sum_{j=1}^m \log(|i_j - f| + 1))$. As weight of any item is at least $1/n^2$, the maximum value of potential is $n \log n$. Thus total time is at most $O(n \log n + m + \sum_{j=1}^m \log(|i_j - f| + 1))$.

Remark 13.2

f can be chosen as any fixed item (finger). Thus this outperforms finger search trees, if any fixed point is used as a finger, but here the finger need not be specified.

13.4.3 Working Set Theorem

Splay trees also have the working set property, that is, if only t different items are being repeatedly accessed, then the time for access is actually $O(\log t)$ instead of $O(\log n)$. In fact, if t_j different items were accessed since the last access of i_j th item, then the amortized time for access of i_j th item is only $O(\log(t_j + 1))$.

This time, we number the accesses from 1 to m in the order in which they occur. Assign weights of $1, 1/4, 1/9, \dots, 1/n^2$ to items in the order of the first access. Item accessed earliest gets the largest weight and those never accessed get the smallest weight. Total weight $W = \sum(1/k^2) < 2 = O(1)$.

It is useful to think of item having weight $1/k^2$ as being in the k th position in a (some abstract) queue. After an item is accessed, we will be putting it in front of the queue, that is, making its weight 1 and “pushing back” items which were originally ahead of it, that is, the weights of items having old weight $1/s^2$ (i.e., items in s th place in the queue) will have a new weight of $1/(s+1)^2$ (i.e., they are now in place $s+1$ instead of place s). The position in the queue will actually be the position in the “move to front” heuristic.

Less informally, we will be changing the weights of items after each access. If the weight of item i_j during access j is $1/k^2$, then after access j , assign a weight 1 to item i_j . And an item having weight $1/s^2, s < k$ gets weight changed to $1/(s+1)^2$.

Effectively, item i_j has been placed at the head of queue (weight becomes $1/1^2$) and weights have been permuted. The value of W , the sum of all weights remains unchanged.

If t_j items were accessed after last access of item i_j , then the weight of item i_j would have been $1/t_j^2$, or the amortized time for j th access is $O(\log(t_j + 1))$.

After the access, as a result of splay, the i_j th item becomes the root, thus the new size of i_j th item is the sum of all weights W —this remains unchanged even after changing weights. As weights of all other items, either remain the same or decrease (from $1/s^2$ to $1/(s+1)^2$), size of all other items also decreases or remains unchanged due to permutation of weights. In other words, as a result of weight reassignment, size of nonroot nodes can decrease and size of the root remains unchanged. Thus weight reassignment can only decrease the potential, or amortized time for weight reassignment is either zero or negative.

Hence, by discussions at the beginning of this section, total time for m accesses on a tree of size at most n is $O(n \log n + \sum \log(t_j + 1))$ where t_j is the number of different items which were accessed since the last access of i_j th item (or from start, if this is the first access).

13.4.4 Other Properties and Conjectures

Splay trees are conjectured [1] to obey “Dynamic Optimality Conjecture” which roughly states that cost for any access pattern for splay trees is of the same order as that of the best possible algorithm. Thus, in amortized sense, the splay trees are the best possible dynamic binary search trees up to a constant multiplicative factor. This conjecture is still open.

However, dynamic finger conjecture for splay trees which says that access which is close to previous access is fast has been proved by Cole [9]. Dynamic finger theorem states that the amortized cost of an access at a distance d from the preceding access is $O(\log(d+1))$; there is, however, $O(n)$ initialization cost. The accesses include searches, insertions, and deletions (but the algorithm for deletions is different) [9]. Thus splay trees can be used in place of finger search trees to sort a partially sorted file by repeated insertions (see Chapter 11).

Splay trees also obey several other optimality properties [10].

13.5 Linking and Cutting Trees

Tarjan [2] and Sleator and Tarjan [1] have shown that splay trees can be used to implement linking and cutting trees.

We are given a collection of rooted trees. Each node will store a value, which can be any real number. These trees can “grow” by combining with another tree *link* and can shrink by losing an edge *cut*. Less informally, the trees are “dynamic” and grow or shrink by following operations (we assume that we are dealing with a forest of rooted trees).

link: If x is root of a tree, and y is any node, not in the tree rooted at x , then make y the parent of x .

cut: Cut or remove the edge between a nonroot node x and its parent.

Let us assume that we want to perform operations like

- Add (or subtract) a value to all ancestors of a node.
- Find the minimum value stored at ancestors of a query node x .

More formally, following operations are to be supported:

find_cost(v): Return the value stored in the node v .

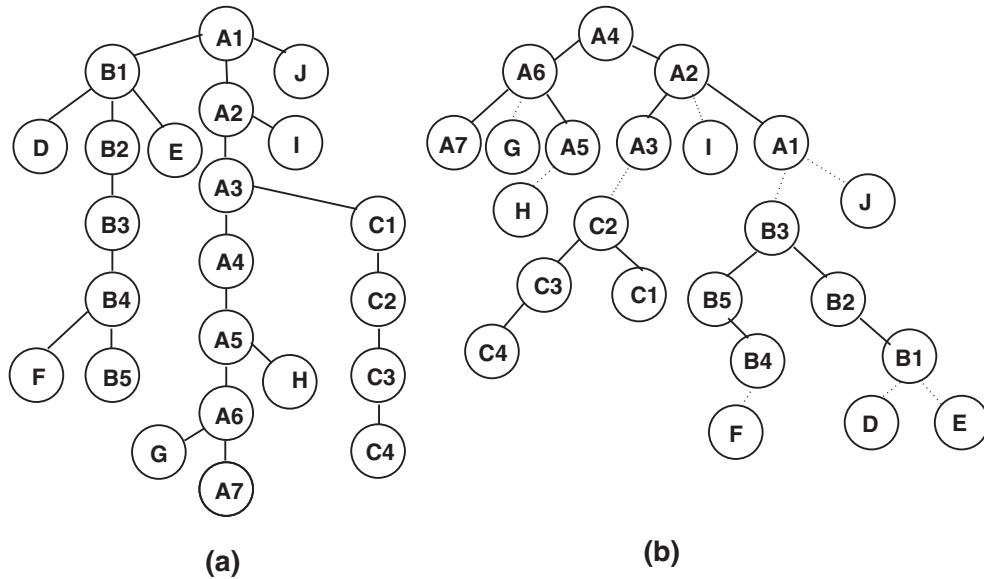

FIGURE 13.4 (a) Original tree and (b) virtual trees: solid and dashed children.

find_root(v): Return the root of the tree containing the node v .

find_min(v): Return the node having the minimum value, on the path from v till $\text{find_root}(v)$, the root of the tree containing v .

In case of ties, choose the node closest to the root.

add_cost(v, δ): Add a real number δ to the value stored in every node on the path from v to the root (i.e., till $\text{find_root}(v)$).

find_size(v): Find the number of nodes in the tree containing the node v .

link(v, w): Here v is a root of a tree. Make the tree rooted at v a child of node w . This operation does nothing if both vertices v and w are in the same tree or v is not a root.

cut(v): Delete the edge from node v to its parent, thus making v a root. This operation does nothing if v is a root.

13.5.1 Data Structure

For the given forest, we make some of the given edges “dashed” and the rest of them are kept solid. Each nonleaf node will have only one “solid” edge to one of its children. All other children will be connected by a dashed edge. To be more concrete, in any given tree, the rightmost link (to its child) is kept solid, and all other links to its other children are made “dashed.”

As a result, the tree will be decomposed into a collection of solid paths. The roots of solid paths will be connected to some other solid path by a dashed edge. A new data structure called a “virtual tree” is constructed. Each linking and cutting tree T is represented by a virtual tree V , containing the same set of nodes. But each solid path of the original tree is modified or converted into a binary tree in the virtual tree; binary trees are as balanced as possible. Thus a virtual tree has a (solid) left child, a (solid) right child, and zero or more (dashed) middle children.

In other words, a virtual tree consists of a hierarchy of solid binary trees connected by dashed edges. Each node has a pointer to its parent, and to its left and right children (see Figure 13.4).

13.5.2 Solid Trees

Recall that each path is converted into a binary tree. Parent (say y) of a node (say x) in the path is the inorder (symmetric order) successor of that node (x) in the solid tree. However, if x is the last node (in symmetric order) in the solid subtree then its parent path will be the parent of the root of the solid subtree containing it (see Figure 13.4). Formally, $\text{Parent}_{\text{path}}(v) = \text{Node}(\text{Inorder}(v) + 1)$.

Note that for any node v , all nodes in the left subtree will have smaller inorder numbers and those in the right subtree will have larger inorder numbers. This ensures that all nodes in the left subtree are descendants and all nodes in the right subtree are ancestors. Thus the parent (in the binary tree) of a left child will be an ancestor (in the original tree). But, parent (in the binary tree) of a right child is a descendant (in the original tree). This order helps us to carry out add_cost effectively.

We need some definitions or notation to proceed.

Let $\text{mincost}(x)$ be the cost of the node having the minimum key value among all descendants of x in the same solid subtree. Then in each node, we store two fields $\delta\text{cost}(x)$ and $\delta\text{min}(x)$. We define,

$\delta\text{min}(x) = \text{cost}(x) - \text{mincost}(x)$. And,

$$\delta\text{cost}(x) = \begin{cases} \text{cost}(x) - \text{cost}(\text{parent}(x)) & \text{if } x \text{ has a solid parent} \\ \text{cost}(x) & \text{otherwise (}x\text{ is a solid tree root).} \end{cases}$$

Fact 13.2

$$\delta\text{min}(x) - \delta\text{cost}(x) = \text{cost}(\text{parent}(x)) - \text{mincost}(x).$$

Thus if u and v are solid children of node z , then

$$\text{mincost}(z) = \min\{\text{cost}(z), \text{mincost}(v), \text{mincost}(w)\} \text{ or}$$

$$\delta\text{min}(z) = \text{cost}(z) - \text{mincost}(z) = \max\{0, \text{cost}(z) - \text{mincost}(v), \text{cost}(z) - \text{mincost}(w)\}.$$

Using Fact 13.2, and the fact $z = \text{parent}(u) = \text{parent}(v)$, we have

Fact 13.3

If u and v are children of z , then

$$\delta\text{min}(z) = \max\{0, \delta\text{min}(u) - \delta\text{cost}(u), \delta\text{min}(v) - \delta\text{cost}(v)\}.$$

For linking and cutting trees, we need two primitive operations—rotation and splicing.

13.5.3 Rotation

Let us discuss rotation first (see [Figure 13.5](#)).

Let w be the parent of v in the solid tree, then rotation of the solid edge $(v, p(v)) \equiv (v, w)$ will make $w = p(v)$ a child of v . Rotation does not have any effect on the middle children. Let a be the left solid child of w and v be the right solid child of w .

Let “nonprimes” denote the values before the rotation and “primes” the values after the rotation of the solid edge (v, w) . We next show that the new values $\delta\text{cost}'$, $\delta\text{min}'$, and $\delta\text{size}'$ can be calculated in terms of old known values.

We assume that b is the left solid child of v and c is the right solid child of v .

First we calculate the new $\delta\text{cost}'$ values in terms of old δcost values. From [Figure 13.5](#),

$$\begin{aligned} \delta\text{cost}'(v) &= \text{cost}(v) - \text{cost}(\text{parent}'(v)) \\ &= \text{cost}(v) - \text{cost}(\text{parent}(w)) \\ &= \text{cost}(v) - \text{cost}(w) + \text{cost}(w) - \text{cost}(\text{parent}(w)) \\ &= \delta\text{cost}(v) + \delta\text{cost}(w). \\ \delta\text{cost}'(w) &= \text{cost}(w) - \text{cost}(v) \\ &= -\delta\text{cost}'(v). \\ \delta\text{cost}'(b) &= \text{cost}(b) - \text{cost}(w) \\ &= \text{cost}(b) - \text{cost}(v) + \text{cost}(v) - \text{cost}(w) \\ &= \delta\text{cost}(b) + \delta\text{cost}(v). \end{aligned}$$

Finally,

$$\delta\text{cost}'(a) = \delta\text{cost}(a) \text{ and } \delta\text{cost}'(c) = \delta\text{cost}(c).$$

We next compute $\delta\text{min}'$ values in terms of δmin and δcost .

$$\begin{aligned} \delta\text{min}'(v) &= \text{cost}(v) - \text{mincost}'(v) \\ &= \text{cost}(v) - \text{mincost}(w) \end{aligned}$$

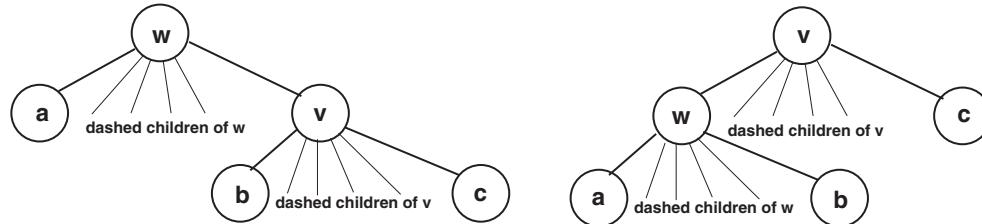

FIGURE 13.5 Rotation in solid trees—rotation of edge (v, w) .

$$\begin{aligned}
&= \text{cost}(v) - \text{cost}(w) + \text{cost}(w) - \text{mincost}(w) \\
&= \delta\text{cost}(v) + \delta\text{min}(w).
\end{aligned}$$

$\delta\text{min}(\)$ of all nodes other than w will remain same, and for w , from Fact 13.3, we have

$$\begin{aligned}
&\delta\text{min}'(w) = \max\{0, \delta\text{min}'(a) - \\
&\delta\text{cost}'(a), \delta\text{min}'(b) - \delta\text{cost}'(b)\} \\
&= \max\{0, \delta\text{min}(a) - \delta\text{cost}(a), \delta\text{min}(b) - \delta\text{cost}(b) - \delta\text{cost}(v)\}.
\end{aligned}$$

13.5.4 Splicing

Let us next look at the other operation, splicing. Let w be the root of a solid tree. And let v be a child of w connected by a dashed edge. If u is the leftmost child of w , then splicing at a dashed child v , of a solid root w , makes v the left child of w . Moreover, the previous left child u now becomes a dashed child of w . Thus informally speaking splicing makes a node the leftmost child of its parent (if the parent is root) and makes the previous leftmost child of parent as dashed.

We next analyze the changes in “cost” and “size” of various nodes after splicing at a dashed child v of solid root w (whose leftmost child is u). As before, “nonprimes” denote the values before the splice and “primes” the values after the splice.

As v was a dashed child of its parent, it was a root earlier (in some solid tree). And as w is also a root,

$$\begin{aligned}
&\delta\text{cost}'(v) = \text{cost}(v) - \text{cost}(w) \\
&= \delta\text{cost}(v) - \delta\text{cost}(w).
\end{aligned}$$

And as u is now the root of a solid tree,

$$\begin{aligned}
&\delta\text{cost}'(u) = \text{cost}(u) \\
&= \delta\text{cost}(u) + \text{cost}(w) \\
&= \delta\text{cost}(u) + \delta\text{cost}(w).
\end{aligned}$$

Finally, $\delta\text{min}'(w) = \max\{0, \delta\text{min}(v) - \delta\text{cost}'(v), \delta\text{min}(\text{right}(w)) - \delta\text{cost}(\text{right}(w))\}$.

All other values are clearly unaffected.

13.5.5 Splay in Virtual Tree

In virtual tree, some edges are solid and some are dashed. Usual splaying is carried out only in the solid trees. To splay at a node x in the virtual tree, following method is used. The algorithm looks at the tree three times, once in each pass, and modifies it. In first pass, by splaying only in the solid trees, starting from the node x , the path from x to the root of the overall tree becomes dashed. This path is made solid by splicing. A final splay at node x will now make x the root of the tree. Less informally, the algorithm is as follows:

Algorithm for Splay(x)

Pass 1: Walk up the virtual tree, but splaying is done only within solid subtree. At the end of this pass, the path from x to root becomes dashed.

Pass 2: Walk up from node x , splicing at each proper ancestor of x . After this step, the path from x to the root becomes solid. Moreover, the node x and all its children in the original tree (the one before pass 1) now become left children.

Pass 3: Walk up from node x to the root, splaying in the normal fashion.

13.5.6 Analysis of Splay in Virtual Tree

Weight of each node in the tree is taken to be the same (say) 1. Size of a node is the total number of descendants—both solid and dashed. And the rank of a node as before is $\text{rank}(x) = \log(\text{size}(x))$. We choose $\alpha = 2$, and hence the potential becomes potential $= 2 \sum_x \text{rank}(x)$. We still have to fix β . Let us analyze the complexity of each pass.

Pass 1: We fix $\beta = 1$. Thus, from Lemma 13.1, the amortized cost of single splaying is at most $6(r(t) - r(x)) + 1$. Hence, the total cost of all splays in this pass will be

$$\begin{aligned}
&\leq 6(r(t_1) - r(x)) + 1 + 6(r(t_2) - r(p(t_1))) + 1 + \dots + 6(r(t_k) - r(p(t_{k-1}))) + 1. \\
&\leq (6(r(t_1) - r(x)) + \dots + 6(r(t_k) - r(p(t_{k-1})))) + k.
\end{aligned}$$

Here, k is number of solid trees in path from x to root. Or the total cost

$$\leq k + (6(r(\text{root}) - r(x)) - 6(r(p(t_{k-1})) - r(t_{k-1}) + \dots + r(p(t_1)) - r(t_1))).$$

Recall that the size includes those of virtual descendants, hence each term in the bracket is nonnegative. Or the total cost $\leq k + 6(r(\text{root}) - r(x))$.

Note that the depth of node x at end of the first pass will be k .

Pass 2: As no rotations are performed, actual time is zero. Moreover as there are no rotations, there is no change in potential. Hence, amortized time is also zero. Alternatively, time taken to traverse k -virtual edges can be accounted by incorporating that in β in pass 3.

Remark 13.3

This means, that in effect, this pass can be done together with Pass 1.

Pass 3: In Pass 1, k extra rotations are performed, (there is a $+k$ factor), thus, we can take this into account, by charging, 2 units for each of the k rotation in Pass 3, hence we set $\beta = 2$. Clearly, the number of rotations is exactly “ k .” Cost will be $6 \log n + 2$. Thus in effect we can now neglect the $+k$ term of pass 1.

Thus total cost for all three passes is $12 \log n + 2$.

13.5.7 Implementation of Primitives for Linking and Cutting Trees

We next show that various primitives for linking and cutting trees described in the beginning of this section can be implemented in terms of one or two calls to a single basic operation—“splay.” We will discuss implementation of each primitive, one by one.

find_cost(v): We are required to find the value stored in the node v . If we splay at node v , then node v becomes the root and $\delta\text{cost}(v)$ will give the required value. Thus the implementation is

splay(v) and return the value at node v .

find_root(v): We have to find the root of the tree containing the node v . Again, if we splay at v , then v will become the tree root. The ancestors of v will be in the right subtree, hence we follow right pointers till root is reached. The implementation is

splay(v), follow right pointers till last node of solid tree, say w is reached, splay(w) and return(w).

find_min(v): We have to find the node having the minimum value, on the path from v till the root of the tree containing v ; in case of ties, we have to choose the node closest to the root. We again splay at v to make v the root, but, this time, we also keep track of the node having the minimum value. As these values are stored in incremental manner, we have to compute the value by an “addition” at each step.

splay(v), use $\delta\text{cost}()$ and $\delta\text{min}()$ fields to walk down to the last minimum cost node after v , in the solid tree, say w , splay(w) and return(w).

add_cost($v, \delta x$): We have to add a real number δx to the values stored in each and every ancestors of node v . If we splay at node v , then v will become the root and all ancestors of v will be in the right subtree. Thus, if we add δx to $\delta\text{cost}(v)$, then in effect, we are adding this value not only to all ancestors (in right subtree) but also to the nodes in the left subtree. Hence, we subtract δx from $\delta\text{cost}()$ value of left child of v . Implementation is

splay(v), add δx to $\delta\text{cost}(v)$, subtract δx from $\delta\text{cost}(\text{LCHILD}(v))$ and return.

For implementing **find_size()**, we find the number of descendants of each node in the original tree. This can be done by looking at nodes in postorder (from leaves upwards). These values are stored (say) in a field “size” which is maintained just like the field “cost.”

find_size(v): We have to find the number of nodes in the tree containing the node v . If we splay at the node v , then v will become the root and by definition of δsize , $\delta\text{size}(v)$ will give the required number.

splay(v) and return($\delta\text{size}(v)$).

link(v, w): If v is a root of a tree, then we have to make the tree rooted at v a child of node w .

Splay(w), and make v a middle (dashed) child of w . Update the number of descendants of w and its ancestors by **add_size($w, \text{size}(v)$)**.

cut(v): If v is not a root, then we have to delete the edge from node v to its parent, thus making v a root. The implementation of this is also obvious:

splay(v), add $\delta\text{cost}(v)$ to $\delta\text{cost}(\text{RCHILD}(v))$, and break link between $\text{RCHILD}(v)$ and v . Update the number of descendants of v and its ancestors by **add_size($w, -\text{size}(v)$)**.

13.6 Case Study: Application to Network Flows

We next discuss application of linking and cutting trees to the problem of finding maximum flow in a network. Input is a directed graph $G = (V, E)$. There are two distinguished vertices s (source) and t (sink). We need a few definitions and some notations [11,12]. Most of the results in this case study are from [11,12].

PreFlow: $g(*, *)$ is a real-valued function having the following properties:

Skew-Symmetry: $g(u, v) = -g(v, u)$

Capacity Constraint: $g(u, v) \leq c(u, v)$

Positive-Flow Excess: $e(v) \equiv \sum_{w=1}^n g(v, w) \geq 0$ for $v \neq s$.

Flow-Excess: Observe that flow-excess at node v is $e(v) = \sum_{w=1}^n g(w, v)$, if $v \neq s$, and flow excess at source s is $e(s) = \infty$.

Flow: $f(*, *)$ is a real-valued function having the following additional property:

Flow Conservation: $\sum_{w=1}^n f(v, w) = 0$ for $v \notin \{s, t\}$

PreFlow: f is a preflow.

Value of flow: $|f| = \sum_{w=1}^n f(s, w)$, the net flow out of source.

Remark 13.4

If $(u, v) \notin E$, then $c(u, v) = c(v, u) = 0$. Thus, $f(u, v) \leq c(u, v) = 0$ and $f(v, u) \leq 0$. By skew-symmetry, $f(u, v) = 0$.

Cut: Cut (S, \bar{S}) is a partition of vertex set, such that $s \in S$ and $t \in \bar{S}$

Capacity of Cut: $c(S, \bar{S}) = \sum_{v \in S, w \in \bar{S}} c(v, w)$.

Preflow across a Cut: $g(S, \bar{S}) = \sum_{v \in S, w \notin S} g(v, w)$.

Residual Capacity: If g is a flow or preflow, then the residual capacity of an edge (v, w) is $r_g(v, w) = c(v, w) - g(v, w)$.

Residual Graph: G_g contains same set of vertices as the original graph G , but only those edges for which residual capacity is positive; these are either the edges of the original graph or their reverse edges.

Valid Labeling: A valid labeling $d()$ satisfies the following properties:

1. $d(t) = 0$
2. $d(v) > 0$ if $v \neq t$
3. if (v, w) is an edge in residual graph, then $d(w) \geq d(v) - 1$.

A trivial labeling is $d(t) = 0$ and $d(v) = 1$ if $v \neq t$.

Remark 13.5

As for each edge (v, w) , $d(v) \leq d(w) + 1$, $\text{dist}(u, t) \geq d(u)$. Thus, label of every vertex from which t is reachable is at most $n - 1$.

Active Vertex: A vertex $v \neq s$ is said to be active if $e(v) > 0$.

The initial preflow is taken to be $g(s, v) = c(s, v)$ and $g(u, v) = 0$ if $u \neq s$.

Flow across a Cut: Please refer to Figure 13.6. Observe that flow conservation is true for all vertices except s and t . In particular sum of flow (total flow) into vertices in set $S - \{s\}$ (set shown between s and cut) is equal to $|f|$ which must be the flow going out of these vertices (into the cut). And this is the flow into vertices (from cut) in set $\bar{S} - \{t\}$ (set after cut before t) which must be equal to the flow out of these vertices into t . Thus the flow into t is $|f|$ which is also the flow through the cut.

Fact 13.4

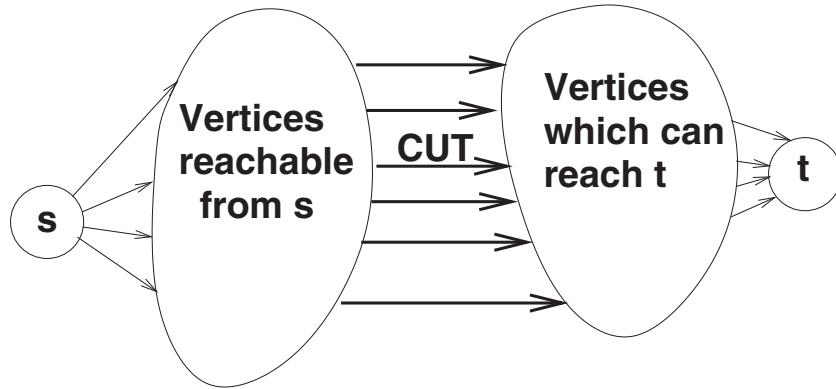

$$\text{As } |f| = f(S, \bar{S}) = \sum_{v \in S, w \notin S} f(v, w) \leq \sum_{v \in S, w \notin S} c(v, w) = c(S, \bar{S}).$$

Thus maximum value of flow is less than minimum capacity of any cut.

Theorem 13.4

[Max-Flow Min-Cut Theorem] $\max |f| = \text{minimum cut}$

Proof. Consider a flow f for which $|f|$ is maximum. Delete all edges for which $(f(u, v) = c(u, v))$ to get the residual graph. Let S be the set of vertices reachable from s in the residual graph. Now, $t \notin S$, otherwise there is a path along which flow can be

FIGURE 13.6 $s - t$ Cut.

increased, contradicting the assumption that flow is maximum. Let \bar{S} be set of vertices not reachable from s . \bar{S} is not empty as $t \in S$. Thus (S, \bar{S}) is an $s - t$ cut and as all edges (v, w) of cut have been deleted, $c(v, w) = f(v, w)$ for edges of cut.

$$|f| = \sum_{v \in S, w \notin S} f(v, w) = \sum_{v \in S, w \notin S} c(v, w) = c(S, \bar{S}).$$

■

Push(v, w)

1. /* v is an active vertex and (v, w) an edge in residual graph with $d(w) = d(v) - 1$ */

Try to move excess from v to w , subject to capacity constraints, that is, send $\delta = \min\{e(v), r_g(v, w)\}$ units of flow from v to w .

2. /* $g(v, w) = g(v, w) + \delta$; $e(v) = e(v) - \delta$ and $e(w) = e(w) + \delta$ */

If $\delta = r_g(v, w)$, then the push is said to be *saturating*.

Relabel(v)

For $v \neq s$, the new distance label is

$$d(v) = \min\{d(w) + 1 | (v, w) \text{ is a residual edge}\}.$$

Preflow-Push Algorithms

Following are some of the properties of preflow-push algorithms:

1. If relabel v results in a new label, $d(v) = d(w^*) + 1$, then as initial labeling was valid, $d_{\text{old}}(v) \leq d_{\text{old}}(w^*) + 1$. Thus labels can only increase. Moreover, the new labeling is clearly valid.
2. If push is saturating, edge (v, w) may get deleted from the graph and edge (w, v) will get added to the residual graph, as $d(w) = d(v) - 1$, $d(v) = d(w) + 1 \geq d(w) - 1$, thus even after addition to the residual graph, conditions for labeling to be valid are satisfied.
3. As a result of initialization, each node adjacent to s gets a positive excess. Moreover all arcs out of s are saturated. In other words in residual graph there is no path from s to t . As distances cannot decrease, there can never be a path from s to t . Thus there will be no need to push flow again out of s .
4. By definition of preflow, flow coming into a node is more than flow going out. This flow must come from source. Thus all vertices with positive excess are reachable from s (in the original network). Thus as s is initially the only node, at any stage of the algorithm, there is a path P_v to a vertex v (in the original network) along which preflow has come from s to v . Thus, in the residual graph, there is reverse path from v to s .
5. Consider a vertex v from which there is a path till a vertex X . As we trace back this path from X , then distance label $d()$ increases by at most one. Thus $d(v)$ can be at most $\text{dist}(v, X)$ larger than $d(X)$. That is $d(v) \leq d(X) + \text{dist}(v, X)$.
6. As for vertices from which t is not reachable, s is reachable, $d(v) \leq d(s) + \text{dist}(s, v) = n + (n - 1) = 2n - 1$ (as $d(s) = n$). Thus maximum label of any node is $2n - 1$.

Fact 13.5

As label of t remains zero, and label of other vertices only increase, the number of Relabels which result in change of labels is $(n - 1)^2$. In each relabel operation, we may have to look at $\text{degree}(v)$ vertices. As each vertex can be relabeled at most $O(n)$ times, time for relabels is $\sum O(n) \times \text{degree}(v) = O(n) \times \sum \text{degree}(v) = O(n) \times O(m) = O(nm)$.

Fact 13.6

If a saturating push occurs from u to v , then $d(u) = d(v) + 1$ and edge (u, v) gets deleted, but edge (v, u) gets added. Edge (u, v) can be added again only if edge (v, u) gets saturated, that is, $d_{\text{now}}(v) = d_{\text{now}}(u) + 1 \geq d(u) + 1 = d(v) + 2$. Thus the edge gets added only if label increases by 2. Thus, for each edge, number of times saturating push can occur is $O(n)$. So the total number of saturating pushes is $O(nm)$.

Remark 13.6

Increase in label of $d(u)$ can make a reverse flow along all arcs (x, u) possible, and not just (v, u) ; in fact there are at most $\text{degree}(u)$ such arcs. Thus number of saturating pushes are $O(nm)$ and not $O(n^2)$.

Fact 13.7

Consider the point in time when the algorithm terminates, that is, when pushes or relabels can no longer be applied. As excess at s is ∞ , excess at s could not have been exhausted. The fact that push/relabel cannot be applied means that there is no path from s to t . Thus, \bar{S}_g , the set of vertices from which t is reachable, and S_g , set of vertices from which s is reachable, form an $s - t$ cut.

Consider an edge (u, v) with $u \in S_g$ and $v \in \bar{S}_g$. As t is reachable from v , there is no excess at v . Moreover, by definition of cut, the edge is not present in residual graph, or in other words, flow in this edge is equal to capacity. By Theorem 13.4, the flow is the maximum possible.

13.7 Implementation without Linking and Cutting Trees

Each vertex will have a list of edges incident at it. It also has a pointer to *current edge* (candidate for pushing flow out of that node). Each edge (u, v) will have three values associated with it $c(u, v)$, $c(v, u)$, and $g(u, v)$.

Push/Relabel(v)

Here we assume that v is an active vertex and (v, w) is current edge of v .

1. If $(d(w) == d(v) - 1) \& \& (r_g(v, w) > 0)$ then send $\delta = \min\{e(v), r_g(v, w)\}$ units of flow from v to w .
2. Else if v has no next edge, make first edge on edge list the current edge and Relabel(v): $d(v) = \min\{d(w) + 1 | (v, w)$ is a residual edge} /* this causes $d(v)$ to increase by at least one */
3. Else make the next edge out of v , the current edge.

Relabeling v requires a single scan of v 's edge list. As each relabeling of v causes $d(v)$ to go up by one, the number of relabeling steps (for v) are at most $O(n)$, each step takes $O(\text{degree}(v))$ time. Thus total time for all relabelings will be:

$O(\sum n \text{degree}(v)) = O(n \sum \text{degree}) = O(n \times 2m) = O(nm)$. Each nonsaturating push clearly takes $O(1)$ time, thus time for algorithm will be $O(nm) + O(\# \text{nonsaturating pushes})$.

Discharge(v)

Keep on applying Push/Relabel(v) until either

1. Entire excess at v is pushed out or
2. Label(v) increases.

FIFO/Queue

Initialize a queue “Queue” to contain s .

Let v be the vertex in front of Queue. Discharge(v), if a push causes excess of a vertex w to become nonzero, add w to the rear of the Queue.

Let phase 1 consists of discharge operations applied to vertices added to the queue by initialization of preflow.

Phase $(i + 1)$ consists of discharge operations applied to vertices added to the queue during phase i .

Let $\Phi = \max\{d(v) | v \text{ is active}\}$, with maximum as zero, if there are no active vertices. If in a phase, no relabeling is done, then the excess of all vertices which were in the queue has been moved. If v is any vertex which was in the queue, then excess has been moved to a node w , with $d(w) = d(v) - 1$. Thus $\max\{d(w) | w \text{ has now become active}\} \leq \max\{d(v) - 1 | v \text{ was active}\} = \Phi - 1$.

Thus, if in a phase, no relabeling is done, Φ decreases by at least one. Moreover, as number of relabeling steps are bounded by $2n^2$, number of passes in which relabeling takes place is at most $2n^2$.

Only way in which Φ can increase is by relabeling. Since the maximum value of a label of any active vertex is $n - 1$, and as a label never decreases, the total of all increases in Φ is $(n - 1)^2$.

As Φ decreases by at least one in a pass in which there is no relabeling, number of passes in which there is no relabeling is $(n - 1)^2 + 2n^2 \leq 3n^2$.

Fact 13.8

Number of passes in FIFO algorithm is $O(n^2)$.

13.8 FIFO Dynamic Tree Implementation

Time for nonsaturating push is reduced by performing a succession of pushes along a single path in one operation [12]. After a nonsaturating push, the edge continues to be admissible and we know its residual capacity. Initially each vertex is made into a one vertex node. Arc of dynamic trees are a subset of admissible arcs. Value of an arc is its admissible capacity (if $(u, \text{parent}(u))$ is an arc, value of arc will be stored at u). Each active vertex is a tree root.

Vertices will be kept in a queue as in FIFO algorithm, but instead of $\text{discharge}(v)$, $\text{Tree-Push}(v)$ will be used. We will further ensure that tree size does not exceed k (k is a parameter to be chosen later). The Tree-Push procedure is as follows.

Tree-Push(v)

$/* v \text{ is active vertex and } (v, w) \text{ is an admissible arc */}$

1. /* link trees rooted at v and the tree containing w by making w the parent of v , if the tree size doesn't exceed k */.
If v is root and $(\text{find_size}(v) + \text{find_size}(w)) \leq k$, then link v and w . Arc (v, w) gets the value equal to the residual capacity of edge (v, w) .
2. If v is root but $\text{find_size}(v) + \text{find_size}(w) > k$, then push flow from v to w .
3. If v is not a tree root, then send $\delta = \min\{e(v), \text{find_cost}(\text{find_min}(v))\}$ units of flow from v , by $\text{add_cost}(v, -\delta)$ /* decrease residual capacity of all arcs */ and while v is not a root and $\text{find_cost}(\text{find_min}(v)) = 0$ do

```
{z := find_min(v); cut(z); /* delete saturated edge */
f(z, parent(z)) := c(z, parent(z));
/* in saturated edge, flow=capacity */
f(parent(z), z) := -c(z, parent(z));
}
```
4. But, if $\text{arc}(v, w)$ is not admissible, replace (v, w) , as current edge by next edge on v 's list. If v has no next edge, then make the first edge, the current edge and cut-off all children of v , and relabel(v).

Analysis

1. Total time for relabeling is $O(nm)$.
2. Only admissible edges are present in the tree, and hence if an edge (u, v) is cut in step (3) or in step (4) then it must be admissible, that is, $d(u) = d(v) + 1$. Edge (v, u) can become admissible and get cut, iff, $d_{\text{then}}(v) = d_{\text{then}}(u) + 1 \geq d(u) + 1 = d(v) + 2$. Thus the edge gets cut again only if label increases by 2. Thus, for each edge, number of times it can get cut is $O(n)$. So total number of cuts are $O(nm)$.
3. As initially, there are at most n -single node trees, number of links are at most $n + \# \text{no_of_cuts} = n + O(nm) = O(nm)$.

Moreover, there is at most one tree operation for each relabeling, cut or link. Further, for each item in queue, one operation is performed. Thus,

Lemma 13.2

The time taken by the algorithm is $O(\log k \times (nm + \#No_of_times_an_item_is_added_to_the_queue))$.

Root-Nodes: Let T_v denote the tree containing node v . Let r be a tree root whose excess has become positive. It can become positive either due to:

1. Push from a nonroot vertex w in Step 3 of the tree-push algorithm
2. Push from a root w in Step 2 /* $\text{find_size}(w) + \text{find_size}(r) > k$ */

Remark 13.7

Push in Step 3 is accompanied by a cut (unless first push is nonsaturating). As the number of cuts is $O(nm)$, number of times Step 3 (when first push is saturating) can occur is $O(nm)$. Thus, we need to consider only the times when first push was nonsaturating, and the excess has moved to the root as far as push in Step 3 is concerned.

In either case let i be the pass in which this happens (i.e., w was added to the queue in pass $(i - 1)$). Let I be the interval from beginning of pass $(i - 1)$ to the time when $e(r)$ becomes positive.

Case 1: (T_w changes during I) T_w can change either due to link or cut. But number of times a link or a cut can occur is $O(nm)$.

Thus this case occurs at most $O(nm)$ time. Thus we may assume that T_w does not change during interval I .

Vertex w is added to the queue either because of relabeling of w or because of a push in Step 2 from (say) a root v to w .

Case 2: (w is added because of relabeling) Number of relabeling steps are $O(n^2)$. Thus number of times this case occurs is $O(n^2)$.

Thus we may assume that w was added to queue because of push from root v to w in Step 2.

Case 3: (push from w was saturating) As the number of saturating pushes is $O(nm)$, this case occurs $O(nm)$ times. Thus we may assume that push from w was nonsaturating.

Case 4: (edge (v, w) was not the current edge at beginning of pass $(i - 1)$). Edge (v, w) will become the current edge, only because either the previous current edge (v, x) got saturated, or because of $\text{relabel}(v)$, or $\text{relabel}(x)$. Note that if entire excess out of v was moved, then (v, w) will remain the current edge.

As number of saturating pushes are $O(nm)$ and number of relabeling are $O(n^2)$, this case can occur at most $O(nm)$ times.

Thus we may assume that (v, w) was the current edge at beginning of pass $(i - 1)$.

Case 5: (T_v changes during interval I) T_v can change either due to link or cut. But the number of times a link or a cut can occur is $O(nm)$. Thus this case occurs at most $O(nm)$ time. Thus we may assume that T_v has not changed during interval I .

Remaining Case: Vertex w was added to the queue because of a nonsaturating push from v to w in Step 2 and (v, w) is still the current edge of v . Moreover, T_v and T_w do not change during the interval I .

A tree at the beginning of the pass $(i - 1)$ can participate in only one pair (T_w, T_v) as T_w , because this push was responsible for adding w to the queue. Observe that vertex w is uniquely determined by r .

And, a tree at the beginning of the pass $(i - 1)$ can participate in only one pair (T_w, T_v) as T_v , because (v, w) was the current edge out of root v , at the beginning of the pass $(i - 1)$ (and is still the current edge). Thus, choice of T_v will uniquely determine T_w (and conversely).

Thus as a tree T_x can participate once in a pair as T_v , and once as T_w , and the two trees are unchanged, we have $\sum_{(v,w)} |T_v| + |T_w| \leq 2n$ (a vertex is in at most one tree). As push from v to w was in Step 2, $\text{find_size}(v) + \text{find_size}(w) > k$ or $|T_v| + |T_w| > k$. Thus the number of such pairs is at most $2n/k$.

But from Fact 13.8, as there are at most $O(n^2)$ passes, the number of such pairs are $O(n^3/k)$.

Nonroot Nodes: Let us count the number of times a nonroot can have its excess made positive. Its excess can only be made positive as a result of push in Step 2. As the number of saturating pushes is $O(nm)$, clearly $O(nm)$ pushes in Step 2 are saturating.

If the push is nonsaturating, then entire excess at that node is moved out, hence it can happen only once after a vertex is removed from Queue. If v was not a root when it was added to the queue, then it has now become a root only because of a cut. But number of cuts is $O(nm)$. Thus we only need to consider the case when v was a root when it was added to the queue. The root was not earlier in queue, because either its excess was then zero, or because its distance label was low. Thus now either

1. Distance label has gone up—this can happen at most $O(n^2)$ times or
2. Now its excess has become positive. This by previous case can happen at most $O(nm + (n^3/k))$ times.

Summary: If k is chosen such that $nm = n^3/k$, or $k = n^2/m$, time taken by the algorithm is $O(nm \log(n^2/m))$.

13.9 Variants of Splay Trees and Top-Down Splaying

Various variants, modifications, and generalization of Splay trees have been studied [13–16]. Two of the most popular “variants” suggested by Sleator and Tarjan [1] are “semi-splay” and “simple-splay” trees. In simple splay trees, the second rotation in the “zig-zag” case is done away with (i.e., we stop at the middle figure in Figure 13.3). Simple splaying can be shown to have a larger constant factor both theoretically [1] and experimentally [14]. In semi-splay [1], in the zig-zig case (see Figure 13.2) we do only the first rotation (i.e., stop at the middle figure) and continue splaying from node y instead of x . Sleator and Tarjan observe that for some access sequences “semi-splaying” may be better but for some others the usual splay is better.

“Top-down” splay trees [1] are another way of implementing splay trees. Both the trees coincide if the node being searched is at an even depth [14], but if the item being searched is at an odd depth, then the top-down and bottom-up trees may differ [14, Theorem 13.2].

Some experimental evidence suggests [3] that top-down splay trees [1,14] are faster in practice as compared to the normal splay trees, but some evidence suggests otherwise [4].

In splay trees as described, we first search for an item, and then restructure the tree. These are called “bottom-up” splay trees. In “top-down” splay trees, we look at two nodes at a time, while searching for the item, and also keep restructuring the tree until the item we are looking for has been located.

Basically, the current tree is divided into three trees, while we move down two nodes at a time searching for the query item.

Left tree: Left tree consists of items known to be smaller than the item we are searching.

Right tree: Similarly, the right tree consists of items known to be larger than the item we are searching.

Middle tree: This is the subtree of the original tree rooted at the current node.

Basically, the links on the access path are broken and the node(s) which we just saw are joined to the bottom right (respectively left) of the left (respectively right) tree if they contain item greater (respectively smaller) than the item being searched. If both nodes are left children or if both are right children, then we make a rotation before breaking the link. Finally, the item at which the search ends is the only item in the middle tree and it is made the root. And roots of left and right trees are made the left and right children of the root.

Acknowledgments

I wish to thank Anjana Singh for pointing an error in the previous version.

14.1 Introduction

In the last couple of decades, there has been a tremendous growth in using randomness as a powerful source of computation. Incorporating randomness in computation often results in a much simpler and more easily implementable algorithms. A number of problem domains, ranging from sorting to stringology, from graph theory to computational geometry, from parallel processing system to ubiquitous internet, have benefited from randomization in terms of newer and elegant algorithms. In this chapter we shall see how randomness can be used as a powerful tool for designing simple and efficient data structures. Solving a real-life problem often involves manipulating complex data objects by variety of operations. We use abstraction to arrive at a mathematical model that represents the real-life objects and convert the real-life problem into a computational problem working on the mathematical entities specified by the model. Specifically, we define *Abstract Data Type (ADT)* as a mathematical model together with a set of operations defined on the entities of the model. Thus, an algorithm for a computational problem will be expressed in terms of the steps involving the corresponding ADT operations. In order to arrive at a computer based implementation of the algorithm, we need to proceed further taking a closer look at the possibilities of implementing the ADTs. As programming languages support only a very small number of built-in types, any ADT that is not a built-in type must be represented in terms of the elements from built-in type and this is where the data structure plays a critical role. One major goal in the design of data structure is to render the operations of the ADT as efficient as possible. Traditionally, data structures were designed to minimize the worst-case costs of the ADT operations. When the worst-case efficient data structures turn out to be too complex and cumbersome to implement, we naturally explore alternative design goals. In one of such design goals, we seek to minimize the total cost of a sequence of operations as opposed to the cost of individual operations. Such data structures are said to be designed for minimizing the amortized costs of operations. Randomization provides yet another avenue for exploration. Here, the goal will be to limit the expected costs of operations and ensure that costs do not exceed certain threshold limits with overwhelming probability.

In this chapter we discuss about the *Dictionary* ADT which deals with sets whose elements are drawn from a fixed universe U and supports operations such as *insert*, *delete* and *search*. Formally, we assume a linearly ordered universal set U and for the sake of concreteness we assume U to be the set of all integers. At any time of computation, the *Dictionary* deals only with a finite subset of U . We shall further make a simplifying assumption that we deal only with sets with distinct values. That is, we

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

never handle a multiset in our structure, though, with minor modifications, our structures can be adjusted to handle multisets containing multiple copies of some elements. With these remarks, we are ready for the specification of the *Dictionary* ADT.

Definition 14.1: (Dictionary ADT)

Let U be a linearly ordered universal set and S denote a finite subset of U . The Dictionary ADT, defined on the class of finite subsets of U , supports the following operations.

Insert (x, S) : For an $x \in U, S \subset U$, generate the set $S \cup \{x\}$.

Delete (x, S) : For an $x \in U, S \subset U$, generate the set $S - \{x\}$.

Search (x, S) : For an $x \in U, S \subset U$, return TRUE if $x \in S$ and return FALSE if $x \notin S$.

Remark : When the universal set is evident in a context, we will not explicitly mention it in the discussions. Notice that we work with sets and not multisets. Thus, *Insert* (x, S) does not produce new set when x is in the set already. Similarly *Delete* (x, S) does not produce a new set when $x \notin S$.

Due to its fundamental importance in a host of applications ranging from compiler design to data bases, extensive studies have been done in the design of data structures for dictionaries. Refer to [Chapters 3](#) and [11](#) for data structures for dictionaries designed with the worst-case costs in mind, and [Chapter 13](#) of this handbook for a data structure designed with amortized cost in mind. In [Chapter 16](#) of this book, you will find an account of *B-Trees* which aim to minimize the disk access. All these structures, however, are deterministic. In this sequel, we discuss two of the interesting randomized data structures for Dictionaries. Specifically

- We describe a data structure called *Skip Lists* and present a comprehensive probabilistic analysis of its performance.
- We discuss an interesting randomized variation of a search tree called *Randomized Binary Search Tree* and compare and contrast the same with other competing structures.

14.2 Preliminaries

In this section we collect some basic definitions, concepts and the results on randomized computations and probability theory. We have collected only the materials needed for the topics discussed in this chapter. For a more comprehensive treatment of randomized algorithms, refer to the book by Motwani and Raghavan [1].

14.2.1 Randomized Algorithms

Every computational step in an execution of a *deterministic algorithm* is uniquely determined by the set of all steps executed prior to this step. However, in a *randomized algorithm*, the choice of the next step may not be entirely determined by steps executed previously; the choice of next step might depend on the outcome of a random number generator. Thus, several execution sequences are possible even for the same input. Specifically, when a randomized algorithm is executed several times, even on the same input, the running time may vary from one execution to another. In fact, the running time is a random variable depending on the random choices made during the execution of the algorithm. When the running time of an algorithm is a random variable, the traditional worst case complexity measure becomes inappropriate. In fact, the quality of a randomized algorithm is judged from the statistical properties of the random variable representing the running time. Specifically, we might ask for bounds for the expected running time and bounds beyond which the running time may exceed only with negligible probability. In other words, for the randomized algorithms, there is no bad input; we may perhaps have an *unlucky* execution.

The type of randomized algorithms that we discuss in this chapter is called *Las Vegas* type algorithms. A *Las Vegas* algorithm always terminates with a correct answer although the running time may be a random variable exhibiting wide variations. There is another important class of randomized algorithms, called *Monte Carlo* algorithms, which have fixed running time but the output may be erroneous. We will not deal with *Monte Carlo* algorithms as they are not really appropriate for basic building blocks such as data structures. We shall now define the notion of efficiency and complexity measures for *Las Vegas* type randomized algorithms.

Since the running time of a *Las Vegas* randomized algorithm on any given input is a random variable, besides determining the expected running time it is desirable to show that the running time does not exceed certain threshold value with very high probability. Such threshold values are called *high probability bounds* or *high confidence bounds*. As is customary in algorithmics, we express the estimation of the expected bound or the high-probability bound as a function of the size of the input. We interpret an execution of a *Las Vegas* algorithm as a *failure* if the running time of the execution exceeds the expected running time or the high-confidence bound.

Definition 14.2: (Confidence Bounds)

Let α, β and c be positive constants. A randomized algorithm A requires resource bound $f(n)$ with

1. $n - \text{exponential}$ probability or very high probability, if for any input of size n , the amount of the resource used by A is at most $\alpha f(n)$ with probability $1 - O(\beta^{-n})$, $\beta > 1$. In this case $f(n)$ is called a *very high confidence bound*.
2. $n - \text{polynomial}$ probability or high probability, if for any input of size n , the amount of the resource used by A is at most $\alpha f(n)$ with probability $1 - O(n^{-c})$. In this case $f(n)$ is called a *high confidence bound*.
3. $n - \log$ probability or very good probability, if for any input of size n , the amount of the resource used by A is at most $\alpha f(n)$ with probability $1 - O((\log n)^{-c})$. In this case $f(n)$ is called a *very good confidence bound*.
4. $n - \text{constant}$ probability, if for any input of size n , the amount of the resource used by A is at most $\alpha f(n)$ with probability $1 - O(\beta^{-\alpha})$, $\beta > 1$.

The practical significance of this definition can be understood from the following discussions. For instance, let A be a *Las Vegas* type algorithm with $f(n)$ as a high confidence bound for its running time. As noted before, the actual running time $T(n)$ may vary from one execution to another but the definition above implies that, for any execution, on any input, $\Pr(T(n) > f(n)) = O(n^{-c})$. Even for modest values of n and c , this bound implies an extreme rarity of failure. For instance, if $n = 1000$ and $c = 4$, we may conclude that the chance that the running time of the algorithm A exceeding the threshold value is one in zillion.

14.2.2 Basics of Probability Theory

We assume that the reader is familiar with basic notions such as *sample space*, *event* and basic *axioms of probability*. We denote as $\Pr(E)$ the probability of the event E . Several results follow immediately from the basic axioms, and some of them are listed in Lemma 14.1.

Lemma 14.1

The following laws of probability must hold:

1. $\Pr(\emptyset) = 0$
2. $\Pr(E^c) = 1 - \Pr(E)$
3. $\Pr(E_1) \leq \Pr(E_2)$ if $E_1 \subseteq E_2$
4. $\Pr(E_1 \cup E_2) = \Pr(E_1) + \Pr(E_2) - \Pr(E_1 \cap E_2) \leq \Pr(E_1) + \Pr(E_2)$

Extending item 4 in Lemma 14.1 to countable unions yields the property known as *sub additivity*. Also known as *Boole's Inequality*, it is stated in Theorem 14.1.

Theorem 14.1: (Boole's Inequality)

$$\Pr(\bigcup_{i=1}^{\infty} E_i) \leq \sum_{i=1}^{\infty} \Pr(E_i)$$

A probability distribution is said to be *discrete* if the sample space S is finite or countable. If $E = \{e_1, e_2, \dots, e_k\}$ is an event, $\Pr(E) = \sum_{i=1}^k \Pr(\{e_i\})$ because all elementary events are mutually exclusive. If $|S| = n$ and $\Pr(\{e\}) = \frac{1}{n}$ for every elementary event e in S , we call the distribution a *uniform distribution* of S . In this case,

$$\begin{aligned} \Pr(E) &= \sum_{e \in E} \Pr(e) \\ &= \sum_{e \in E} \frac{1}{n} \\ &= |E|/|S| \end{aligned}$$

which agrees with our intuitive and a well-known definition that probability is the ratio of the favorable number of cases to the total number of cases, when all the elementary events are equally likely to occur.

14.2.3 Conditional Probability

In several situations, the occurrence of an event may change the uncertainties in the occurrence of other events. For instance, insurance companies charge higher rates to various categories of drivers, such as those who have been involved in traffic accidents, because the probabilities of these drivers filing a claim is altered based on these additional factors.

Definition 14.3: (Conditional Probability)

The *conditional probability* of an event E_1 given that another event E_2 has occurred is defined by $Pr(E_1/E_2)$ (" $Pr(E_1/E_2)$ " is read as "the probability of E_1 given E_2 ").

Lemma 14.2

$$Pr(E_1/E_2) = \frac{Pr(E_1 \cap E_2)}{Pr(E_2)}, \text{ provided } Pr(E_2) \neq 0.$$

Lemma 14.2 shows that the conditional probability of two events is easy to compute. When two or more events do not influence each other, they are said to be independent. There are several notions of independence when more than two events are involved. Formally,

Definition 14.4: (Independence of two events)

Two events are *independent* if $Pr(E_1 \cap E_2) = Pr(E_1)Pr(E_2)$, or equivalently, $Pr(E_1/E_2) = Pr(E_1)$.

Definition 14.5: (Pairwise independence)

Events E_1, E_2, \dots, E_k are said to be *pairwise independent* if $Pr(E_i \cap E_j) = Pr(E_i)Pr(E_j)$, $1 \leq i \neq j \leq n$.

Given a partition S_1, \dots, S_k of the sample space S , the probability of an event E may be expressed in terms of mutually exclusive events by using conditional probabilities. This is known as the *law of total probability in the conditional form*.

Lemma 14.3: (Law of total probability in the conditional form)

$$\text{For any partition } S_1, \dots, S_k \text{ of the sample space } S, Pr(E) = \sum_{i=1}^k Pr(E/S_i) Pr(S_i).$$

The law of total probability in the conditional form is an extremely useful tool for calculating the probabilities of events. In general, to calculate the probability of a complex event E , we may attempt to find a partition S_1, S_2, \dots, S_k of S such that both $Pr(E/S_i)$ and $Pr(S_i)$ are easy to calculate and then apply Lemma 14.3. Another important tool is *Bayes' Rule*.

Theorem 14.2: (Bayes' Rule)

For events with non-zero probabilities,

1. $Pr(E_1/E_2) = \frac{Pr(E_2/E_1)Pr(E_1)}{Pr(E_2)}$
2. If S_1, S_2, \dots, S_k is a partition, $Pr(S_i/E) = \frac{Pr(E/S_i)Pr(S_i)}{\sum_{j=1}^k Pr(E/S_j)Pr(S_j)}$

Proof. Part (1) is immediate by applying the definition of conditional probability; Part (2) is immediate from Lemma 14.3. ■

14.2.3.1 Random Variables and Expectation

Most of the random phenomena are so complex that it is very difficult to obtain detailed information about the outcome. Thus, we typically study one or two numerical parameters that we associate with the outcomes. In other words, we focus our attention on certain real-valued functions defined on the sample space.

Definition 14.6

A *random variable* is a function from a sample space into the set of real numbers. For a random variable X , $R(X)$ denotes the *range* of the function X .

Having defined a random variable over a sample space, an event of interest may be studied through the values taken by the random variables on the outcomes belonging to the event. In order to facilitate such a study, we supplement the definition of a random variable by specifying how the probability is assigned to (or distributed over) the values that the random variable may assume. Although a rigorous study of random variables will require a more subtle definition, we restrict our attention to the following simpler definitions that are sufficient for our purposes.

A random variable X is a *discrete random variable* if its range $R(X)$ is a finite or countable set (of real numbers). This immediately implies that any random variable that is defined over a finite or countable sample space is necessarily discrete. However, discrete random variables may also be defined on uncountable sample spaces. For a random variable X , we define its *probability mass function* (*pmf*) as follows:

Definition 14.7: (Probability mass function)

For a random variable X , the *probability mass function* $p(x)$ is defined as $p(x) = \Pr(X = x), \forall x \in R(X)$.

The probability mass function is also known as the *probability density function*. Certain trivial properties are immediate, and are given in Lemma 14.4.

Lemma 14.4

The probability mass function $p(x)$ must satisfy

1. $p(x) \geq 0, \forall x \in R(X)$
2. $\sum_{x \in R(X)} p(x) = 1$

Let X be a discrete random variable with probability mass function $p(x)$ and range $R(X)$. The *expectation* of X (also known as the *expected value* or *mean* of X) is its average value. Formally,

Definition 14.8: (Expected value of a discrete random variable)

The *expected value* of a discrete random variable X with probability mass function $p(x)$ is given by $E(X) = \mu_X = \sum_{x \in R(X)} xp(x)$.

Lemma 14.5

The expected value has the following properties:

1. $E(cX) = cE(X)$ if c is a constant
2. (Linearity of expectation) $E(X + Y) = E(X) + E(Y)$, provided the expectations of X and Y exist

Finally, a useful way of computing the expected value is given by Theorem 14.3.

Theorem 14.3

If $R(X) = \{0, 1, 2, \dots\}$, then $E(X) = \sum_{i=1}^{\infty} \Pr(X \geq i)$.

Proof.

$$\begin{aligned} E(X) &= \sum_{i=0}^{\infty} i \Pr(X = i) \\ &= \sum_{i=0}^{\infty} i(\Pr(X \geq i) - \Pr(X \geq i+1)) \\ &= \sum_{i=1}^{\infty} \Pr(X \geq i) \end{aligned}$$

14.2.4 Some Basic Distributions

14.2.4.1 Bernoulli Distribution

We have seen that a coin flip is an example of a random experiment and it has two possible outcomes, called *success* and *failure*. Assume that success occurs with probability p and that failure occurs with probability $q = 1 - p$. Such a coin is called p -biased coin. A coin flip is also known as *Bernoulli Trial*, in honor of the mathematician who investigated extensively the distributions that arise in a sequence of coin flips.

Definition 14.9

A random variable X with range $R(X) = \{0, 1\}$ and probability mass function $Pr(X = 1) = p$, $Pr(X = 0) = 1 - p$ is said to follow the Bernoulli Distribution. We also say that X is a Bernoulli random variable with parameter p .

14.2.4.2 Binomial Distribution

Let $\binom{n}{k}$ denote the number of k -combinations of elements chosen from a set of n elements. Recall that $\binom{n}{k} = \frac{n!}{k!(n-k)!}$ and $\binom{n}{0} = 1$ since $0! = 1$. $\binom{n}{k}$ denotes the *binomial coefficients* because they arise in the expansion of $(a + b)^n$.

Define the random variable X to be the number of successes in n flips of a p -biased coin. The variable X satisfies the *binomial distribution*. Specifically,

Definition 14.10: (Binomial distribution)

A random variable with range $R(X) = \{0, 1, 2, \dots, n\}$ and probability mass function

$$Pr(X = k) = b(k, n, p) = \binom{n}{k} p^k q^{n-k}, \text{ for } k = 0, 1, \dots, n$$

satisfies the *binomial distribution*. The random variable X is called a binomial random variable with parameters n and p .

Theorem 14.4

For a binomial random variable X , with parameters n and p , $E(X) = np$ and $Var(X) = npq$.

14.2.4.3 Geometric Distribution

Let X be a random variable X denoting the number of times we toss a p -biased coin until we get a success. Then, X satisfies the *geometric distribution*. Specifically,

Definition 14.11: (Geometric distribution)

A random variable with range $R(X) = \{1, 2, \dots, \infty\}$ and probability mass function $Pr(X = k) = q^{k-1}p$, for $k = 1, 2, \dots, \infty$ satisfies the *geometric distribution*. We also say that X is a geometric random variable with parameter p .

The probability mass function is based on $k - 1$ failures followed by a success in a sequence of k independent trials. The mean and variance of a geometric distribution are easy to compute.

Theorem 14.5

For a geometrically distributed random variable X , $E(X) = \frac{1}{p}$ and $Var(X) = \frac{q}{p^2}$.

14.2.4.4 Negative Binomial distribution

Fix an integer n and define a random variable X denoting the number of flips of a p -biased coin to obtain n successes. The variable X satisfies a negative binomial distribution. Specifically,

Definition 14.12

A random variable X with $R(X) = \{0, 1, 2, \dots\}$ and probability mass function defined by

$$\begin{aligned} Pr(X = k) &= \binom{k-1}{n-1} p^n q^{k-n} \quad \text{if } k \geq n \\ &= 0 \quad \text{if } 0 \leq k < n \end{aligned} \tag{14.1}$$

is said to be a *negative binomial random variable* with parameters n and p .

Equation 14.1 follows because, in order for the n^{th} success to occur in the k^{th} flip there should be $n - 1$ successes in the first $k - 1$ flips and the k^{th} flip should also result in a success.

Definition 14.13

Given n identically distributed independent random variables X_1, X_2, \dots, X_n , the sum

$$S_n = X_1 + X_2 + \dots + X_n$$

defines a new random variable. If n is a finite, fixed constant then S_n is known as the *deterministic sum* of n random variables.

On the other hand, if n itself is a random variable, S_n is called a *random sum*.

Theorem 14.6

Let $X = X_1 + X_2 + \dots + X_n$ be a deterministic sum of n identical independent random variables. Then

1. If X_i is a Bernoulli random variable with parameter p then X is a binomial random variable with parameters n and p .
2. If X_i is a geometric random variable with parameter p , then X is a negative binomial with parameters n and p .
3. If X_i is a (negative) binomial random variable with parameters r and p then X is a (negative) binomial random variable with parameters nr and p .

Deterministic sums and random sums may have entirely different characteristics as the following theorem shows.

Theorem 14.7

Let $X = X_1 + \dots + X_N$ be a random sum of N geometric random variables with parameter p . Let N be a geometric random variable with parameter α . Then X is a geometric random variable with parameter αp .

14.2.5 Tail Estimates

Recall that the running time of a *Las Vegas* type randomized algorithm is a random variable and thus we are interested in the probability of the running time exceeding a certain threshold value.

Typically we would like this probability to be very small so that the threshold value may be taken as the figure of merit with high degree of confidence. Thus we often compute or estimate quantities of the form $Pr(X \geq k)$ or $Pr(X \leq k)$ during the analysis of randomized algorithms. Estimates for the quantities of the form $Pr(X \geq k)$ are known as *tail estimates*. The next two theorems state some very useful tail estimates derived by Chernoff. These bounds are popularly known as *Chernoff bounds*. For simple and elegant proofs of these and other related bounds you may refer [2].

Theorem 14.8

Let X be a sum of n independent random variables X_i with $R(X_i) \subseteq [0, 1]$. Let $E(X) = \mu$. Then,

$$Pr(X \geq k) \leq \left(\frac{\mu}{k}\right)^k \left(\frac{n-\mu}{n-k}\right)^{n-k} \quad \text{for } k > \mu \tag{14.2}$$

$$\leq \left(\frac{\mu}{k}\right)^k e^{k-\mu} \quad \text{for } k > \mu \tag{14.3}$$

$$Pr(X \geq (1+\epsilon)\mu) \leq \left[\frac{e^\epsilon}{(1+\epsilon)^{(1+\epsilon)}}\right]^\mu \quad \text{for } \epsilon \geq 0 \tag{14.4}$$

Theorem 14.9

Let X be a sum of n independent random variables X_i with $R(X_i) \subseteq [0, 1]$. Let $E(X) = \mu$. Then,

$$\Pr(X \leq k) \leq \left(\frac{\mu}{k}\right)^k \left(\frac{n-\mu}{n-k}\right)^{n-k} \quad k < \mu \quad (14.5)$$

$$\leq \left(\frac{\mu}{k}\right)^k e^{k-\mu} \quad k < \mu \quad (14.6)$$

$$\Pr(X \leq (1-\epsilon)\mu) \leq e^{-\frac{\mu\epsilon^2}{2}}, \text{ for } \epsilon \in (0, 1) \quad (14.7)$$

Recall that a deterministic sum of several geometric variables results in a negative binomial random variable. Hence, intuitively, we may note that only the upper tail is meaningful for this distribution. The following well-known result relates the upper tail value of a negative binomial distribution to a lower tail value of a suitably defined binomial distribution. Hence all the results derived for lower tail estimates of the binomial distribution can be used to derive upper tail estimates for negative binomial distribution. This is a very important result because finding bounds for the right tail of a negative binomial distribution directly from its definition is very difficult.

Theorem 14.10

Let X be a negative binomial random variable with parameters r and p . Then, $\Pr(X > n) = \Pr(Y < r)$ where Y is a binomial random variable with parameters n and p .

14.3 Skip Lists

Linked list is the simplest of all dynamic data structures implementing a *Dictionary*. However, the complexity of *Search* operation is $O(n)$ in a *Linked list*. Even the *Insert* and *Delete* operations require $O(n)$ time if we do not specify the exact position of the item in the list. *Skip List* is a novel structure, where using randomness, we construct a number of progressively smaller lists and maintain this collection in a clever way to provide a data structure that is competitive to balanced tree structures. The main advantage offered by skip list is that the codes implementing the dictionary operations are very simple and resemble list operations. No complicated structural transformations such as *rotations* are done and yet the expected time complexity of *Dictionary* operations on *Skip Lists* are quite comparable to that of AVL trees or splay trees. *Skip Lists* are introduced by Pugh [3].

Throughout this section let $S = \{k_1, k_2, \dots, k_n\}$ be the set of keys and assume that $k_1 < k_2 < \dots < k_n$.

Definition 14.14

Let $S_0, S_1, S_2, \dots, S_r$ be a collection of sets satisfying

$$S = S_0 \supseteq S_1 \supseteq S_2 \supseteq \dots \supseteq S_r = \emptyset$$

Then, we say that the collection $S_0, S_1, S_2, \dots, S_r$ defines a *leveling with r levels on S* . The keys in S_i are said to be in level i , $0 \leq i \leq r$. The set S_0 is called the base level for the leveling scheme. Notice that there is exactly one empty level, namely S_r . The level number $l(k)$ of a key $k \in S$ is defined by

$$l(k) = \max\{i \mid k \in S_i\}.$$

In other words, $k \in S_0, S_1, S_2, \dots, S_{l(k)}$ but $k \notin S_{l(k)+1} \dots S_r$.

For an efficient implementation of the dictionary, instead of working with the current set S of keys, we would rather work with a leveling of S . The items of S_i will be put in the *increasing order* in a linked list denoted by L_i . We attach the special keys $-\infty$ at the beginning and $+\infty$ at the end of each list L_i as sentinels. In practice, $-\infty$ is a key value that is smaller than any key we consider in the application and $+\infty$ denotes a key value larger than all the possible keys. A leveling of S is implemented by maintaining all the lists $L_0, L_1, L_2, \dots, L_r$ with some more additional links as shown in Figure 14.1. Specifically, the box containing a key k in L_i will have a pointer to the box containing k in L_{i-1} . We call such pointers *descent pointers*. The links connecting items of the same list are called *horizontal pointers*. Let B be a pointer to a box in the skip list. We use the notations $Hnext[B]$, and $Dnext[B]$, for the horizontal and descent pointers of the box pointed by B respectively. The notation $key[B]$ is used to denote the key stored in the box pointed by B . The name of the skip list is nothing but a pointer to the box containing $-\infty$ in the r th level as shown

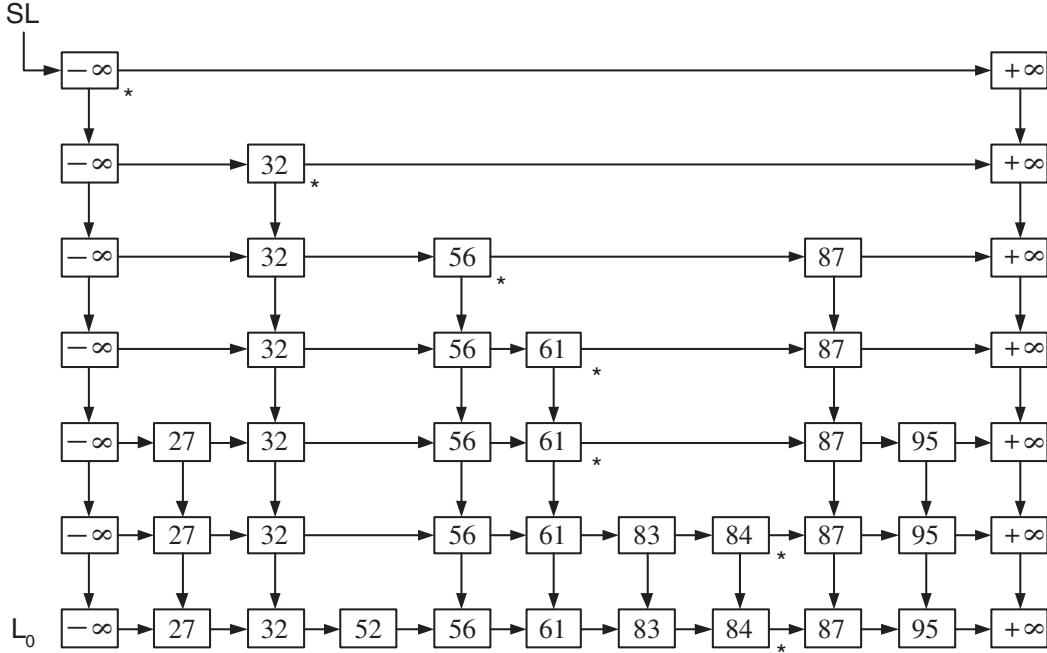

FIGURE 14.1 A Skip List. The starred nodes are marked by $\text{Mark}(86, \text{SL})$.

in the figure. From the Figure 14.1 it is clear that L_i has horizontal pointers that skip over several intermediate elements of L_{i-1} . That is why this data structure is called the *Skip List*.

How do we arrive at a leveling for a given set? We may construct S_{i+1} from S_i in a systematic, deterministic way. While this may not pose any problem for a static search problem, it will be extremely cumbersome to implement the dynamic dictionary operations. This is where randomness is helpful. To get S_{i+1} from S_i , we do the following. For each element k of S_i toss a coin and include k in S_{i+1} iff we get *success* in the coin toss. If the coin is p -biased, we expect $|S_{i+1}|$ to be roughly equal to $p|S_i|$. Starting from S , we may repeatedly obtain sets corresponding to successive levels. Since the coin tosses are independent, there is another useful, and equivalent way to look at our construction. For each key k in S , keep tossing a coin until we get a *failure*. Let h be the number of successes before the first failure. Then, we include k in h further levels treating $S = S_0$ as the base level. In other words, we include k in the sets S_1, S_2, \dots, S_h . This suggests us to define a random variable Z_i for each key $k_i \in S_0$ to be the number of times we toss a p -biased coin before we obtain a *failure*. Since Z_i denotes the number of additional copies of k_i in the skip list, the value $\max\{Z_i : 1 \leq i \leq n\}$ defines the highest nonempty level. Hence, we have,

$$r = 1 + \max\{Z_i : 1 \leq i \leq n\} \quad (14.8)$$

$$|SL| = n + Z_1 + Z_2 + \dots + Z_n + 2r + 2 \quad (14.9)$$

where r is the number of levels and $|SL|$ is the number of boxes or the space complexity measure of the *Skip List*. In the expression for $|SL|$ we have added n to count the keys in the base level and $2r + 2$ counts the sentinel boxes containing $+\infty$ and $-\infty$ in each level.

14.4 Structural Properties of Skip Lists

14.4.1 Number of Levels in Skip List

Recall that $r = 1 + \max_i\{Z_i\}$. Notice that $Z_i \geq k$ iff the coin tossed for k_i gets a run of at least k successes right from the beginning and this happens with probability p^k . Since $r \geq k$ iff at least one of $Z_i \geq k - 1$, we easily get the following fact from Boole's inequality

$$\Pr(r \geq k) \leq np^{k-1}$$

Choosing $k = 4 \log_{1/p} n + 1$, we immediately obtain a high confidence bound for the number of levels. In fact,

$$\begin{aligned} Pr(r \geq 4 \log n + 1) &\leq nn^{-4} \\ &= \frac{1}{n^3} \end{aligned} \quad (14.10)$$

We obtain an estimation for the expected value of r , using the formula stated in theorem (14.3) as follows:

$$\begin{aligned} E(r) &= \sum_{i=1}^{\infty} Pr(r \geq i) \\ &= \sum_{i=1}^{4 \log n} Pr(r \geq i) + \sum_{i>4 \log n} Pr(r \geq i) \\ &\leq \sum_{i=1}^{4 \log n} 1 + \sum_{i>4 \log n}^{\infty} np^{i-1} \\ &= 4 \log n + np^{4 \log n} (1 + p + p^2 + \dots) \\ &= 4 \log n + n \cdot \frac{1}{n^4} \cdot (1-p)^{-1} \text{ if base of the log is } 1/p \\ &\leq 4 \log n + 1 \text{ for sufficiently large } n \end{aligned}$$

Thus $E(r) = O(\log n)$

Hence,

Theorem 14.11

The expected number of levels in a skip list of n elements is $O(\log n)$. In fact, the number is $O(\log n)$ with high probability.

14.4.2 Space Complexity

Recall that the space complexity, $|SL|$ is given by

$$|SL| = Z_1 + Z_2 + \dots + Z_n + n + 2r + 2.$$

As we know that $r = O(\log n)$ with high probability, let us focus on the sum

$$Z = Z_1 + Z_2 + \dots + Z_n.$$

Since Z_i is a geometric random variable with parameter p , Z is a negative binomial random variable by theorem 14.6.

Thus $E(Z) = \frac{n}{p} = O(n)$.

We can in fact show that Z is $O(n)$ with very high probability.

Now, from theorem (14.10) $Pr(Z > 4n) = Pr(X < n)$ where X is a binomial distribution with parameters $4n$ and p . We now assume that $p = 1/2$ just for the sake of simplicity in arithmetic.

In the first Chernoff bound mentioned in theorem (14.9), replacing n , μ and k respectively with $4n$, $2n$ and n , we obtain,

$$\begin{aligned} Pr(X < n) &\leq \left(\frac{2n}{n}\right)^n \left(\frac{2n}{3n}\right)^{3n} \\ &= \left(2 \cdot \frac{2^3}{3^3}\right)^n \\ &= \left(\frac{16}{27}\right)^n \\ &= \left(\frac{27}{16}\right)^{-n} \end{aligned}$$

This implies that $4n$ is in fact a very high confidence bound for Z . Since $|SL| = Z + n + 2r + 2$, we easily conclude that

Theorem 14.12

The space complexity of a skip list for a set of size n is $O(n)$ with very high probability.

14.5 Dictionary Operations

We shall use a simple procedure called *Mark* in all the dictionary operations. The procedure *Mark* takes an arbitrary value x as input and marks in each level the box containing the largest key that is less than x . This property implies that insertion, deletion or search should all be done next to the marked boxes. Let $M_i(x)$ denote the box in the i^{th} level that is marked by the procedure call $\text{Mark}(x, \text{SL})$. Recall the convention used in the linked structure that name of a box in a linked list is nothing but a pointer to that box. The keys in the marked boxes $M_i(x)$ satisfy the following condition :

$$\text{key}[M_i(x)] < x \leq \text{key}[\text{Hnext}[M_i(x)]] \quad \text{for all } 0 \leq i \leq r. \quad (14.11)$$

The procedure *Mark* begins its computation at the box containing $-\infty$ in level r . At any current level, we traverse along the level using horizontal pointers until we find that the next box is containing a key larger or equal to x . When this happens, we mark the current box and use the *descent pointer* to reach the next lower level and work at this level in the same way. The procedure stops after marking a box in level 0. See [Figure 14.1](#) for the nodes marked by the call $\text{Mark}(86, \text{SL})$.

```

Algorithm Mark(x, SL)
-- x is an arbitrary value.
-- r is the number of levels in the skip list SL.
1. Temp = SL.
2. For i = r down to 0 do
   While (key[Hnext[Temp]] < x)
      Temp = Hnext[Temp];
      Mark the box pointed by Temp;
      Temp = Dnext[Temp];
3. End.

```

We shall now outline how to use marked nodes for *Dictionary* operations. Let $M_0(x)$ be the box in level 0 marked by $\text{Mark}(x)$. It is clear that the box next to $M_0(x)$ will have x iff $x \in S$. Hence our algorithm for *Search* is rather straight forward.

To insert an item in the *Skip List*, we begin by marking the *Skip List* with respect to the value x to be inserted. We assume that x is not already in the *Skip List*. Once the marking is done, inserting x is very easy. Obviously x is to be inserted next to the marked boxes. But in how many levels we insert x ? We determine the number of levels by tossing a coin on behalf of x until we get a *failure*. If we get h successes, we would want x to be inserted in all levels from 0 to h . If $h \geq r$, we simply insert x at all the existing levels and create a new level consisting of only $-\infty$ and $+\infty$ that corresponds to the empty set. The insertion will be done starting from the base level. However, the marked boxes are identified starting from the highest level. This means, the *Insert* procedure needs the marked boxes in the reverse order of its generation. An obvious strategy is to push the marked boxes in a stack as and when they are marked in the *Mark* procedure. We may pop from the stack as many marked boxes as needed for insertion and then insert x next to each of the popped boxes.

The deletion is even simpler. To delete a key x from S , simply mark the *Skip List* with respect to x . Note that if x is in L_i , then it will be found next to the marked box in L_i . Hence, we can use the *horizontal pointers* in the marked boxes to delete x from each level where x is present. If the deletion creates one or more empty levels, we ignore all of them and retain only one level corresponding to the empty set. In other words, the number of levels in the *Skip List* is reduced in this case. In fact, we may delete an item “on the fly” during the execution of the *Mark* procedure itself. As the details are simple we omit pseudo codes for these operations.

14.6 Analysis of Dictionary Operations

It is easy to see that the cost of *Search*, *Insert* and *Delete* operations are dominated by the cost of *Mark* procedure. Hence we shall analyze only the *Mark* procedure. The *Mark* procedure starts at the ‘ r ’th level and proceeds like a downward walk on a staircase and ends at level 0. The complexity of *Mark* procedure is clearly proportional to the number of edges it traversed. It is advantageous to view the same path as if it is built from level 0 to level r . In other words, we analyze the building of the path in a direction opposite to the direction in which it is actually built by the procedure. Such an analysis is known as *backward analysis*.

Henceforth let P denote the path from level 0 to level r traversed by $\text{Mark}(x)$ for the given fixed x . The path P will have several vertical edges and horizontal edges. (Note that at every box either P moves vertically above or moves horizontally to the left). Clearly, P has r vertical edges. To estimate number of horizontal edges, we need the following lemmas.

Lemma 14.6

Let the box b containing k at level i be marked by $\text{Mark}(x)$. Let a box w containing k be present at level $i+1$. Then, w is also marked.

Proof. Since b is marked, from Equation 14.11, we get that there is no value between k and x in level i . This fact holds good for L_{i+1} too because $S_{i+1} \subseteq S_i$. Hence the lemma. \blacksquare

Lemma 14.7

Let the box b containing k at level i be marked by $\text{Mark}(x)$. Let $k \notin L_{i+1}$. Let u be the first box to the left of b in L_i having a “vertical neighbor” w . Then w is marked.

Proof. Let $w.\text{key} = u.\text{key} = y$. Since b is marked, k satisfies condition (14.11). Since u is the first node in the left of b having a vertical neighbor, none of the keys with values in between y and x will be in L_{i+1} . Also, $k \notin L_{i+1}$ according to our assumption in the lemma. Thus y is the element in L_{i+1} that is just less than x . That is, y satisfies the condition (14.11) at level $i+1$. Hence the w at level $i+1$ will be marked. \blacksquare

Lemmas (14.6 and 14.7) characterize the segment of P between two successive marked boxes. This allows us to give an incremental description of P in the following way.

P starts from the marked box at level 0. It proceeds vertically as far as possible (lemma 14.6) and when it cannot proceed vertically it proceeds horizontally. At the “first” opportunity to move vertically, it does so (lemma 14.7), and continues its vertical journey. Since for any box a vertical neighbor exists only with a probability p , we see that P proceeds from the current box vertically with probability p and horizontally with probability $(1-p)$.

Hence, the number of horizontal edges of P in level i is a geometric random variable, say, Y_i , with parameter $(1-p)$. Since the number of vertical edges in P is exactly r , we conclude,

Theorem 14.13

The number of edges traversed by $\text{Mark}(x)$ for any fixed x is given by $|P| = r + (Y_0 + Y_1 + Y_2 + \dots + Y_{r-1})$ where Y_i is a geometric random variable with parameters $1-p$ and r is the random variable denoting the number of levels in the Skip List.

Our next mission is to obtain a high confidence bound for the size of P . As we have already derived high confidence bound for r , let focus on the sum $H_r = Y_0 + Y_1 + \dots + Y_{r-1}$ for a while. Since r is a random variable H_r is not a deterministic sum of random variables but a *random sum* of random variables.

Hence we cannot directly apply theorem (14.6) and the bounds for negative binomial distributions.

Let X be the event of the random variable r taking a value less than or equal to $4 \log n$. Note that $P(\bar{X}) < \frac{1}{n^3}$ by (14.10). From the law of total probability, Boole’s inequality and equation (14.10) we get,

$$\begin{aligned} Pr(H_r > 16 \log n) &= Pr([H_r > 16 \log n] \cap X) + Pr([H_r > 16 \log n] \cap \bar{X}) \\ &= Pr([H_r > 16 \log n] \cap r \leq 4 \log n) + Pr([H_r > 16 \log n] \cap \bar{X}) \\ &\leq \sum_{k=0}^{4 \log n} Pr(H_k > 16 \log n) + Pr(\bar{X}) \\ &\leq (1 + 4 \log n) Pr(H_{4 \log n} > 16 \log n) + \frac{1}{n^3} \end{aligned}$$

Now $Pr(H_{4 \log n} > 16 \log n)$ can be computed in a manner identical to the one we carried out in the space complexity analysis. Notice that $H_{4 \log n}$ is a deterministic sum of geometric random variables. Hence we can apply theorems (14.9) and (14.10) to derive a high confidence bound. Specifically, by theorem (14.10),

$$Pr(H_{4 \log n} > 16 \log n) = Pr(X < 4 \log n),$$

where X is a binomial random variable with parameters $16 \log n$ and p . Choosing $p = 1/2$ allows us to set $\mu = 8 \log n$, $k = 4 \log n$ and replace n by $16 \log n$ in the first inequality of theorem (14.9). Putting all these together we obtain,

$$\begin{aligned} \Pr(H_{4 \log n} > 16 \log n) &= \Pr(X < 4 \log n) \\ &\leq \left(\frac{8 \log n}{4 \log n} \right)^{4 \log n} \left(\frac{8 \log n}{12 \log n} \right)^{12 \log n} \\ &= \left(2 \cdot \frac{2^3}{3^3} \right)^{4 \log n} \\ &= \left(\frac{16}{27} \right)^{4 \log n} \\ &< \left(\frac{1}{8} \right)^{\log n} \\ &= \frac{1}{n^3} \end{aligned}$$

Therefore

$$\begin{aligned} \Pr(H_r > 16 \log n) &< (1 + 4 \log n) \left(\frac{1}{n^3} \right) + \frac{1}{n^3} \\ &< \frac{1}{n^2} \quad \text{if } n \geq 32 \end{aligned}$$

This completes the derivation of a high confidence bound for H_r . From this, we can easily obtain a bound for expected value of H_r . We use theorem (14.3) and write the expression for $E(H_r)$ as

$$E(H_r) = \sum_{i=1}^{16 \log n} \Pr(H_r \geq i) + \sum_{i>16 \log n} \Pr(H_r \geq i).$$

The first sum is bounded above by $16 \log n$ as each probability value is less than 1 and by the high confidence bound that we have established just now, we see that the second sum is dominated by $\sum_{i=1}^{\infty} 1/i^2$ which is a constant. Thus we obtain,

$$E(H_r) \leq 16 \log n + c = O(\log n).$$

Since $P = r + H_r$ we easily get that $E(|P|) = O(\log n)$ and $|P| = O(\log n)$ with probability greater than $1 - O(\frac{1}{n^2})$. Observe that we have analyzed $\text{Mark}(x)$ for a given fixed x . To show that the high confidence bound for any x , we need to proceed little further. Note that there are only $n + 1$ distinct paths possible with respect to the set $\{-\infty = k_0, k_1, \dots, k_n, k_{n+1} = +\infty\}$, each corresponding to the x lying in the internal $[k_i, k_{i+1})$, $i = 0, 1, \dots, n$.

Therefore, for any x , $\text{Mark}(x)$ walks along a path P satisfying $E(|P|) = O(\log n)$ and $|P| = O(\log n)$ with probability greater than $1 - O(\frac{1}{n})$.

Summarizing,

Theorem 14.14

The Dictionary operations Insert, Delete, and Search take $O(\log n)$ expected time when implemented using Skip Lists. Moreover, the running time for Dictionary operations in a Skip List is $O(\log n)$ with high probability.

14.7 Randomized Binary Search Trees

A *Binary Search Tree* (BST) for a set S of keys is a binary tree satisfying the following properties.

- a. Each node has exactly one key of S . We use the notation $v.\text{key}$ to denote the key stored at node v .
- b. For all node v and for all nodes u in the left subtree of v and for all nodes w in the right subtree of v , the keys stored in them satisfy the so called *search tree property*:

$$u.\text{key} < v.\text{key} < w.\text{key}$$

The complexity of the dictionary operations are bounded by the height of the binary search tree. Hence, ways and means were explored for controlling the height of the tree during the course of execution. Several clever balancing schemes were discovered with varying degrees of complexities. In general, the implementation of balancing schemes are tedious and we may have to perform a number of rotations which are complicated operations. Another line of research explored the potential of possible randomness in the input data. The idea was to completely avoid balancing schemes and hope to have “short” trees due to randomness in input. When only random insertion are done, we obtain so called *Randomly Built Binary Tree* (RBRT). RBRTs have been shown to have $O(\log n)$ expected height.

What is the meaning of random insertion? Suppose we have already inserted the values $a_1, a_2, a_3, \dots, a_{k-1}$. These values, when considered in sorted order, define k intervals on the real line and the new value to be inserted, say x , is equally likely to be in any of the k intervals.

The first drawback of RBRT is that this assumption may not be valid in practice and when this assumption is not satisfied, the resulting tree structure could be highly skewed and the complexity of search as well as insertion could be as high as $O(n)$. The second major drawback is when deletion is also done on these structures, there is a tremendous degradation in the performance. There is no theoretical results available and extensive empirical studies show that the height of an RBRT could grow to $O(\sqrt{n})$ when we have arbitrary mix of insertion and deletion, even if the randomness assumption is satisfied for inserting elements. Thus, we did not have a satisfactory solution for nearly three decades.

In short, the randomness was not preserved by the deletion operation and randomness preserving binary tree structures for the dictionary operations was one of the outstanding open problems, until an elegant affirmative answer is provided by Martinez and Roura in their landmark paper [4].

In this section, we shall briefly discuss about structure proposed by Martinez and Roura.

Definition 14.15: (Randomized Binary Search Trees)

Let T be a binary search tree of size n . If $n = 0$, then $T = \text{NULL}$ and it is a random binary search tree. If $n > 0$, T is a random binary search tree iff both its left subtree L and right subtree R are independent random binary search trees and

$$\Pr\{\text{Size}(L) = i | \text{Size}(T) = n\} = \frac{1}{n}, 0 \leq i \leq n.$$

The above definition implies that every key has the same probability of $\frac{1}{n}$ for becoming the root of the tree. It is easy to prove that the expected height of a RBST with n nodes is $O(\log n)$. The RBSTs possess a number of interesting structural properties and the classic book by Mahmoud [5] discusses them in detail. In view of the above fact, it is enough if we prove that when insert or delete operation is performed on a RBST, the resulting tree is also an RBST.

14.7.1 Insertion in RBST

When a key x is inserted in a tree T of size n , we obtain a tree T' of size $n + 1$. For T' , as we observed earlier, x should be in the root with probability $\frac{1}{n+1}$. This is our starting point.

```

Algorithm Insert(x, T)
- L is the left subtree of the root
- R is the right subtree of the root
1. n = size(T);
2. r = random(0, n);
3. If (r = n) then
    Insert_at_root(x, T);
4. If (x < key at root of T) then
    Insert(x, L);
Else
    Insert(x, R);

```

To insert x as a root of the resulting tree, we first split the current tree into two trees labeled $T_<$ and $T_>$, where $T_<$ contains all the keys in T that are smaller than x and $T_>$ contains all the keys in T that are larger than x . The output tree T' is constructed by placing x at the root and attaching $T_<$ as its left subtree and $T_>$ as its right subtree. The algorithm for splitting a tree T into $T_<$ and $T_>$ with respect to a value x is similar to the partitioning algorithm done in *quicksort*. Specifically, the algorithm *split(x, T)* works as follows. If T is empty, nothing needs to be done; both $T_<$ and $T_>$ are empty. When T is non-empty we compare x with $\text{Root}(T).\text{key}$. If $x < \text{Root}(T).\text{key}$, then root of T as well as the right subtree of T belong to $T_>$. To compute $T_<$ and the remaining

part of $T_{>}$ we recursively call $\text{split}(x, L)$, where L is the left subtree for the root of T . If $x > \text{Root}(T).\text{key}$, $T_{<}$ is built first and recursion proceeds with $\text{split}(x, R)$. The details are left as easy exercise.

We shall first prove that $T_{<}$ and $T_{>}$ are independent Random Binary Search Trees. Formally,

Theorem 14.15

Let $T_{<}$ and $T_{>}$ be the BSTs produced by $\text{split}(x, T)$. If T is a random BST containing the set of keys S , then $T_{<}$ and $T_{>}$ are RBSTs containing the keys $S_{<} = \{y \in S \mid y < x\}$ and $S_{>} = \{y \in S \mid y > x\}$, respectively.

Proof. Let $\text{size}(T) = n > 0$, $x > \text{Root}(T).\text{key}$, we will show that for any $z \in S_{<}$, the probability that z is the root of $T_{<}$ is $1/m$ where $m = \text{size}(T_{<})$. In fact,

$$\begin{aligned} & \Pr(z \text{ is root of } T_{<} \mid \text{root of } T \text{ is less than } x) \\ &= \frac{\Pr(z \text{ is root of } T_{<} \text{ and root of } T \text{ is less than } x)}{\Pr(\text{root of } T \text{ is less than } x)} \\ &= \frac{1/n}{m/n} = \frac{1}{m}. \end{aligned}$$

The independence of $T_{<}$ and $T_{>}$ follows from the independence of L and R of T and by induction. ■

We are now ready to prove that randomness is preserved by insertion. Specifically,

Theorem 14.16

Let T be a RBST for the set of keys S and $x \notin S$, and assume that $\text{insert}(s, T)$ produces a tree, say T' for $S \cup \{x\}$. Then, T' is a RBST.

Proof. A key $y \in S$ will be at the root of T' iff

1. y is at root of T .
2. x is not inserted at the root of T'

As (1) and (2) are independent events with probability $\frac{1}{n}$ and $\frac{n}{n+1}$, respectively, it follows that $\text{Prob}(y \text{ is at root of } T') = \frac{1}{n} \cdot \frac{n}{n+1} = \frac{1}{n+1}$. The key x can be at the root of T' only when $\text{insert}(x, T)$ invokes $\text{insert-at-root}(x, T)$ and this happens with probability $\frac{1}{n+1}$. Thus, any key in $S \cup \{x\}$ has the probability of $\frac{1}{n+1}$ for becoming the root of T' . The independence of left and right subtrees of T' follows from independence of left and right subtrees of T , induction, and the previous theorem. ■

14.7.2 Deletion in RBST

Suppose $x \in T$ and let T_x denote the subtree of T rooted at x . Assume that L and R are the left and right subtrees of T_x . To delete x , we build a new BST $T_x' = \text{Join}(L, R)$ containing the keys in L and R and replace T_x by T_x' . Since pseudocode for deletion is easy to write, we omit the details.

We shall take a closer look at the details of the *Join* routine. We need couple of more notations to describe the procedure *Join*. Let L_l and L_r denote the left and right subtrees of L and R_l and R_r denote the left and right subtrees of R , respectively. Let a denote the root of L and b denote the root of R . We select either a or b to serve as the root of T_x with appropriate probabilities. Specifically, the probability for a becoming the root of T_x is $\frac{m}{m+n}$ and for b it is $\frac{n}{m+n}$ where $m = \text{size}(L)$ and $n = \text{size}(R)$.

If a is chosen as the root, the its left subtree L_l is not modified while its right subtree L_r is replaced with $\text{Join}(L_r, R)$. If b is chosen as the root, then its right subtree R_r is left intact but its left subtree R_l is replaced with $\text{Join}(L, R_l)$. The join of an empty tree with another tree T is T it self and this is the condition used to terminate the recursion.

```
Algorithm Join(L, R)
-- L and R are RBSTs with roots a and b and size m and n respectively.
-- All keys in L are strictly smaller than all keys in R.
-- $L_l$ and $L_r$ respectively denote the left and right subtree of L.
-- $R_l$ and $R_r$ are similarly defined for R.
```

1. If (L is NULL) return R .
2. If (R is NULL) return L .
3. Generate a random integer i in the range $[0, n+m-1]$.

```

4. If ( i < m ) {* the probability for this event is m/(n+m).*}
    L_x = Join(L_l,R);
    return L;
else   {* the probability for this event is n/(n+m).*}
    R_l = Join(L,R_l);
    return R;

```

It remains to show that *Join* of two RBSTs produces RBST and deletion preserves randomness in RBST.

Theorem 14.17

The Algorithm *Join*(L,R) produces a RBST under the conditions stated in the algorithm.

Proof. We show that any key has the probability of $1/(n + m)$ for becoming the root of the tree output by *Join*(L,R). Let x be a key in L. Note that x will be at the root of *Join*(L,R) iff

- x was at the root of L before the *Join* operation, and,
- The root of L is selected to serve as the root of the output tree during the *Join* operation.

The probability for the first event is $1/m$ and the second event occurs with probability $m/(n + m)$. As these events are independent, it follows that the probability of x at the root of the output tree is $\frac{1}{m} \cdot \frac{m}{n+m} = \frac{1}{n+m}$. A similar reasoning holds good for the keys in R. ■

Finally,

Theorem 14.18

If T is a RBST for a set K of keys, then *Delete*(x,T) outputs a RBST for $K - \{x\}$.

Proof. We sketch only the chance counting argument. The independence of the subtrees follows from the properties of *Join* operation and induction. Let $T' = \text{Delete}(x, T)$. Assume that $x \in K$ and size of K is n . We have to prove that for any $y \in K, y \neq x$, the probability for y in root of T' is $1/(n - 1)$. Now, y will be at the root of T' iff either x was at the root of T and its deletion from T brought y to the root of T' or y was at the root of T(so that deletion of x from T did not dislocate y). The former happens with a probability $\frac{1}{n} \cdot \frac{1}{n-1}$ and the probability of the later is $\frac{1}{n}$. As these events are independent, we add the probabilities to obtain the desired result. ■

14.8 Bibliographic Remarks

In this chapter we have discussed two randomized data structures for Dictionary ADT. Skip Lists are introduced by Pugh in 1990 [3]. A large number of implementations of this structure by a number of people available in the literature, including the one by the inventor himself. Sedgewick gives an account of the comparison of the performances of Skip Lists with the performances of other balanced tree structures [6]. See [7] for a discussion on the implementation of other typical operations such as merge. Pugh argues how Skip Lists are more efficient in practice than balanced trees with respect to Dictionary operations as well as several other operations. Pugh has further explored the possibilities of performing concurrent operations on Skip Lists in Reference [8]. For a more elaborate and deeper analysis of Skip Lists, refer the PhD thesis of Papadakis [9]. In his thesis, he has introduced deterministic skip lists and compared and contrasted the same with a number of other implementations of Dictionaries. Sandeep Sen [10] provides a crisp analysis of the structural properties of Skip Lists. Our analysis presented in this chapter is somewhat simpler than Sen's analysis and our bounds are derived based on different tail estimates of the random variables involved.

The randomized binary search trees are introduced by Martinez and Roura in their classic paper [4] which contains many more details than discussed in this chapter. In fact, we would rate this paper as one of the best written papers in data structures. Seidel and Aragon have proposed a structure called probabilistic priority queues [11] and it has a comparable performance. However, the randomness in their structure is achieved through randomly generated real numbers (called priorities) while the randomness in Martinez and Roura's structure is inherent in the tree itself. Besides this being simpler and more elegant, it solves one of the outstanding open problems in the area of search trees.

15.1 Introduction

The concept of the “weighted path length” is important in data compression and searching. In case of data compression lengths of paths correspond to lengths of code-words. In case of searching they correspond to the number of elementary searching steps. By a *length of a path* we mean usually its number of edges.

Assume we have n weighted items, where w_i is the non-negative *weight* of the i^{th} item. We denote the sequence of weights by $S = (w_1 \dots w_n)$. We adopt the convention that the items have unique names. When convenient to do so, we will assume that those names are the positions of items in the list, namely integers in $[1 \dots n]$.

We consider a binary tree T , where the items are placed in vertices of the trees (in leaves only or in every node, depending on the specific problem). We define the minimum weighted path length (cost) of the tree T as follows:

$$\text{cost}(T) = \sum_{i=1}^n w_i \text{level}_T(i)$$

where level_T is the *level function* of T , that is, $\text{level}_T(i)$ is the level (or depth) of i in T , defined to be the length of the path in T from the root to i .

In some special cases (lopsided trees) the edges can have different lengths and the path length in this case is the sum of individual lengths of edges on the path.

In this chapter we concentrate on several interesting algorithms in the area:

- Huffman algorithm constructing optimal prefix-free codes in time $O(n \log n)$, in this case the items are placed in leaves of the tree, the original order of items can be different from their order as leaves;
- A version of Huffman algorithm which works in $O(n)$ time if the weights of items are sorted
- Larmore-Hirschberg algorithm for optimal height-limited Huffman trees working in time $O(n \times L)$, where L is the upper bound on the height, it is an interesting algorithm transforming the problem to so called “coin-collector,” see [1].

- Construction of optimal binary search trees (OBST) in $O(n^2)$ time using certain property of “splitting points” of subtrees. In case of OBST every node (also internal) contains exactly one item. (Binary search trees are defined in [Chapter 3](#).)
- Construction of optimal alphabetic trees (OAT) in $O(n \log n)$ time: the Garsia-Wachs algorithm [2]. It is a version of an earlier algorithm of Hu-Tucker [3,4] for this problem. The correctness of this algorithm is nontrivial and this algorithm (as well as Hu-Tucker) and these are the most interesting algorithms in the area.
- Construction of optimal lopsided trees, these are the trees similar to Huffman trees except that the edges can have some lengths specified.
- Short discussion of parallel algorithms

Many of these algorithms look “mysterious,” in particular the Garsia-Wachs algorithm for optimal alphabetic trees. This is the version of the Hu-Tucker algorithm. Both algorithms are rather simple to understand in how they work and their complexity, but correctness is a complicated issue.

Similarly one can observe a mysterious behavior of the Larmore-Hirschberg algorithm for height-limited Huffman trees. Its “mysterious” behavior is due to the strange reduction to the seemingly unrelated problem of the *coin collector*.

The algorithms relating the cost of binary trees to shortest paths in certain graphs are also not intuitive, for example the algorithm for lopsided trees, see [5], and parallel algorithm for alphabetic trees, see [6]. The efficiency of these algorithms relies on the *Monge property* of related matrices. Both sequential and parallel algorithms for Monge matrices are complicated and interesting.

The area of weighted paths in trees is especially interesting due to its applications (compression, searching) as well as to their relation to many other interesting problems in combinatorial algorithmics.

15.2 Huffman Trees

Assume we have a text x of length N consisting of n different letters with repetitions. The alphabet is a finite set Σ . Usually we identify the i -th letter with its number i . The letter i appears w_i times in x . We need to encode each letter in binary, as $h(a)$, where h is a morphism of alphabet Σ into binary words, in a way to minimize the total length of encoding and guarantee that it is uniquely decipherable, this means that the extension of the morphism h to all words over Σ is one-to-one. The words $h(a)$, where $a \in \Sigma$, are called codewords or codes.

The special case of uniquely decipherable codes are *prefix-free* codes: none of the code is a prefix of another one. The prefix-free code can be represented as a binary tree, with left edges corresponding to zeros, and right edge corresponding to ones.

Let $S = \{w_1, w_2, \dots, w_n\}$ be the sequence of weights of items. Denote by $HuffmanCost(S)$ the total cost of minimal encoding (weighted sum of lengths of code-words) and by $HT(S)$ the tree representing an optimal encoding. Observe that several different optimal trees are possible. The basic algorithm is a greedy algorithm designed by Huffman, the corresponding trees and codes are called Huffman trees and Huffman codes.

Example Let $text = abracadabra$. The number of occurrences of letters are

$$w_a = 5, w_b = 2, w_c = 1, w_d = 1, w_r = 2.$$

We treat letters as items, and the sequence of weights is:

$$S = (5, 2, 1, 1, 2)$$

An optimal tree of a prefix code is shown in [Figure 15.1](#). We have, according to the definition of weighted path length:

$$HuffmanCost(S) = 5 * 1 + 2 * 2 + 1 * 4 + 1 * 4 + 2 * 3 = 23$$

The corresponding prefix code is:

$$h(a) = 0, h(b) = 10, h(c) = 1100, h(d) = 1101, h(r) = 111.$$

We can encode the original text *abracadabra* using the codes given by paths in the prefix tree. The coded text is then 01011101100011010101110, that is a word of length 23.

If for example the initial code words of letters have length 5, we get the compression ratio $55/23 \approx 2.4$.

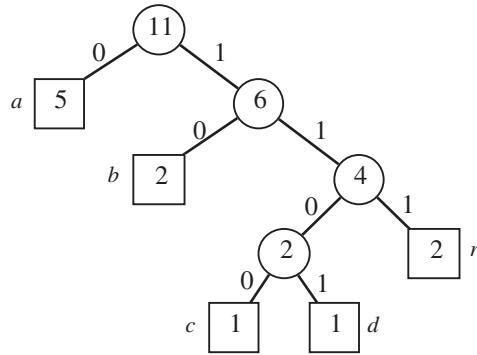

FIGURE 15.1 A Huffman tree T for the items a, b, c, d, r and the weight sequence $S = (5, 2, 1, 1, 2)$. The numbers in internal nodes are sums of weights of leaves in corresponding subtrees. Observe that weighted path length of the tree is the total sum of values in internal nodes. Hence $HuffmanCost(S) = 2 + 4 + 6 + 11 = 23$.

15.2.1 $O(n \log n)$ Time Algorithm

The basic algorithm is the *greedy* algorithm given by Huffman. In this algorithm we can assume that two items of smallest weight are at the bottom of the tree and they are sons of a same node. The *greedy* approach in this case is to minimize the cost *locally*.

Two smallest weight items are *combined* into a single *package* with weight equal to the sum of weights of these small items. Then we proceed recursively. The following observation is used.

Observation Assume that the numbers in internal nodes are sums of weights of leaves in corresponding subtrees. Then the total weighted path length of the tree is the total sum of values in internal nodes.

Due to the observation we have for $|S| > 1$:

$$HuffmanCost(S) = HuffmanCost(S - \{u, w\}) + u + w,$$

where u, w are two minimal elements of S . This implies the following algorithm, in which we assume that initially S is stored in a min-priority queue. The algorithm is presented below as a recursive function $HuffmanCost(S)$ but it can be easily written without recursion. The algorithm computes only the total cost.

Theorem 15.1

Huffman algorithm constructs optimal tree in $O(n \log n)$ time

Proof. In an optimal tree we can exchange two items which are sons of a same father at a bottom level with two smallest weight items. This will not increase the cost of the tree. Hence there is an optimal tree with two smallest weight items being sons of a same node. This implies correctness of the algorithm.

The complexity is $O(n \log n)$ since each operation in the priority queue takes $O(\log n)$ time and there are $O(n)$ operations of Extract-Min. ■

```

function HuffmanCost( $S$ )
{Huffman algorithm: recursive version}
{computes only the cost of minimum weighted tree}

1. if  $S$  contains only one element  $u$  then return 0;
2.  $u = \text{Extract Min}(S); w = \text{ExtractMin}(S);$ 
3.  $\text{insert}(u+w, S);$ 
4. return  $HuffmanCost(S) + u + w$ 
  
```

The algorithm in fact computes only the cost of Huffman tree, but the tree can be created on-line in the algorithm. Each time we combine two items we create their father and create links son-father. In the course of the algorithm we keep a forest (collection of trees). Eventually this becomes a single Huffman tree at the end.

15.2.2 Linear Time Algorithm for Presorted Sequence of Items

There is possible an algorithm using “simple” queues with constant time operations of inserting and deleting elements from the queue if the items are *presorted*.

Theorem 15.2

If the weights are already sorted then the Huffman tree can be constructed in linear time.

Proof. If we have sorted queues of remaining original items and remaining newly created items (packages) then it is easy to see that two smallest items can be chosen from among 4 items, two first elements of each queue. This proves correctness.

Linear time follows from constant time costs of single queue operations. ■

Linear-Time Algorithm {linear time computation of the cost for presorted items}

1. initialize empty queues Q, S;
total_cost = 0;
2. place original n weights into nondecreasing order into S;
the smallest elements at the front of S;
3. **while** $|Q| + |S| > 2$ **do** {
 - let u, w be the smallest elements chosen from the first two elements of Q and of S;
 - remove u, w from $Q \cup S$; insert($u + w$, Q);
 - $total_cost = total_cost + (u + w)$;
}
4. **return** total_cost

15.2.3 Relation between General Uniquely Decipherable Codes and Prefix-free Codes

It would seem that, for some weight sequences, in the class of uniquely decipherable codes there are possible codes which beat every Huffman (prefix-free) code. However it happens that prefix-free codes are optimal within the whole class of uniquely decipherable codes. It follows immediately from the next three lemmas.

Lemma 15.1

For each full (each internal node having exactly two sons) binary tree T with leaves $1 \dots n$ we have:

$$\sum_{i=1}^n 2^{-level_T(i)} = 1$$

Proof. Simple induction on n . ■

Lemma 15.2

For each uniquely decipherable code S with word lengths $\ell_1, \ell_2, \dots, \ell_k$ on the alphabet $\{0, 1\}$ we have :

$$\sum_{i=1}^k 2^{-\ell_i} \leq 1$$

Proof. For a set W of words on the alphabet $\{0, 1\}$ define:

$$C(W) = \sum_{x \in W} 2^{-|x|}$$

We have to show that $C(S) \leq 1$. Let us first observe the following simple fact.

Observation.

If S is uniquely decipherable then $C(S)^n = C(S^n)$ for all $n \geq 1$.

The proof that $C(S) \leq 1$ is now by contradiction, assume $C(S) > 1$. Let c be the length of the longest word in S . Observe that

$$C(\Sigma^k) = 1 \text{ for each } k, C(S^n) \leq C(\{x \in \Sigma^* : 1 \leq |x| \leq cn\}) = cn$$

Denote $q = C(S)$. Then we have:

$$C(S)^n = q^n \leq cn$$

For $q > 1$ this inequality is not true for all n , since

$$\lim q^n/(cn) = +\infty \text{ if } q > 1$$

Therefore it should be $q \leq 1$ and $C(S) \leq 1$. This completes the proof. ■

Lemma 15.3

[Kraft's inequality] There is a prefix code with word lengths $\ell_1, \ell_2, \dots, \ell_k$ on the alphabet $\{0, 1\}$ iff

$$\sum_{i=1}^k 2^{-\ell_i} \leq 1 \tag{15.1}$$

Proof. It is enough to show how to construct such a code if the inequality holds. Assume the lengths are sorted in the increasing order. Assume we have a (potentially) infinite full binary tree. We construct the next codeword by going top-down, starting from the root. We assign to the i -th codeword, for $i = 1, 2, 3, \dots, k$, the lexicographically first path of length ℓ_i , such that the bottom node of this path has not been visited before. It is illustrated in [Figure 15.2](#). If the path does not exist then this means that in this moment we covered with paths a full binary tree, and the actual sum equals 1. But some other lengths remained, so it would be :

$$\sum_{i=1}^k 2^{-\ell_i} > 1$$

a contradiction. This proves that the construction of a prefix code works, so the corresponding prefix-free code covering all lengths exists. This completes the proof. ■

The lemmas imply directly the following theorem.

Theorem 15.3

A uniquely decipherable code with prescribed word lengths exists iff a prefix code with the same word lengths exists.

We remark that the problem of testing unique decipherability of a set of codewords is complete in nondeterministic logarithmic space, see [7].

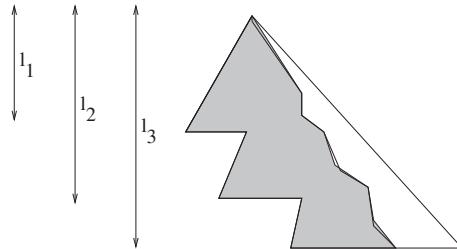

FIGURE 15.2 Graphical illustration of constructing prefix-free code with prescribed lengths sequence satisfying Kraft inequality.

15.2.4 Huffman Codes and Entropy

The performance of Huffman codes is related to a measure of information of the source text, called the *entropy* (denoted by \mathcal{E}) of the alphabet. Let w_a be n_a/N , where n_a is the number of occurrences of a in a given text of length N . In this case the sequence S of weights w_a is normalized $\sum_{i=1}^n w_i = 1$.

The quantity w_a can be now viewed as the probability that letter a occurs at a given position in the text. This probability is assumed to be independent of the position. Then, the entropy of the alphabet according to w_a 's is defined as

$$\mathcal{E}(A) = - \sum_{a \in A} w_a \log w_a.$$

The entropy is expressed in bits (\log is a base-two logarithm). It is a lower bound of the average length of the code words $h(a)$,

$$m(A) = \sum_{a \in A} w_a \cdot |h(a)|.$$

Moreover, Huffman codes give the best possible approximation of the entropy (among methods based on coding of the alphabet). This is summarized in the following theorem whose proof relies on the inequalities from Lemma 15.2.

Theorem 15.4

Assume the weight sequence A of weights is normalized. The total cost $m(A)$ of any uniquely decipherable code for A is at least $\mathcal{E}(A)$, and we have

$$\mathcal{E}(A) \leq \text{HuffmanCost}(A) \leq \mathcal{E}(A) + 1$$

15.2.5 Huffman Algorithm for t -ary Trees

An important generalization of Huffman algorithm is to t -ary trees. Huffman algorithm generalizes to the construction of prefix codes on alphabet of size $t > 2$. The trie of the code is then an *almost full* t -ary tree.

We say that t -ary tree is almost full if all internal nodes have exactly t sons, except possibly one node, which has less sons, in these case all of them should be leaves (let us call this one node a *defect* node).

We perform similar algorithm to Huffman method for binary trees, except that each time we select t items (original or combined) of smallest weight.

There is one technical difficulty. Possibly we start by selecting a smaller number of items in the first step. If we know t and the number of items then it is easy to calculate number q of sons of the defect node, for example if $t = 3$ and $n = 8$ then the defect node has two sons. It is easy to compute the number q of sons of the defect node due to the following simple fact.

Lemma 15.4

If T is a full t -ary tree with m leaves then $m \bmod (t - 1) = 1$.

We start the algorithm by combining q smallest items. Later each time we combine exactly t values. To simplify the algorithm we can add the smallest possible number of dummy items of weight zero to make the tree full t -ary tree.

15.3 Height Limited Huffman Trees

In this section only, for technical reason, we assume that the length of the path is the number of its vertices. For a sequence S of weights the total cost is changed by adding the sum of weights in S .

Assume we have the same problem as in the case of Huffman trees with additional restriction that the height of the tree is limited by a given parameter L . A beautiful algorithm for this problem has been given by Larmore and Hirschberg, see [8].

15.3.1 Reduction to the Coin Collector Problem

The main component of the algorithm is the reduction to the following problem in which the crucial property play powers of two. We call a real number dyadic iff it has a finite binary representation.

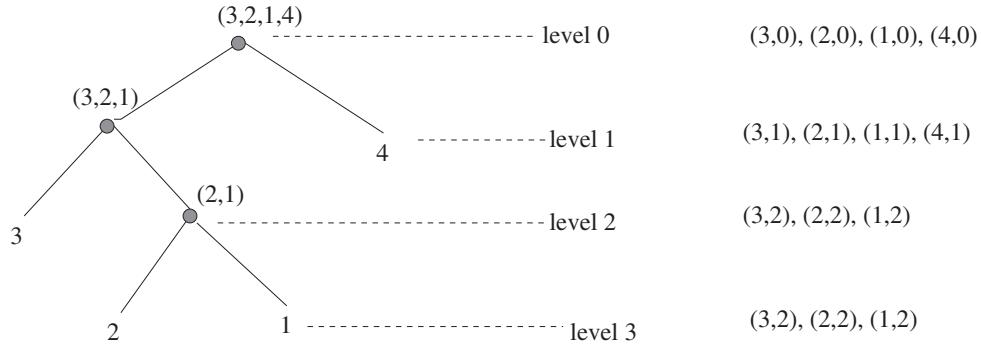

FIGURE 15.3 A Huffman tree T for the items 1, 2, 3, 4 of height limited by 4 and the corresponding solution to the Coin Collector problem. Each node of the tree can be treated as a *package* consisting of leaves in the corresponding subtree. Assume $\text{weight}(i) = i$. Then in the corresponding Coin Collector problem we have $\text{weight}(i, h) = i$, $\text{width}(i, h) = 2^{-h}$.

Coin Collector problem:

Input: A set I of m items and dyadic number X , each element of I has a *width* and a *weight*, where each width is a (possibly negative) power of two, and each weight is a positive real number.

Output: $\text{CoinColl}(I, X)$ - the minimum total weight of a subset $S \subseteq I$ whose widths sum to X .

The following trivial lemma plays important role in the reduction of height limited tree problem to the Coin Collector problem.

Lemma 15.5

Assume T is a full binary tree with n leaves, then

$$\sum_{v \in T} 2^{-\text{level}_T(v)} = n + 1$$

Assume we have Huffman coding problem with n items with the sequence of weights $W = w_1, w_2, \dots, w_n$. We define an instance of the Coin Collector problem as follows:

- $I_W = \{(i, l) : i \in [1 \dots n], l \in [1, \dots L]\}$,
- $\text{width}(i, l) = 2^{-l}$, $\text{weight}(i, l) = w_i$ for each i, l
- $X_W = n + 1$.

The intuition behind this strange construction is to view nodes as packages consisting of original items (elements in the leaves). The internal node v which is a *package* consisting of (leaves in its subtree) items i_1, i_2, \dots, i_k can be treated as a set of coins $(i_1, h), (i_2, h), \dots, (i_k, h)$, where h is the level of v , and $\text{weight}(i_j, h) = \text{weight}(i_j)$. The total weight of the set of coins is the cost of the Huffman tree.

Example Figure 15.3 shows optimal Huffman tree for $S = (1, 2, 3, 4)$ with height limited by 4, and the optimal solution to the corresponding Coin Collector problem. The sum of widths of the coins is $4+1$, and the total weight is minimal. It is the same as the cost of the Huffman tree on the left, assuming that leaves are also contributing their weights (we scale cost by the sum of weights of S).

Hirschberg and Larmore, see [8], have shown the following fact.

Lemma 15.6

The solution $\text{CoinColl}(I_W, X_W)$ to the Coin Collector Problem is the cost of the optimal L -height restricted Huffman tree for the sequence W of weights.

15.3.2 The Algorithm for the Coin Collector Problem

The height limited Huffman trees problem is thus reduced to the Coin Collector Problem. The crucial point in the solution of the latter problem is the fact that weights are powers of two.

Denote $\text{MinWidth}(X)$ to be the smallest power of two in binary representation of number X . For example $\text{MinWidth}(12) = 4$ since $12 = 8 + 4$. Denote by $\text{MinItem}(I)$ the item with the smallest width in I .

Lemma 15.7

If the items are sorted with respect to the weight then the Coin Collector problem can be solved in linear time (with respect to the total number $|I|$ of coins given in the input).

Proof. The recursive algorithm for the Coin Collector problem is presented below as a recursive function $\text{CoinColl}(I, X)$. There are several cases depending on the relation between the smallest width of the item and minimum power of two which constitutes the binary representation of X . In the course of the algorithm the set of weights shrinks as well as the size of X . The linear time implementation of the algorithm is given in References 1. ■

```

function CC( $I, X$ ); {Coin Collector Problem}
  {compute nnimal weight of a subset of  $I$  of total width  $X$ }
   $x := \text{MinItem}(X); r := \text{width}(x);$ 
  if  $r > \text{MinWidth}(X)$  then
    no solution exists else
    if  $r = \text{MinWidth}(X)$  then
      return  $\text{CC}(I - \{x\}, X - r) + \text{weight}(x)$  else
    if  $r < \text{MinWidth}(X)$  and there is only one item of width  $r$  then
      return  $\text{CC}(I - \{x\}, X)$  else
        let  $x, x'$  be two items of smallest weight and width  $r$ ,
        create new item  $y$  such that
         $\text{width}(y) = 2r, \text{weight}(y) = \text{weight}(x) + \text{weight}(x');$ 
      return  $\text{CC}(I - \{x, x'\} \cup \{y\}, X)$ 

```

The last two lemmas imply the following fact.

Theorem 15.5

The problem of the Huffman tree for n items with height limited by L can be solved in $O(n \cdot L)$ time.

Using complicated approach of the Least Weight Concave Subsequence the complexity has been reduced to $n\sqrt{L \log n} + n \log n$ in Reference 9. Another small improvement is by Schieber [10]. An efficient approximation algorithm is given in References 11–13. The dynamic algorithm for Huffman trees is given in Reference 14.

15.4 Optimal Binary Search Trees

Assume we have a sequence of $2n + 1$ weights (nonnegative reals)

$$\alpha_0, \beta_1, \alpha_1, \beta_2, \dots, \alpha_{n-1}, \beta_n, \alpha_n$$

Let $\text{Tree}(\alpha_0, \beta_1, \alpha_1, \beta_2, \dots, \alpha_{n-1}, \beta_n, \alpha_n)$ be the set of all full binary weighted trees with n internal nodes, where the i -th internal node (in the in-order) has the weight β_i , and the i -th external node (the leaf, in the left-to-right order) has the weight α_i . The in-order traversal results if we visit all nodes in a recursive way, first the left subtree, then the root, and afterwards the right subtree.

If T is a binary search tree then define the *cost* of T as follows:

$$\text{cost}(T) = \sum_{v \in T} \text{level}_T(v) \cdot \text{weight}(v).$$

Let $\text{OPT}(\alpha_0, \beta_1, \dots, \alpha_{n-1}, \beta_n, \alpha_n)$ be the set of trees $\text{Tree}(\alpha_0, \beta_1, \dots, \alpha_{n-1}, \beta_n, \alpha_n)$ whose cost is minimal.

We use also terminology from Reference 15. Let K_1, \dots, K_n be a sequence of n weighted items (keys), which are to be placed in a binary search tree. We are given $2n + 1$ weights (probabilities): $q_0, p_1, q_1, p_2, q_2, p_3, \dots, q_{n-1}, p_n, q_n$ where

- p_i is the probability that K_i is the search argument;
- q_i is the probability that the search argument lies between K_i and K_{i+1} .

The OBST problem is to construct an optimal binary search tree, the keys K_i 's are to be stored in internal nodes of this binary search tree and in its external nodes special items are to be stored. The i -th special item K'_i corresponds to all keys which are strictly between K_i and K_{i+1} . The binary search tree is a full binary tree whose nodes are labeled by the keys. Using the abstract terminology introduced above the OBST problem consists of finding a tree $T \in OPT(q_0, p_1, q_1, p_2, \dots, q_{n-1}, p_n, q_n)$, see an example tree in Figure 15.4.

Denote by $obst(i, j)$ the set $OPT(q_i, p_{i+1}, q_{i+1}, \dots, q_{j-1}, p_j, q_j)$. Let $cost(i, j)$ be the cost of a tree in $obst(i, j)$, for $i < j$, and $cost(i, i) = q_i$. The sequence $q_i, p_{i+1}, q_{i+1}, \dots, q_{j-1}, p_j, q_j$ is here the subsequence of $q_0, p_1, q_1, p_2, \dots, q_{n-1}, p_n, q_n$, consisting of some number of consecutive elements which starts with q_i and ends with q_j . Let

$$w(i, j) = q_i + p_{i+1} + q_{i+1} + \dots + q_{j-1} + p_j + q_j$$

The dynamic programming approach to the computation of the OBST problem relies on the fact that the subtrees of an optimal tree are also optimal. If a tree $T \in obst(i, j)$ contains in the root an item K_k then its left subtree is in $obst(i, k - 1)$ and its right subtree is in $obst(k, j)$. Moreover, when we join these two subtrees then the contribution of each node increases by one (as one level is added), so the increase is $w(i, j)$. Hence the costs obey the following *dynamic programming recurrences* for $i < j$:

$$cost(i, j) = \min\{cost(i, k - 1) + cost(k, j) + w(i, j) : i < k \leq j\}.$$

Denote the smallest value of k which minimizes the above equation by $cut(i, j)$. This is the first point giving an optimal decomposition of $obst(i, j)$ into two smaller (son) subtrees. Optimal binary search trees have the following crucial property (proved in Reference 16, see Figure 15.5 for graphical illustration)

$$\text{monotonicity property: } i \leq i' \leq j \leq j' \implies cut(i, j) \leq cut(i', j')$$

The property of monotonicity, the cuts and the quadratic algorithm for the OBST were first given by Knuth. The general dynamic programming recurrences were treated by Yao [17], in the context of reducing cubic time to quadratic.

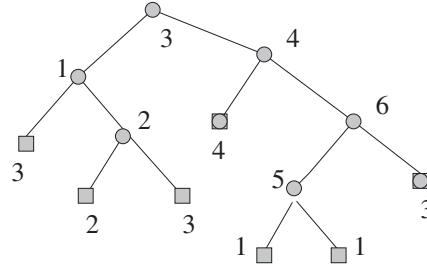

FIGURE 15.4 A binary search tree for the sequences: $\beta = (\beta_1, \beta_2, \dots, \beta_6) = (1, 2, 3, 4, 5, 6)$, $\alpha = (\alpha_0, \alpha_1, \dots, \alpha_6) = (3, 2, 3, 4, 1, 1, 3)$. We have $cut(0, 6) = 3$.

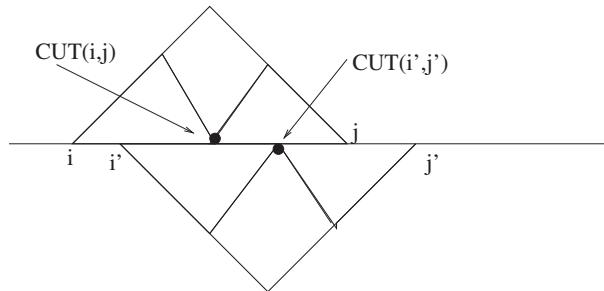

FIGURE 15.5 Graphical illustration of the monotonicity property of cuts.

Theorem 15.6

Optimal binary search trees can be computed in $O(n^2)$ time.

Proof. The values of $\text{cost}(i, j)$ are computed by tabulating them in an array. Such tabulation of costs of smaller subproblems is the basis of the *dynamic programming* technique. We use the same name *cost* for this array. It can be computed in $O(n^3)$ time, by processing diagonal after diagonal, starting with the central diagonal.

In case of optimal binary search trees this can be reduced to $O(n^2)$ using additional tabulated values of the cuts in table *cut*. The k -th diagonal consists of entries i, j such that $j - i = k$. If we have computed cuts for k -th diagonal then for (i, j) on the $(k + 1)$ -th diagonal we know that

$$\text{cut}(i, j - 1) \leq \text{cut}(i, j) \leq \text{cut}(i + 1, j)$$

Hence the total work on the $(k + 1)$ -th diagonal is proportional to the sum of telescoping series:

$$\begin{aligned} & \text{cut}(1, k + 1) - \text{cut}(0, k) + \text{cut}(2, k + 2) - \text{cut}(1, k + 1) + \\ & \text{cut}(3, k + 3) - \text{cut}(2, k + 2) + \dots \text{cut}(n - k, k) - \text{cut}(n - k - 1, k - 1) \end{aligned}$$

which is $O(n)$. Summing over all diagonals gives quadratic total time to compute the tables of cuts and costs. Once the table $\text{cost}(i, j)$ is computed then the construction of an optimal tree can be done in quadratic time by tracing back the values of *cuts*. ■

15.4.1 Approximately Optimal Binary Search Trees

We can attempt to reduce time complexity at the cost of slightly increased cost of the constructed tree. A common-sense approach would be to insert the keys in the order of decreasing frequencies. However this method occasionally can give quite bad trees.

Another approach would be to choose the root so that the total weights of items in the left and right trees are as close as possible. However it is not so good in pessimistic sense.

The combination of this methods can give quite satisfactory solutions and the resulting algorithm can be linear time, see [18]. Average subquadratic time has been given in Reference 19.

15.5 Optimal Alphabetic Tree Problem

The alphabetic tree problem looks very similar to the Huffman problem, except that the leaves of the alphabetic tree (read left-to-right) should be in the same order as in the original input sequence. Similarly as in Huffman coding the binary tree must be *full*, that is, each internal node must have exactly two sons.

The main difficulty is that we cannot localize easily two items which are to be combined.

Assume we have a sequence of n weighted items, where w_i is the non-negative *weight* of the i^{th} item. We write $\alpha = w_1 \dots w_n$. The sequence will be changing in the course of the algorithm.

An alphabetic tree over α is an ordered binary tree T with n leaves, where the i^{th} leaf (in left-to-right order) corresponds to the i^{th} item of The optimal alphabetic tree problem (OAT problem) is to find an alphabetic tree of minimum cost.

The Garsia-Wachs algorithm solves the alphabetic tree problem, it is a version of an earlier algorithm by Hu and Tucker, see [4]. The strangest part of the algorithm is that it permutes α , though the final tree should have the order of leaves the same as the order of items in the original sequence. We adopt the convention that the items of α have unique names, and that these names are preserved when items are moved. When convenient to do so, we will assume that those names are the positions of items in the list, namely integers in $[1 \dots n]$.

15.5.1 Computing the Cost of Optimal Alphabetic Tree

First we show how to compute only the cost of the whole tree, however this computation does not give automatically an optimal alphabetic tree, since we will be permuting the sequence of items. Each time we combine two adjacent items in the current permutation, however these items are not necessarily adjacent in the original sequence, so in any legal alphabetic tree they cannot be sons of a same father.

The alphabetic tree is constructed by reducing the initial sequence of items to a shorter sequence in a manner similar to that of the Huffman algorithm, with one important difference. In the Huffman algorithm, the minimum pair of items are combined, because it can be shown that they are siblings in the optimal tree. If we could identify two adjacent items that are siblings in the optimal alphabetic tree, we could combine them and then proceed recursively. Unfortunately, there is no known way to identify such a pair. Even a minimal pair may not be siblings. Consider the weight sequence $(8 \ 7 \ 7 \ 8)$. The second and the third items are not siblings in any optimal alphabetic tree.

Instead, the HT and GW algorithms, as well as the algorithms of [6,20–22], operate by identifying a pair of items that have the same level in the optimal tree. These items are then combined into a single “package,” reducing the number of items by one. The details on how this process proceeds differ in the different algorithms. Define, for $1 \leq i < n$, the i^{th} two-sum:

$$\text{TwoSum}(i) = w_i + w_{i+1}$$

A pair of adjacent items $(i, i + 1)$ is a *locally minimal pair* (or *lmp* for short) if

$$\begin{array}{lll} \text{TwoSum}(i-1) & \geq & \text{TwoSum}(i) & \text{if } i > 1 \\ \text{TwoSum}(i) & < & \text{TwoSum}(i+1) & \text{if } i \leq n-2 \end{array}$$

A locally minimal pair which is currently being processed is called the *active pair*.

The Operator Move. If w is any item in a list π of weighted items, define $\text{RightPos}(w)$ to be the predecessor of the nearest right larger or equal neighbor of w . If w has no right larger or equal neighbor, define $\text{RightPos}(w)$ to be $|\pi| + 1$.

Let $\text{Move}(w, \pi)$ be the operator that changes π by moving w if w is inserted between positions $\text{RightPos}(w) - 1$ and $\text{RightPos}(w)$. For example

$$\text{Move}(7, (2, 5, 7, 2, 4, 9, 3, 4)) = (2, 5, 2, 4, 7, 9, 3, 4)$$

```

function GW( $\pi$ ); { $\pi$  is a sequence of names of items}
  {restricted version of the Garsia-Wachs algorithm}
  {computing only the cost of optimal alphabetic tree}
  if  $\pi = (\nu)$  ( $\pi$  consists of a single item)
  then return 0
  else
    find any locally minimal pair  $(u, w)$  of  $\pi$ 
    create a new item  $x$  whose weight is  $\text{weight}(u) + \text{weight}(w)$ ;
    replace the pair  $u, v$  by the single item  $x$ ;
    {the items  $u, v$  are removed}
     $\text{Move}(v, \pi)$ ;
    return GW( $\pi$ ) +  $\text{weight}(v)$ ;

```

Correctness of the algorithm is a complicated issue. There are two simplified proofs, see [23,24] and we refer to these papers for detailed proof. In Reference 23 only the rightmost minimal pair can be processed each time, while [24] gives correctness of general algorithm when any minimal pair is processed, this is important in parallel computation, when we process simultaneously many such pairs. The proof in Reference 24 shows that correctness is due to *well-shaped* bottom segments of optimal alphabetic trees, this is expressed as a *structural theorem* in Reference 24 which gives more insight into the global structure of optimal alphabetic trees.

For $j > i + 1$ denote by $\pi_{i,j}$ the sequence π in which elements $i, i + 1$ are moved just before left of j .

Theorem 15.7

[Correctness of the GW algorithm]

Let $(i, i + 1)$ be a locally minimal pair and $\text{RightPos}(i, i + 1) = j$, and let T' be a tree over the sequence $\pi_{i,j}$, optimal among all trees over $\pi_{i,j}$ in which $i, i + 1$ are siblings. Then there is an optimal alphabetic tree T over the original sequence $\pi = (1, \dots, n)$ such that $T \cong T'$.

Correctness can be also expressed as equivalence between some classes of trees.

Two binary trees T_1 and T_2 are said to be **level equivalent** (we write $T_1 \cong T_2$) if T_1 , and T_2 have the same set of leaves (possibly in a different order) and $\text{level}_{T_1} = \text{level}_{T_2}$.

Denote by $\text{OPT}(i)$ the set of all alphabetic trees over the leaf-sequence $(1, \dots, n)$ which are optimal among trees in which i and $i + 1$ are at the same level. Assume the pair $(i, i + 1)$ is locally minimal. Let $\text{OPT}_{\text{moved}}(i)$ be the set of all alphabetic trees over the leaf-sequence $\pi_{i,j}$ which are optimal among all trees in which leaves i and $i + 1$ are at the same level, where $j = \text{RightPos}(i, i + 1)$.

Two sets of trees OPT and OPT' are said to be *level equivalent*, written $\text{OPT} \cong \text{OPT}'$, if, for each tree $T \in \text{OPT}$, there is a tree $T' \in \text{OPT}'$ such that $T' \cong T$, and vice versa.

Theorem 15.8

Let $(i, i + 1)$ be a locally minimal pair. Then

1. $\text{OPT}(i) \cong \text{OPT}_{\text{moved}}(i)$.
2. $\text{OPT}(i)$ contains an optimal alphabetic tree T .
3. $\text{OPT}_{\text{moved}}(i)$ contains a tree T' with $i, i + 1$ as siblings.

15.5.2 Construction of Optimal Alphabetic Tree

The full Garsia-Wachs algorithm first computes the level tree. This tree can be easily constructed in the function $GW(\pi)$ when computing the cost of alphabetic tree. Each time we sum weights of two items (original or newly created) then we create new item which is their father with the weight being the sum of weights of sons.

Once we have a level tree, the optimal alphabetic tree can be constructed easily in linear time. Figures 15.6 through 15.8 show the process of construction the level tree and construction an optimal alphabetic tree knowing the levels of original items.

Lemma 15.8

Assume we know level of each leaf in an optimal alphabetic tree. Then the tree can be constructed in linear time.

Proof. The levels give the “shape” of the tree, see Figure 15.8.

Assume $l_1, l_2, l_3, \dots, l_n$ is the sequence of levels. We scan this sequence from left-to-right until we find *the first* two levels l_i, l_{i+1} which are the same. Then we know that the leaves i and $i + 1$ are sons of a same father, hence we link these leaves to a newly created father and we remove these leaves, in the level sequence the pair l_i, l_{i+1} is replaced by a single level $l_i - 1$. Next we check if $l_{i-1} = l_i - 1$, if not we search to the right. We keep the scanned and newly created levels on the stack. The total time is linear. ■

There are possible many different optimal alphabetic trees for the same sequence, Figure 15.9 shows an alternative optimal alphabetic tree for the same example sequence.

Theorem 15.9

Optimal alphabetic tree can be constructed in $O(n \log n)$ time.

Proof. We keep the array of levels of items. The array *level* is global of size $(2n - 1)$. Its indices are the names of the nodes, that is, the original n items and the $(n - 1)$ nodes (“packages”) created during execution of the algorithm. The algorithm works in quadratic time, if implemented in a naive way. Using priority queues, it works in $O(n \log n)$ time. Correctness follows directly from Theorem 15.7. ■

15.5.3 Optimal Alphabetic Trees for Presorted Items

We have seen that Huffman trees can be constructed in linear time if the weights are presorted. Larmore and Przytycka, see [21] have shown that slightly weaker similar result holds for alphabetic trees as well:

assume that weights of items are sortable in linear time, then the alphabetic tree problem can be solved in $O(n \log \log n)$ time.

Open problem Is it possible to construct alphabetic trees in linear time in the case when the weights are sortable in linear time?

15.6 Optimal Lopsided Trees

The problem of finding optimal prefix-free codes for unequal letter costs consists of finding a minimal cost prefix-free code in which the encoding alphabet consists of unequal cost (length) letters, of lengths α and β , $\alpha \leq \beta$. We restrict ourselves here only to binary trees. The code is represented by a *lopsided tree*, in the same way as a Huffman tree represents the solution of the Huffman coding problem. Despite the similarity, the case of unequal letter costs is much harder than the classical Huffman problem; no polynomial time algorithm is known for general letter costs, despite a rich literature on the problem, for example, [25,26]. However there are known polynomial time algorithms when α and β are integer constants [26].

The problem of finding the minimum cost tree in this case was first studied by Karp [27] in 1961 who solved the problem by reduction to integer linear programming, yielding an algorithm exponential in both n and β . Since that time there has been much work on various aspects of the problem such as; bounding the cost of the optimal tree, Altenkamp and Mehlhorn [28], Kapoor

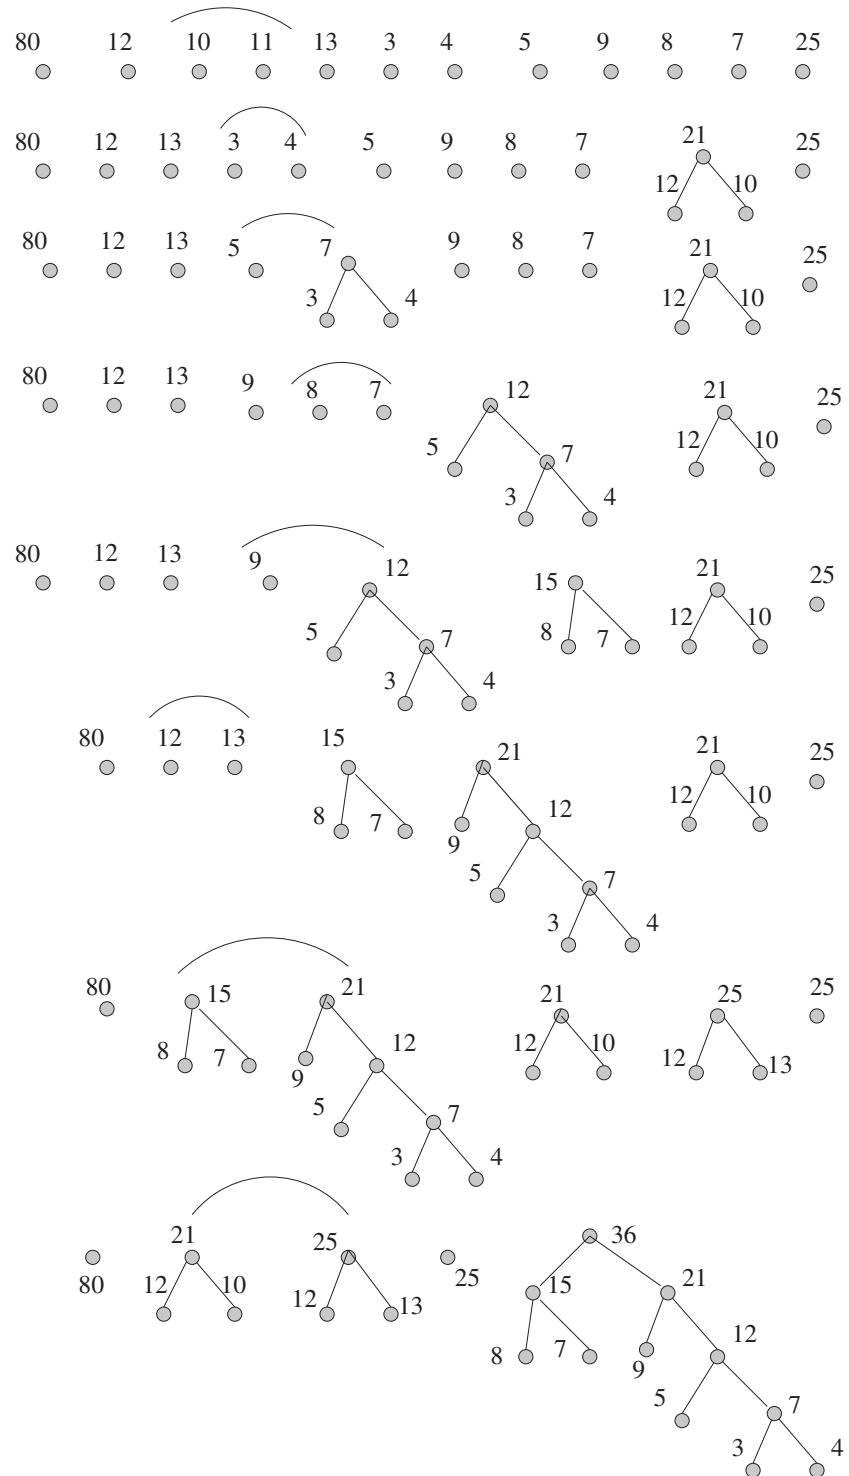

FIGURE 15.6 The first 7 phases of Garsia-Wachs algorithm.

and Reingold [29] and Savari [30]; the restriction to the special case when all of the weights are equal, Cot [31], Perl Gary and Even [32], and Choi and Golin [33]; and approximating the optimal solution, Gilbert [34]. Despite all of these efforts it is still, surprisingly, not even known whether the basic problem is polynomial-time solvable or in NP -complete.

Golin and Rote [26] describe an $O(n^{\beta+2})$ -time dynamic programming algorithm that constructs the tree in a top-down fashion.

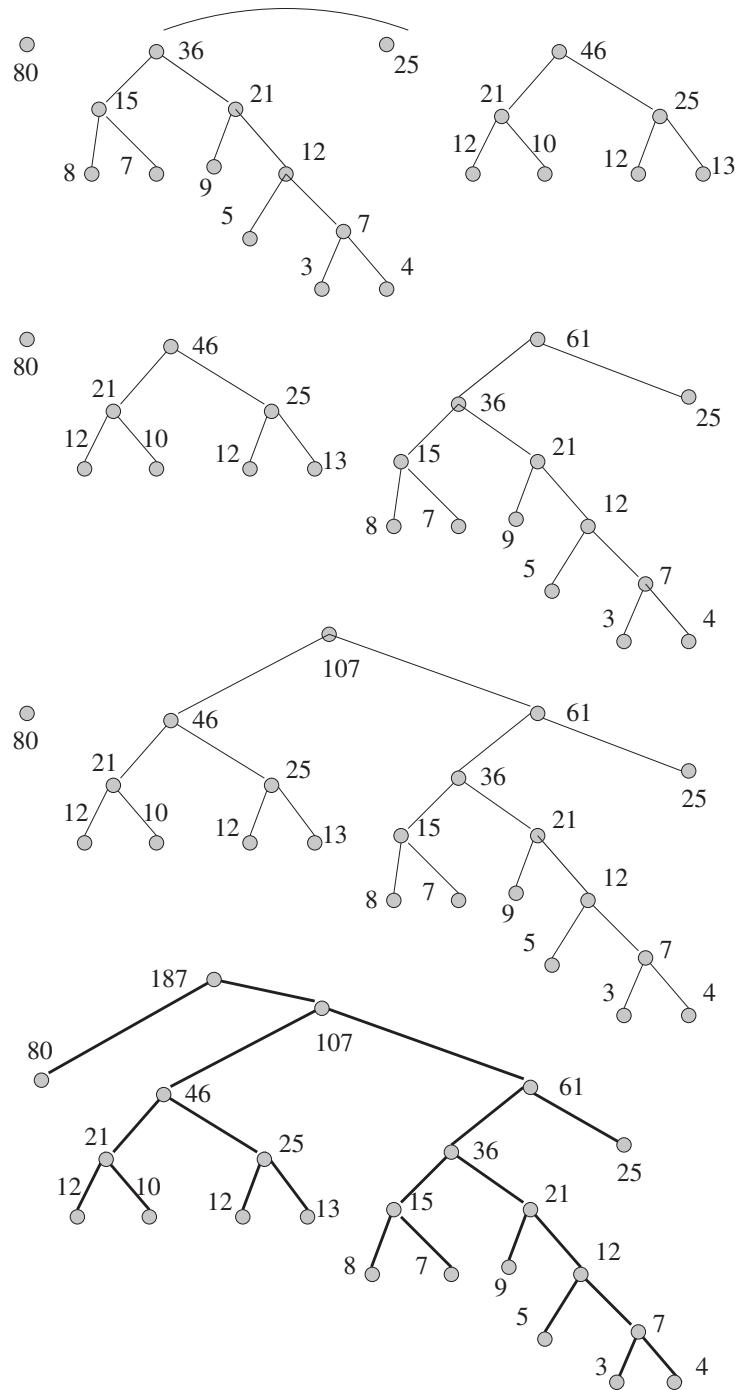

FIGURE 15.7 The last phases of Garsia-Wachs algorithm. The final tree is the level tree (but not alphabetic tree). The total cost (sum of values in internal nodes equal to 538) and the levels of original items are the same as in optimal alphabetic tree. The level sequence for the original sequence (80, 12, 10, 11, 13, 3, 4, 5, 9, 8, 7, 25) is: $\mathcal{L} = (1, 4, 4, 4, 4, 7, 7, 6, 5, 5, 3)$.

This has been improved using a different approach (monotone-matrix concepts, for example, the *Monge property* and the SMAWK algorithm [35]).

Theorem 15.10: [5]

Optimal lopsided trees can be constructed in $O(n^\beta)$ time.

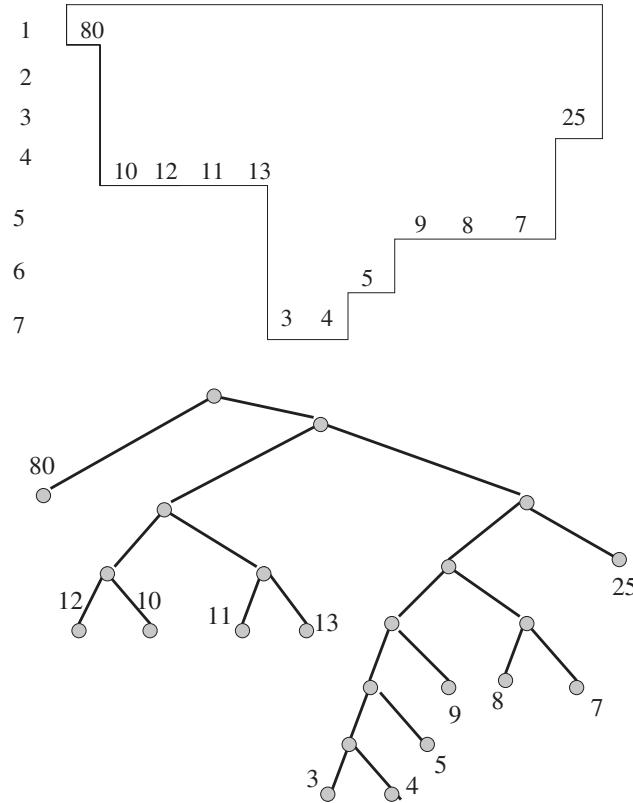

FIGURE 15.8 The shape of the optimal tree given by the level sequence and the final optimal alphabetic tree (cost = 538) corresponding to this shape and to the weight sequence (80, 12, 10, 11, 13, 3, 4, 5, 9, 8, 7, 25).

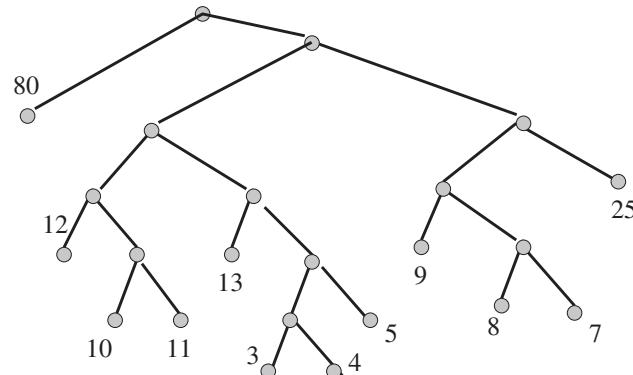

FIGURE 15.9 An alternative optimal alphabetic tree (cost = 538) for the same weight sequence.

This is the most efficient known algorithm for the case of small β ; in practice the letter costs are typically small (e.g., Morse codes).

Recently a scheme of an efficient approximating algorithm has been given.

Theorem 15.11: [36]

There is a polynomial time approximation scheme for optimal lopsided trees.

15.7 Parallel Algorithms

As a model of parallel computations we choose the *Parallel Random Access Machines* (PRAM), see [37]. From the point of view of parallel complexity two parameters are of interest: parallel time (usually we require polylogarithmic time) and total work (time multiplied by the number of processors).

The sequential greedy algorithm for Huffman coding is quite simple, but unfortunately it appears to be inherently sequential. Its parallel counterpart is much more complicated, and requires a new approach. The global structure of Huffman trees must be explored in depth.

A full binary tree T is said to be *left-justified* if it satisfies the following properties:

1. the depths of the leaves are in non-increasing order from left to right,
2. let u be a left brother of v , and assume that the height of the subtree rooted at v is at least l . Then the tree rooted at u is full at level l , which means that u has 2^l descendants at distance l .

15.7.1 Basic Property of Left-Justified Trees

Let T be a left-justified binary tree. Then, T consists of one leftmost branch and the subtrees hanging from this branch have logarithmic height.

Lemma 15.9

Assume that the weights w_1, w_2, \dots, w_n are pairwise distinct and in increasing order. Then, there is Huffman tree for (w_1, w_2, \dots, w_n) that is left-justified.

The left-justified trees are used together with efficient algorithm for the CLWS problem (the *Concave Least Weight Subsequence* problem, to be defined below) to show the following fact.

Theorem 15.12: [38]

The parallel Huffman coding problem can be solved in polylogarithmic time with quadratic work.

Hirschberg and Larmore [8] define the *Least Weight Subsequence* (LWS) problem as follows: Given an integer n , and a real-valued weight function $w(i, j)$ defined for integers $0 \leq i < j \leq n$, find a sequence of integers $\bar{\alpha} = (0 = \alpha_0 < \alpha_1 < \dots < \alpha_{k-1} < \alpha_k = n)$ such that $w(\bar{\alpha}) = \sum_{i=0}^{k-1} w(\alpha_i, \alpha_{i+1})$ is minimized. Thus, the LWS problem reduces trivially to the minimum path problem on a weighted directed acyclic graph. The *Single Source* LWS problem is to find such a minimal sequence $0 = \alpha_0 < \alpha_1 < \dots < \alpha_{k-1} < \alpha_k = m$ for all $m \leq n$. The weight function is said to be *concave* if for all $0 \leq i_0 \leq i_1 < j_0 \leq j_1 \leq n$,

$$w(i_0, j_0) + w(i_1, j_1) \leq w(i_0, j_1) + w(i_1, j_0). \quad (15.2)$$

The inequality (15.2) is also called the *quadrangle inequality* [17].

The LWS problem with the restriction that the weight function is concave is called the *Concave Least Weight Subsequence* (CLWS) problem. Hirschberg and Larmore [8] show that the LWS problem can be solved in $O(n^2)$ sequential time, while the CLWS problem can be solved in $O(n \log n)$ time. Wilber [39] gives an $O(n)$ -time algorithm for the CLWS problem.

In the parallel setting, the CLWS problem seems to be more difficult. The best current polylogarithmic time algorithm for the CLWS problem uses concave matrix multiplication techniques and requires $O(\log^2 n)$ time with $n^2/\log^2 n$ processors.

Larmore and Przytycka [40] have shown how to compute efficiently CLWS in sublinear time with the total work smaller than quadratic. Using this approach they showed the following fact (which has been later slightly improved [41,42]).

Theorem 15.13

Optimal Huffman tree can be computed in $O(\sqrt{n} \log n)$ time with linear number of processors.

Karpinski and Nekrich have shown an efficient parallel algorithm which *approximates* optimal Huffman code, see [43]. Similar, but much more complicated algorithm works for alphabetic trees. Again the CLWS algorithm is the main tool.

Theorem 15.14: [6]

Optimal alphabetic tree can be constructed in polylogarithmic time with quadratic number of processors.

In case of general binary search trees the situation is more difficult. Polylogarithmic time algorithms need huge number of processors. However sublinear parallel time is easier.

Theorem 15.15: [44,45]

The OBST problem can be solved in (a) polylogarithmic time with $O(n^6)$ processors, (b) in sublinear time and quadratic total work.

16.1 Introduction

We have seen binary search trees in [Chapters 3 and 11](#). When data volume is large and does not fit in memory, an extension of the binary search tree to disk-based environment is the B-tree, originally invented by Bayer and McCreight [1]. In fact, since the B-tree is always balanced (all leaf nodes appear at the same level), it is an extension of the *balanced* binary search tree. Since each disk access exchanges a whole block of information between memory and disk rather than a few bytes, a node of the B-tree is expanded to hold more than two child pointers, up to the block capacity. To guarantee worst-case performance, the B-tree requires that every node (except the root) has to be at least half full. An exact match query, insertion or deletion need to access $O(\log_B n)$ nodes, where B is the page capacity in number of child pointers, and n is the number of objects.

Nowadays, every database management system (see [Chapter 62](#) for more on applications of data structures to database management systems) has implemented the B-tree or its variants. Since the invention of the B-tree, there have been many variations proposed. In particular, Knuth [2] defined the B*-tree as a B-tree in which every node has to be at least 2/3 full (instead of just 1/2 full). If a page overflows during insertion, the B*-tree applies a local redistribution scheme to delay splitting the node till two another sibling node is also full. At this time, the two nodes are split into three. Perhaps the best variation of the B-tree is the B+-tree, whose idea was originally suggested by Knuth [2], but whose name was given by Comer [3]. (Before Comer, Knuth used the name B*-tree to represent both B*-tree and B+-tree.) In a B+-tree, every object stays at the leaf level. Update and query algorithms need to be modified from those of the original B-tree accordingly.

The idea of the B-tree also motivates the design of many other disk-based index structures like the R-tree [4], the state-of-art spatial index structure ([Chapter 22](#)).

In this chapter, we describe the B-tree and B+-tree in more detail. In Section 16.2, we briefly describe the disk-based environment and we introduce some notations. The B-tree is described in section 16.3, while the B+-tree is described in Section 16.4. Finally, in Section 16.5 we further discuss some related issues.

16.2 The Disk-Based Environment

Most application software deal with data. For instance, a registration application may keep the name, address and social security number of all students. The data has to be stored somewhere. There are three levels of storage. The computer CPU deals directly with the **primary storage**, which means the main memory (as well as cache). While data stored at this level can be accessed quickly,

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

† We have used this author's affiliation from the first edition of this handbook, but note that this may have changed since then.

we cannot store everything in memory for two reasons. First, memory is expensive. Second, memory is volatile, that is, if there is a power failure, information stored in memory gets lost.

The **secondary storage** stands for magnetic disks. Although it has slower access, it is less expensive and it is non-volatile. This satisfies most needs. For data which do not need to be accessed often, they can also be stored in the **tertiary storage**, for example, tapes.

Since the CPU does not deal with disk directly, in order for any piece of data to be accessed, it has to be read from disk to memory first. Data is stored on disk in units called **blocks** or **pages**. Every disk access has to read/write one or multiple blocks. That is, even if we need to access a single integer stored in a disk block which contains thousands of integers, we need to read the whole block in. This tells us why internal memory data structures cannot be directly implemented as external-memory index structures.

Consider the binary search tree as an example. Suppose we implement every node as a disk block. The storage would be very inefficient. If a disk page is 8 KB (=8192 bytes), while a node in the binary search tree is 16 bytes (four integers: a key, a value, and two child pointers), we know every page is only 0.2% full. To improve space efficiency, we should store multiple tree nodes in one disk page. However, the query and update will still be inefficient. The query and update need to access $O(\log_2 n)$ nodes, where n is the number of objects. Since it is possible that every node accessed is stored in a different disk page, we need to access $O(\log_2 n)$ disk pages. On the other hand, the B-tree query/update needs to access only $O(\log_B n)$ disk pages, which is a big improvement. A typical value of B is 100. Even if there are as many as billions of objects, the height of a B-tree, $\log_B n$, will be at most 4 or 5.

A fundamental question that the database research addresses is how to reduce the gap between memory and disk. That is, given a large amount of data, how to organize them on disk in such a way that they can efficiently be updated and retrieved. Here we measure efficiency by counting the total number of disk accesses we make. A disk access can be either a read or a write operation. Without going into details on how the data is organized on disk, let's make a few assumptions. First, assume each disk page is identified by a number called its *pageID*. Second, given a *pageID*, there is a function *DiskRead* which reads the page into memory. Correspondingly, there is a *DiskWrite* function which writes the in-memory page onto disk. Third, we are provided two functions which allocate a new disk page and deallocate an existing disk page.

The four functions are listed below.

- **DiskRead:** given a *pageID*, read the corresponding disk page into memory and return the corresponding memory location.
- **DiskWrite:** given the location of an in-memory page, write the page to disk.
- **AllocatePage:** find an unoccupied *pageID*, allocate space for the page in memory and return its memory location.
- **DeallocatePage:** given a *pageID*, mark the corresponding disk page as being unoccupied.

In the actual implementation, we should utilize a memory buffer pool. When we need to access a page, we should first check if it is already in the buffer pool, and we access the disk only when there is a buffer miss. Similarly, when we want to write a page out, we should write it to the buffer pool. An actual *DiskWrite* is performed under two circumstances: (a) The buffer pool is full and one page needs to be switched out of buffer. (b) The application program terminates. However, for our purposes we do not differentiate disk access and buffer pool access.

16.3 The B-tree

The problem which the B-tree aims to solve is: given a large collection of objects, each having a *key* and an *value*, design a disk-based index structure which efficiently supports query and update.

Here the query that is of interest is the *exact-match query*: given a key k , locate the value of the object with $\text{key} = k$. The update can be either an insertion or a deletion. That is, insert a new object into the index, or delete from the index an object with a given key.

16.3.1 B-tree Definition

A B-tree is a tree structure where every node corresponds to a disk page and which satisfies the following properties:

- A node (leaf or index) x has a value $x.\text{num}$ as the number of objects stored in x . It also stores the list of $x.\text{num}$ objects in increasing key order. The key and value of the i^{th} object ($1 \leq i \leq x.\text{num}$) are represented as $x.\text{key}[i]$ and $x.\text{value}[i]$, respectively.
- Every leaf node has the same depth.
- An index node x stores, besides $x.\text{num}$ objects, $x.\text{num}+1$ child pointers. Here each child pointer is a *pageID* of the corresponding child node. The i^{th} child pointer is denoted as $x.\text{child}[i]$. It corresponds to a key range $(x.\text{key}[i-1], x.\text{key}[i])$. This means that in the i^{th} sub-tree, any object key must be larger than $x.\text{key}[i-1]$ and smaller than $x.\text{key}[i]$. For instance,

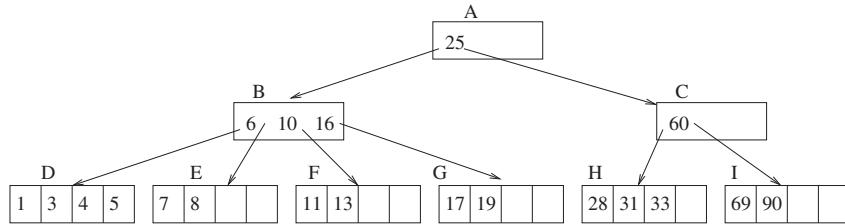

FIGURE 16.1 An example of a B-tree.

in the sub-tree referenced by $x.child[1]$, the object keys are smaller than $x.key[1]$. In the sub-tree referenced by $x.child[2]$, the objects keys are between $x.key[1]$ and $x.key[2]$, and so on.

- Every node except the root node has to be at least half full. That is, suppose an index node can hold up to $2B$ child pointers (besides, of course, $2B - 1$ objects), then any index node except the root must have at least B child pointers. A leaf node can hold more objects, since no child pointer needs to be stored. However, for simplicity we assume a leaf node holds between B and $2B$ objects.
- If the root node is an index node, it must have at least two children.

A special case of the B-tree is when $B = 2$. Here every index node must have 2 or 3 or 4 child pointers. This special case is called the **2-3-4 tree**.

Figure 16.1 shows an example of a B-tree. In particular, it's a 2-3-4 tree.

In the figure, every index node contains between 2 and 4 child pointers, and every leaf node contains between 2 and 4 objects. The root node A is an index node. Currently it has one object with key=25 and two child pointers. In the left sub-tree, every object has key<25. In the right sub-tree, every object has key>25. Every leaf node (D through I) are located at the same depth: their distance to A is 2. Currently, there are two pages which are full: an index node B and a leaf node D.

16.3.2 B-tree Query

To find the value of an object with $key=k$, we call the *Query* algorithm given below. The parameters are the tree root pageID and the search key k . The algorithm works as follows. It follows (at most) a single path from root to leaf. At each index node along the path, there can be at most one sub-tree whose key range contains k . A recursive call on that sub-tree is performed (step 2c). Eventually, we reach a leaf node (step 3a). If there exists an object in the node with $key=k$, the algorithm returns the value of the object. Otherwise, the object does not exist in the tree and *NULL* is returned. Since the index nodes of the B-tree also stores objects, it is possible that the object with $key=k$ is found in an index node. In this case, the algorithm returns the object value without going down to the next level (step 2a).

Algorithm *Query*(*pageID*, k)

Input: *pageID* of a B-tree node, a key k to be searched.

Output: *value* of the object with $key=k$; *NULL* if non-exist.

1. $x = DiskRead(pageID)$.
2. **if** x is an index node
 - a. If there is an object o in x s.t. $o.key = k$, return $o.value$.
 - b. Find the child pointer $x.child[i]$ whose key range contains k .
 - c. **return** *Query*($x.child[i]$, k).
3. **else**
 - a. If there is an object o in x s.t. $o.key = k$, return $o.value$. Otherwise, return *NULL*.
4. **end if**

As an example, Figure 16.2 shows how to perform a search query for $k = 13$. At node A, we should follow the left sub-tree since $k < 25$. At node B, we should follow the third sub-tree since $10 < k < 16$. Now we reach a leaf node F. An object with $key=13$ is found in the node.

If the query wants to search for $k = 12$, we still examine the three nodes A, B, F. This time, no object with $key=12$ is found in F, and thus the algorithm returns *NULL*. If the search key is 10 instead, the algorithm only examines node A and B. Since in node B such an object is found, the algorithm stops there.

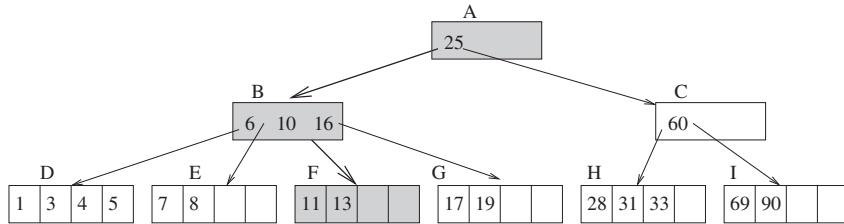

FIGURE 16.2 Query processing in a B-tree.

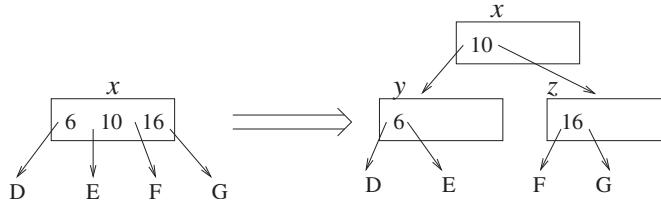

FIGURE 16.3 Splitting the root node increases the height of the tree.

Notice that in the Query algorithm, only *DiskRead* function is called. The other three functions, for example, *DiskWrite* are not needed as the algorithm does not modify the B-tree. Since the query algorithm examines a single path from root to leaf, the complexity of the algorithm in number of I/Os is $O(\log_B n)$, where n is the number of objects.

16.3.3 B-tree Insertion

To insert a new object with key k and value v into the index, we call the *Insert* algorithm given below.

Algorithm *Insert*($root, k, v$)

Input: $root$ pageID of a B-tree, the key k and the value v of a new object.

Prerequisite: The object does not exist in the tree.

Action: Insert the new object into the B-tree.

1. $x = \text{DiskRead}(root)$.
2. **if** x is full
 - a. $y = \text{AllocatePage}()$, $z = \text{AllocatePage}()$.
 - b. Locate the middle object o_i stored in x . Move the objects to the left of o_i into y . Move the objects to the right of o_i into z . If x is an index page, also move the child pointers accordingly.
 - c. $x.\text{child}[1] = y.\text{pageID}$, $x.\text{child}[2] = z.\text{pageID}$.
 - d. $\text{DiskWrite}(x)$, $\text{DiskWrite}(y)$, $\text{DiskWrite}(z)$.
3. **end if**
4. $\text{InsertNotFull}(x, k, v)$.

Basically, the algorithm makes sure that root page is not currently full, and then it calls the *InsertNotFull* function to insert the object into the tree. If the root page x is full, the algorithm will split it into two nodes y and z , and node x will be promoted to a higher level, thus increasing the height of the tree.

This scenario is illustrated in Figure 16.3. Node x is a full root page. It contains three objects and four child pointers. If we try to insert some record into the tree, the root node is split into two nodes y and z . Originally, x contains $x.\text{num} = 3$ objects. The left object (key=6) is moved to a new node y . The right object (key=16) is moved to a new node z . The middle object (key=10) remains in x . Correspondingly, the child pointers D, E, F, G are also moved. Now, x contains only one object (key=10). We make it as the new root, and make y and z be the two children of it.

To insert an object into a sub-tree rooted by a non-full node x , the following algorithm *InsertNotFull* is used.

Algorithm *InsertNotFull*(x, k, v)

Input: an in-memory page x of a B-tree, the key k and the value v of a new object.

Prerequisite: page x is not full.

Action: Insert the new object into the sub-tree rooted by x .

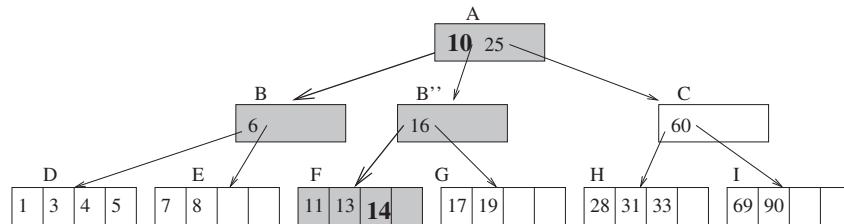

FIGURE 16.4 Inserting an object with key=14 into the B-tree of Figure 16.2 Since node B is full, it is split into two (B and B''). The object is recursively inserted into the sub-tree rooted by B'' . At the lowest level, it is stored in node F.

1. **if** x is a leaf page
 - a. Insert the new object into x , keeping objects in sorted order.
 - b. $DiskWrite(x)$.
2. **else**
 - a. Find the child pointer $x.child[i]$ whose key range contains k .
 - b. $w = DiskRead(x.child[i])$.
 - c. **if** w is full
 - i. $y = AllocatePage()$.
 - ii. Locate the middle object o_j stored in w . Move the objects to the right of o_j into y . If w is an index page, also move the child pointers accordingly.
 - iii. Move o_j into x . Accordingly, add a child pointer in x (to the right of o_j) pointing to y .
 - iv. $DiskWrite(x), DiskWrite(y), DiskWrite(w)$.
 - v. If $k < o_j.key$, call $InsertNotFull(w, k, v)$; otherwise, call $InsertNotFull(y, k, v)$.
 - d. **else**
 - $InsertNotFull(w, k, v)$.
 - e. **end if**
3. **end if**

Algorithm $InsertNotFull$ examines a single path from root to leaf, and eventually insert the object into some leaf page. At each level, the algorithm follows the child pointer whose key range contains the key of the new object (step 2a). If no node along the path is full, the algorithm recursively calls itself on each of these nodes (step 2d) till the leaf level, where the object is inserted into the leaf node (step 1).

Consider the other case when some node w along the path is full (step 2c). The node is first split into two (w and y). The right half of the objects from w are moved to y , while the middle object is pushed into the parent node. After the split, the key range of either w or y , but not both, contains the key of the new object. A recursive call is performed on the correct node.

As an example, consider inserting an object with key=14 into the B-tree of Figure 16.2. The result is shown in Figure 16.4. The child pointers that are followed are thick. When we examine the root node A, we follow the child pointer to B. Since B is full, we first split it into two, by moving the right half of the objects (only one object in our case, with key=16) into a new node B'' . The child pointers to F and G are moved as well. Further, the previous middle object in B (key=10) is moved to the parent node A. A new child pointer to B'' is also generated in A. Now, since the key of the new object is 14, which is bigger than 10, we recursively call the algorithm on B'' . At this node, since $14 < 16$, we recursively call the algorithm on node F. Since F is a leaf node, the algorithm finishes by inserting the new object into F. The accessed disk pages are shown as shadowed.

16.3.4 B-tree Deletion

This section describes the $Delete$ algorithm which is used to delete an object with key= k from the B-tree. It is a recursive algorithm. It takes (besides k) as parameter a tree node, and it will perform deletion in the sub-tree rooted by that node.

We know that there is a single path from the root node to the node x that contains k . The $Delete$ algorithm examines this path. Along the path, at each level when we examine node x , we first make sure that x has at least one more element than half full (except the case when x is the root). The reasoning behind this is that in order to delete an element from the sub-tree rooted by x , the number of element stored in x can be reduced at most by one. If x has one more element than half full (minimum occupancy), it can be guaranteed that x will not underflow. We distinguish three cases:

1. x is a leaf node;

2. x is an index node which contains an object with key = k ;
3. x is an index node which does not contain an object with key = k .

We first describe the *Delete* algorithm and then discuss the three cases in more detail.

Algorithm *Delete*(x, k)

Input: an in-memory node x of a B-tree, the key k to be deleted.

Prerequisite: an object with key = k exists in the sub-tree rooted by x .

Action: Delete the object from the sub-tree rooted by x .

1. **if** x is a leaf page
 - a. Delete the object with key = k from x .
 - b. *DiskWrite*(x).
2. **else if** x does not contain the object with key = k
 - a. Locate the child $x.child[i]$ whose key range contains k .
 - b. $y = \text{DiskRead}(x.child[i])$.
 - c. **if** y is exactly half full
 - i. If the sibling node z immediate to the left (right) of y has at least one more object than minimally required, add one more object to y by moving $x.key[i]$ from x to y and move that last (first) object from z to x . If y is an index node, the last (first) child pointer in z is also moved to y .
 - ii. Otherwise, any immediate sibling of y is exactly half full. Merge y with an immediate sibling.
 - d. *Delete*(y, k).
3. **else**
 - a. If the child y that precedes k in x has at least one more object than minimally required, find the predecessor k' of k in the sub-tree rooted by y , recursively delete k' from the sub-tree and replace k with k' in x .
 - b. Otherwise, y is exactly half full. We check the child z that immediately follows k in x . If z has at least one more object than minimally required, find the successor k' of k in the sub-tree rooted by z , recursively delete k' from the sub-tree and replace k with k' in x .
 - c. Otherwise, both y and z are half full. Merge them into one node and push k down to the new node as well. Recursively delete k from this new node.
4. **end if**

Along the search path from the root to the node containing the object to be deleted, for each node x we encounter, there are three cases. The simplest scenario is when x is a leaf node (step 1 of the algorithm). In this case, the object is deleted from the node and the algorithm returns. Note that there is no need to handle underflow. The reason is: if the leaf node is root, there is only one node in the tree and it is fine if it has only a few objects; otherwise, the previous recursive step has already guaranteed that x has at least one more object than minimally required.

Steps 2 and 3 of the algorithm correspond to two different cases of dealing with an index node.

For step 2, the index node x does not contain the object with key = k . Thus there exists a child node y whose key range contains k . After we read the child node into memory (step 2b), we will recursively call the *Delete* algorithm on the sub-tree rooted by y (step 2d). However, before we do that, step 2(c) of the algorithm makes sure that y contains at least one more object than half full.

Suppose we want to delete 5 from the B-tree shown in [Figure 16.2](#). When we are examining the root node A , we see that child node B should be followed next. Since B has two more objects than half full, the recursion goes to node B . In turn, since D has two more objects than minimum occupancy, the recursion goes to node D , where the object can be removed.

Let's examine another example. Still from the B+-tree shown in [Figure 16.2](#), suppose we want to delete 33. The algorithm finds that the child node $y = C$ is half full. One more object needs to be incorporated into node C before a recursive call on C is performed. There are two sub-cases. The first sub-case is when one immediate sibling z of node y has at least one more object than minimally required. This case corresponds to step 2(c)i of the algorithm. To handle this case, we drag one object down from x to y , and we push one object from the sibling node up to x . As an example, the deletion of object 33 is shown in [Figure 16.5](#).

Another sub-case is when all immediate siblings of y are exactly half full. In this case, we merge y with one sibling. In our 2-3-4-tree example, an index node which is half full contains one object. If we merge two such nodes together, we also drag an object from the parent node of them down to the merged node. The node will then contain three objects, which is full but does not overflow.

For instance, suppose we want to delete object 31 from [Figure 16.5](#). When we are examining node $x = C$, we see that we need to recursively delete in the child node $y = H$. Now, both immediate siblings of H are exactly half full. So we need to merge H with

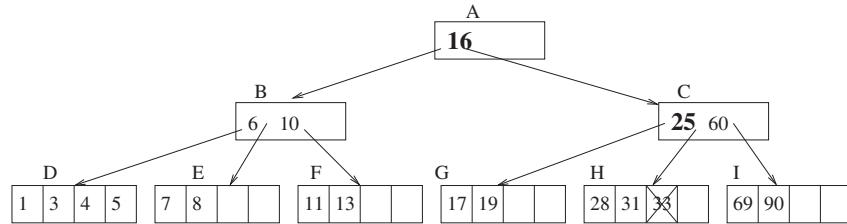

FIGURE 16.5 Illustration of step 2(c)i of the *Delete* algorithm. Deleting an object with key=33 from the B-tree of Figure 16.2. At node A, we examine the right child. Since node C only had one object before, a new object was added to it in the following way: the object with key=25 is moved from A to C, and the object with key=16 is moved from B to A. Also, the child pointer pointing to G is moved from B to C.

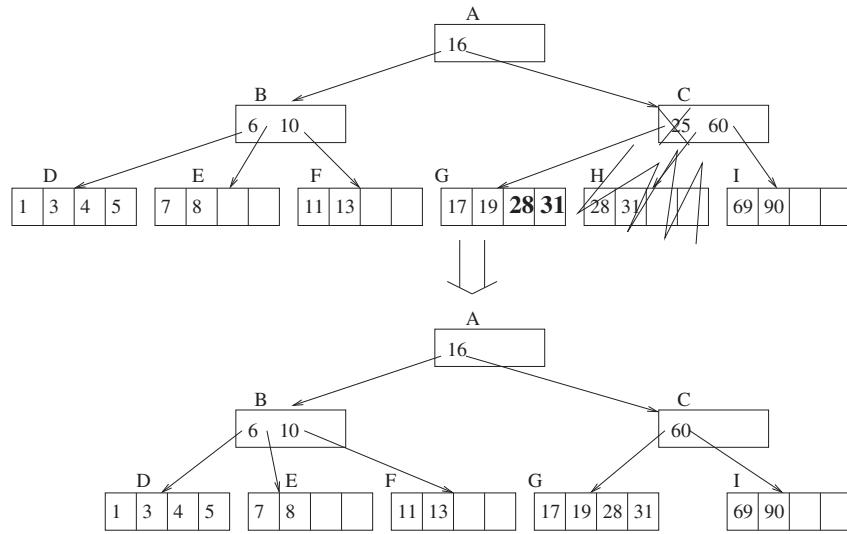

FIGURE 16.6 Illustration of step 3(c) of the *Delete* algorithm. Deleting an object with key=25 from the B-tree of Figure 16.5. At node A, we examine the right child. We see that node C contains the object with key=25. We cannot move an object up from a child node of C, since both children G and H (around key 25) are exactly half full. The algorithm merges these two nodes into one, by moving objects 28 and 31 from H to G and then deleting H. Node C loses an object (key=25) and a child pointer (to H).

a sibling, say G. Besides moving the remaining object 28 from H to G, we also should drag object 25 from the parent node C to G. The figure is omitted for this case.

The third case is that node x is an index node which contains the object to be deleted. Step 3 of algorithm *Delete* corresponds to this scenario. We cannot simply delete the object from x , because we also need to decrement the number of child pointers by one. In Figure 16.5, suppose we want to delete object with key=25, which is stored in index node C. We cannot simply remove the object, since C would have one object but three child pointers left. Now, if child node G immediately to the left of key 25 had three or more objects, the algorithm would execute step 3(a) and move the last object from G into C to fill in the space of the deleted object. Step 3(b) is a symmetric step which shows that we can move an object from the right sub-tree.

However, in our case, both child nodes G and H are half full and thus cannot contribute an object. Step 3(c) of the algorithm corresponds to this case. As shown in Figure 16.6, the two nodes are merged into one.

16.4 The B+-tree

The most well-known variation of the B-tree is the B+-tree. There are two major differences from the B-tree. First, all objects in the B+-tree are kept in leaf nodes. Second, all leaf nodes are linked together as a double-linked list.

The structure of the B+-tree looks quite similar to the B-tree. Thus we omit the details. We do point out that in an index node of a B+-tree, different from the B-tree, we do not store object values. We still store object keys, though. However, since all objects are stored in the leaf level, the keys stored in index nodes act as *routers*, as they direct the search algorithm to go to the correct child node at each level.

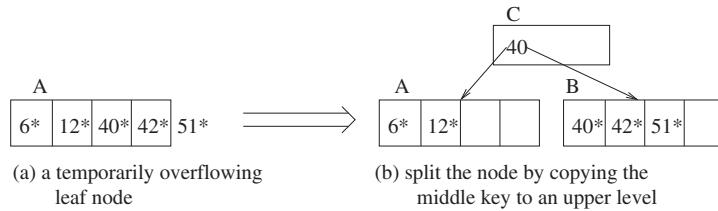

FIGURE 16.7 Illustration of a leaf-node split in the B+-tree. The middle key 40 (same as the first key in the right node) is copied up to the parent node.

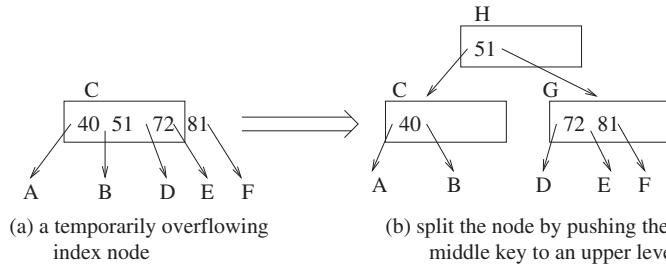

FIGURE 16.8 Illustration of an index-node split in the B+-tree. The middle key 51 is pushed up to the parent node.

16.4.1 Copy-up and Push-up

One may wonder where the routers in the index nodes come from. To understand this, let's look at an example. Initially, the B+-tree has a single node which is a leaf node. After $2B$ insertions, the root node becomes full. In Figure 16.7a, if we try to insert an object to the node A when it is already full, it temporarily overflows. To handle the overflow, the B+-tree will split the node into two nodes A and B. Furthermore, a new node C is generated, which is the new root of the tree. The first key in leaf node B is **copied** up to C. The result B+-tree is shown in Figure 16.7b.

We point out that a key in an index node may be validly replaced by some other keys, unlike in a leaf node. For instance, in node C of Figure 16.7b, we can replace the key 40–35. As long as it is smaller than all keys in the left sub-tree and bigger than or equal to all keys in the right sub-tree, it is fine.

To emphasize the fact that the keys in an index node are different from the keys in a leaf node (a key in an index node is not a real object), in the B+-tree figures we will attach a (*) to each key in a leaf node.

As a comparison, consider the split of an index node. In Figure 16.8a, the index node C temporarily overflows. It is split into two, C and G. Since before the split, C was the tree root, a new root node H is generated. See Figure 16.8b. Here the middle key 51 in the original node C is **pushed** up to the parent node.

16.4.2 B+-tree Query

As in the B-tree, the B+-tree supports the *exact-match query* which finds the object with a given key. Furthermore, the B+-tree can efficiently support the *range query*, which finds the objects whose keys are in a given range.

To perform the exact-match query, the B+-tree follows a single path from root to leaf. In the root node, there is a single child pointer whose key range contains the key to be searched for. If we follow the child pointer to the corresponding child node, inside the child node there is also a single child pointer whose key range contains the object to be searched for. Eventually, we reach a leaf node. The object to be searched, if it exists, must be located in this node. As an example, Figure 16.9 shows the search path if we search key=42.

Beside the exact-match query, the B+-tree also supports the *range query*. That is, find all objects whose keys belong to a range R . In order to do so, all the leaf nodes of a B+-tree are linked together. If we want to search for all objects whose keys are in the range $R = [low, high]$, we perform an exact match query for key= low . This leads us to a leaf node l . We examine all objects in l , and then we follow the sibling link to the next leaf node, and so on. The algorithm stops when an object with key > $high$ is met. An example is shown in Figure 16.10.

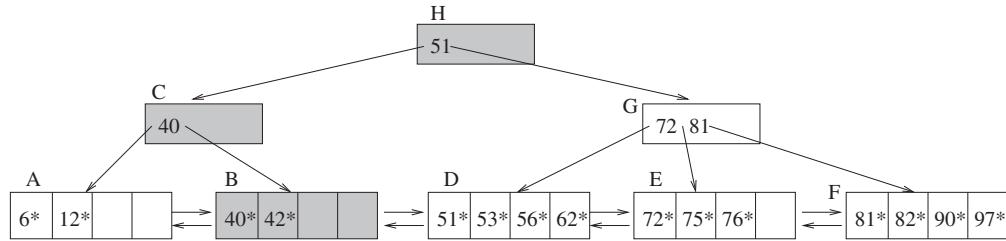

FIGURE 16.9 Illustration of the exact-match query algorithm in the B+-tree. To search for an object with key= 42, nodes H, C and B are examined.

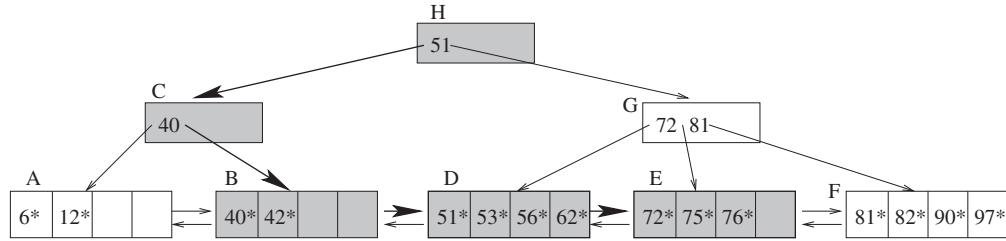

FIGURE 16.10 Illustration of the range query algorithm in the B+-tree. To search for all objects with keys in the range [42,75], the first step is to follow a path from root to leaf to find key 42 (H, C and B are examined). The second step is to follow the right-sibling pointers between leaf nodes and examine D, E. The algorithm stops at E as an object with key= 76 is found.

16.4.3 B+-tree Insertion

Since all objects in the B+-tree are located at the leaf level, the insertion algorithm of the B+-tree is actually easier than that in the B-tree. We basically follow the exact-match query to find the leaf node which should contain the object if it were in the tree. Then we insert the object into the leaf node.

What needs to be taken care of is when the leaf node overflows and is split into two. In this case, a key and a child pointer are inserted into the parent node. This may in turn cause the parent node to overflow, and so on. In the worst case, all nodes along the insertion path are split. If the root node splits into two, the height of the tree increases by one. The insertion algorithm is given below.

Algorithm *Insert*(root, k, v)

Input: the *root* pageID of a B+-tree, the key *k* and the value *v* of a new object.

Prerequisite: the object with key=*k* does not exist in the tree.

Action: Insert the new object into the B+-tree.

1. Starting with the root node, perform an exact-match for key= *k* till a leaf node. Let the search path be x_1, x_2, \dots, x_h , where x_1 is the root node, x_h is the leaf node where the new object should be inserted into, and x_i is the parent node of x_{i+1} where $1 \leq i \leq h-1$.
2. Insert the new object with key= *k* and value = *v* into x_h .
3. Let $i = h$.
4. **while** x_i overflows
 - a. Split x_i into two nodes, by moving the larger half of the keys into a new node x'_i . If x_i is a leaf node, link x'_i into the double-linked list among leaf nodes.
 - b. Identify a key *kk* to be inserted into the parent level along with the child pointer pointing to x'_i . The choice of *kk* depends on the type of node x_i . If x_i is a leaf node, we need to perform *Copy-up*. That is, the smallest key in x'_i is copied as *kk* to the parent level. On the other hand, if x_i is an index node, we need to perform *Push-up*. This means the smallest key in x'_i is removed from x'_i and then stored as *kk* in the parent node.
 - c. **if** $i == 1$ /* the root node overflows */
 - i. Create a new index node as the new root. In the new root, store one key=*kk* and two child pointers to x_i and x'_i .
 - ii. **return**
 - d. **else**

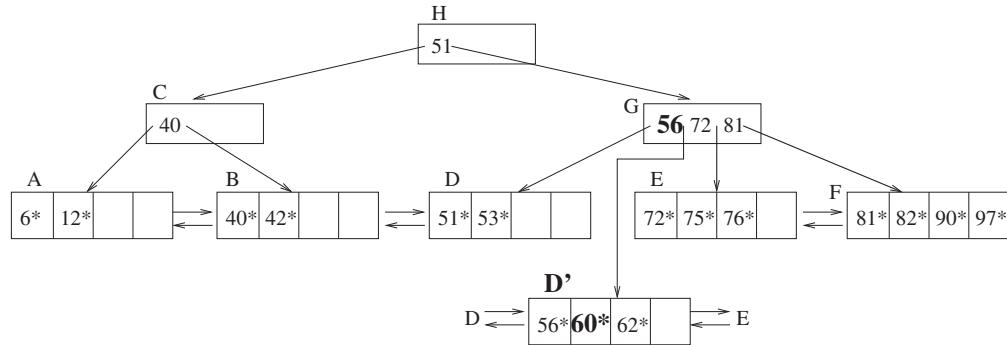

FIGURE 16.11 After inserting an object with key= 60 into the B+-tree shown in Figure 16.9. Leaf node D splits into two. The middle key 56 is copied up to the parent node G.

- i. Insert a key kk and a child pointer pointing to x'_i into node x_{i-1} .
- ii. $i = i - 1$.
- e. **end if**
5. **end while**

As an example, Figure 16.11 shows how to insert an object with key= 60 into the B+-tree shown in Figure 16.9.

16.4.4 B+-tree Deletion

To delete an object from the B+-tree, we first examine a single path from root to the leaf node containing the object. Then we remove the object from the node. At this point, if the node is at least half full, the algorithm returns. Otherwise, the algorithm tries to re-distribute objects between a sibling node and the underflowing node. If redistribution is not possible, the underflowing node is merged with a sibling.

Algorithm Delete($root, k$)

Input: the $root$ pageID of a B+-tree, the key k of the object to be deleted.

Prerequisite: the object with key= k exists in the tree.

Action: Delete the object with key= k from the B+-tree.

1. Starting with the root node, perform an exact-match for key= k . Let the search path be x_1, x_2, \dots, x_h , where x_1 is the root node, x_h is the leaf node that contains the object with key= k , and x_i is the parent node of x_{i+1} . ($1 \leq i \leq h - 1$)
2. Delete the object with key= k from x_h .
3. If $h == 1$, **return**. This is because the tree has only one node which is the root node, and we do not care whether a root node underflows or not.
4. Let $i = h$.
 - a. **while** x_i underflows
 - a. **if** an immediate sibling node s of x_i has at least one more entry than minimum occupancy
 - i. Re-distribute entries evenly between s and x_i .
 - ii. Corresponding to the re-distribution, a key kk in the parent node x_{i-1} needs to be modified. If x_i is an index node, kk is dragged down to x_i and a key from s is pushed up to fill in the place of kk . Otherwise, kk is simply replaced by a key in s .
 - iii. **return**
 - b. **else**
 - i. Merge x_i with a sibling node s . Delete the corresponding child pointer in x_{i-1} .
 - ii. If x_i is an index node, drag the key in x_{i-1} , which previously divides x_i and s , into the new node x_i . Otherwise, delete that key in x_{i-1} .
 - iii. $i = i - 1$.
 - c. **end if**

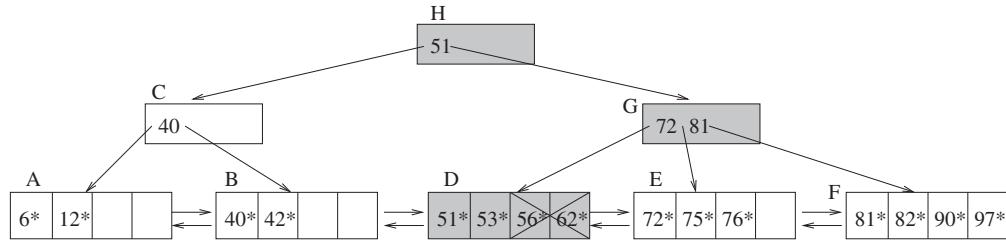

FIGURE 16.12 After deleting keys 56 and 62 from the B+-tree of Figure 16.9. Both keys are deleted from leaf node D , which still satisfies the minimum occupancy.

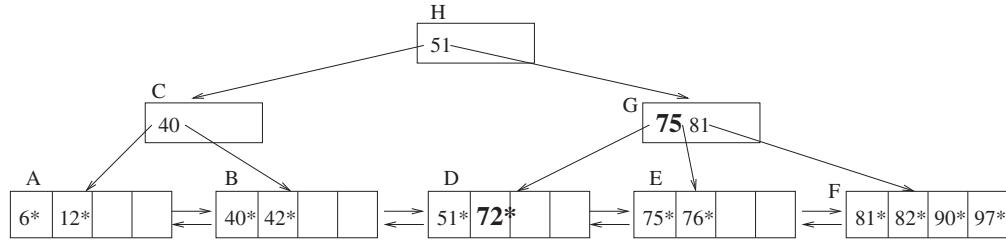

FIGURE 16.13 After deleting key 53 from Figure 16.12. Objects in D and E are redistributed. A key in G is modified.

Step 1 of the algorithm follows a single path from root to leaf to find the object to be deleted. Step 2 deletes the object. The algorithm will finish at this point if any of the following two conditions hold. One, if the tree has a single node (step 3). Two, the leaf node is at least half full after the deletion (the while loop of step 4 is skipped).

As an example, suppose we delete object 56 and then 62 from the B+-tree shown in Figure 16.9. The deletions go to the same leaf node D , where no underflow occurs. The result is shown in Figure 16.12.

Now, let's try to delete key 53 from Figure 16.12. This time D underflows. Step 4 of the *Delete* algorithm handles underflows. In general, when a node x_i underflows, the algorithm tries to borrow some entries from a sibling node s , as described in step 4(a). Note that we could borrow just one entry to avoid underflow in x_i . However, this is not good because next time we delete something from x_i , it will underflow again. Instead, the algorithm **redistribute** entries evenly between x_i and s . Assume x_i has $B - 1$ objects and s has $B + k$ objects, where $k \in [1..B]$. After redistribution, both x_i and s will have $B + (k - 1)/2$ objects. Thus x_i can take another $(k - 1)/2$ deletions before another underflow occurs.

In our example, to delete key 53 from node D , we re-distribute objects in D and E , by moving 72^* into D . As discussed in step 4(a)ii of the algorithm, we also needs to modify a key in the parent node G . In our case, since D is a leaf node, we simply replace the key 72 by 75 in node G . Here 75 is the smallest key in E . The result after the redistribution is shown in Figure 16.13. As a comparison, consider the hypothetical case when D were an index node. In this case, we would drag down the key 72 from G to D and push up a key from E to G .

Let's proceed the example further by deleting object 72 from the tree in Figure 16.13. Now, the node D underflows, and redistribution is not possible (since E , the only immediate sibling of D , is exactly half full). Step 4(b) of the *Delete* algorithm tells us to merge D and E together. Correspondingly, a key and a child pointer need to be deleted from the parent node G . Since D is a leaf node, we simply delete the key 75 and the child pointer from G . The result is shown in Figure 16.14. As a comparison, imagine D were an index node. We would still remove key 75 and the child pointer from G , but we would keep the key 75 in node D .

One may wonder why in the redistribution and the merge algorithms, the leaf node and the index node are treated differently. The reason is because when we generated an index entry, we had treated two cases differently: the case when the entry points to a leaf node and the case when the entry points to a index node. This is discussed at the beginning of Section 16.4. To generate a new entry pointing to a leaf node, we copied the smallest key from the leaf node. But to generate a new entry pointing to an index node, we pushed a key from the child node up. A key which was copied up can be safely deleted later (when merge occurs). But a key which was pushed up must be kept somewhere. If we delete it from a parent node, we should drag it down to a child node.

As a running example of merging index nodes, consider deleting object 42 from the B+-tree of Figure 16.14. Node B underflows, and it is merged with A . Correspondingly, in the parent node C , the key 40 and the child pointer to B are deleted. The temporary result is shown in Figure 16.15. It's temporary since node C underflows.

To handle the underflow of node C , it is merged with G , its sole sibling node. As a consequence, the root node H now has only one child. Thus, H is removed and C becomes the new root. We point out that to merge two index nodes C and G , a key is

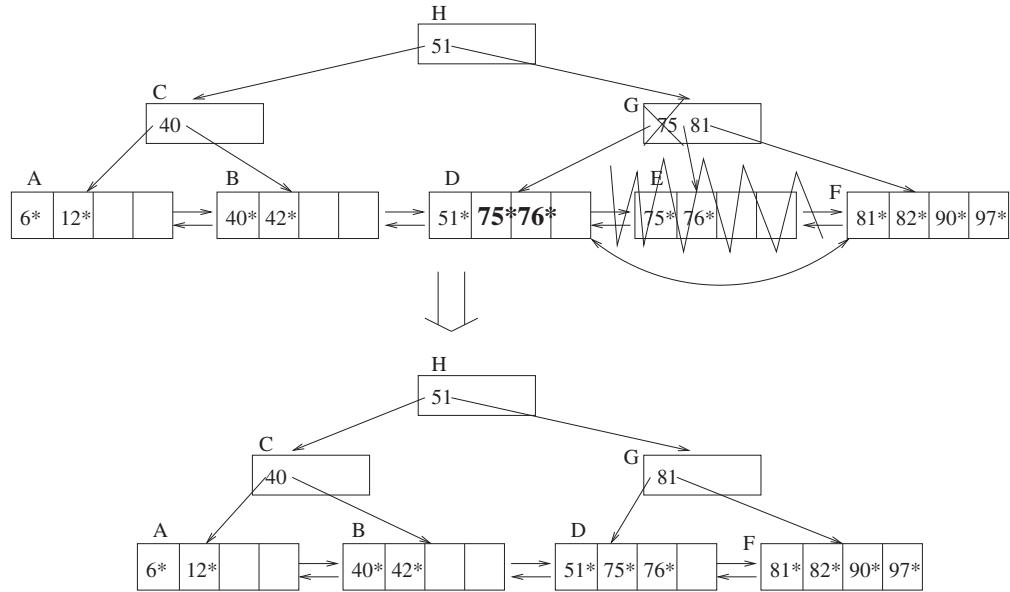

FIGURE 16.14 After deleting keys 72 from [Figure 16.13](#). This figure corresponds to the scenario described in step 4(b) of the *Delete* algorithm. In particular, the example illustrates the merge of two leaf nodes (*D* and *E*). Node *D* underflows, but redistribution is not possible. From the parent node *G*, key 75 and child pointer to *E* are removed.

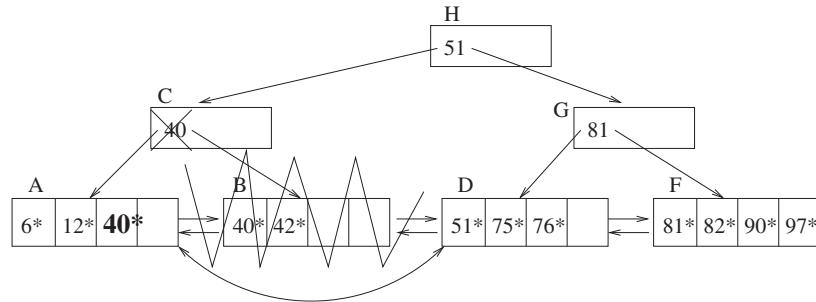

FIGURE 16.15 Temporary tree in the middle of deleting object 42 from [Figure 16.14](#). Nodes *A* and *B* are merged. Key 40 and child pointer to *B* are removed from *C*.

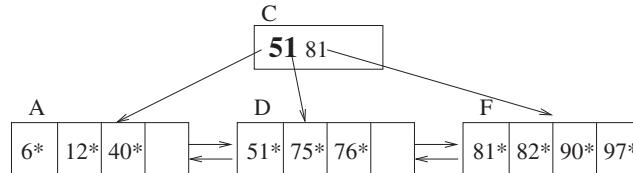

FIGURE 16.16 After the deletion of object 42 is finished. This figure illustrates an example of merging two index nodes. In particular, index nodes *C* and *G* are merged. The key 51 is dragged down from the parent node *H*. Since that is the only key in root *H*, node *C* becomes the new root and the height of the tree is decreased by one.

dragged down from the parent node (versus being deleted in the case of merging leaf nodes). The final result after completing the deletion of 42* is shown in [Figure 16.16](#).

16.5 Further Discussions

In this section we discuss various issues of the B-tree and the B+-tree.

16.5.1 Efficiency Analysis

Theorem: In the B-tree or the B+-tree, the I/O cost of insertion, deletion and exact-match query is $O(\log_B n)$. In the B+-tree, the I/O cost of a range search is $O(\log_B n + t/B)$. Here B is the minimum page capacity in number of records, n is the total number of objects in the tree, and t is the number of objects in the range query result.

The correctness of the theorem can be seen from the discussion of the algorithms. Basically, for both the B-tree and the B+-tree, all the insertion, deletion and exact-match query algorithms examine a single path from root to leaf. At each node, the algorithm might examine up to two other nodes. However, asymptotically the complexity of these algorithms are equal to the height of the tree. Since there are n objects, and the minimum fan-out of the tree is B , the height of the tree is $O(\log_B n)$. So the complexity of the algorithms is $O(\log_B n)$ as well.

For the range query in the B+-tree, $\log_B n$ nodes are examined to find the leaf node that contains the low value of the query range. By following the sibling pointers in the leaf nodes, the other leaf nodes that contain objects in the query range are also found. Among all the leaf nodes examined, except for the first and the last, every node contains at least B objects in the query result. Thus if there are t objects in the query result, the range query complexity is $O(\log_B n + t/B)$.

16.5.2 Why Is the B+-tree Widely Accepted?

One can safely claim that the B+-tree has been included in at least 99%, if not all, of the database management systems (DBMS). No other index structure has received so much attention. Why is that?

Let's do some calculation. First, we point out that a practical number of minimum occupancy of a B+-tree is $B = 100$. Thus the fan-out of the tree is between 100 and 200. Analysis has shown that in a real-world B+-tree, the average page capacity is about 66.7% full. Or, a page typically contains $200 * 66.7\% = 133$ entries. Here is the relationship between the height of the tree and the number of objects that can hold in a typical B+-tree:

- $height=0$: B+-tree holds 133 objects on average. There is a single node, which is 66.7% full.
- $height=1$: B+-tree holds $133^2 = 17,689$ objects. There are 133 leaf nodes, each holds 133 objects.
- $height=2$: B+-tree holds $133^3 = 2,352,637$ objects.
- $height=3$: B+-tree holds $133^4 = 312,900,721$ (over 0.3 billion) objects.

The first two levels of the B+-tree contains $1 + 133 = 134$ disk pages. This is very small. If a disk page is 4 KB large, 134 disk pages occupy $134 * 4 \text{ KB} = 536 \text{ KB}$ disk space. It's quite reasonable to assume that the first two levels of the B+-tree always stays in memory.

The calculations lead to this discovery: in a large database with 0.3 billion objects, to find one object we only need to access two disk pages! This is unbelievably good.

16.5.3 Bulk-Loading a B+-tree

In some cases, we are given a large set of records and we are asked to build a B+-tree index. Of course, we can start with an empty B+-tree and insert one record at a time using the Insert algorithm. However, this approach is not efficient, as the I/O cost is $O(n \cdot \log_B n)$.

Many systems have implemented the *bulk-loading* utility. The idea is as follows. First, sort the objects. Use the objects to fill in leaf nodes in sequential order. For instance, if a leaf node holds up to $2B$ objects, the $2B$ smallest objects are stored in page 1, the next $2B$ objects are stored in page 2, etc. Next, build the index nodes at one level up. Assume an index node holds up to $2B$ child pointers. Create the first index node as the parent of the first $2B$ leaf nodes. Create the second index node as the parent of the next $2B$ leaf nodes, etc. Then, build the index nodes at two levels above the leaf level, and so on. The process stops when there is only one node at a level. This node is the tree root.

If the objects are sorted already, the bulk-loading algorithm has an I/O cost of $O(n/B)$. Otherwise, the bulk-loading algorithm has asymptotically the same I/O cost as external sort, which is $O(n/B \cdot \log_B n)$. Notice that even if the bulk-loading algorithm performs a sorting first, it is still B times faster than inserting objects one at a time into the structure.

16.5.4 Aggregation Query in a B+-tree

The B+-tree can also be used to answer the *aggregation query*: “given a key range R , find the aggregate value of objects whose keys are in R .” The standard SQL supports the following aggregation operators: COUNT, SUM, AVG, MIN, MAX. For instance, the COUNT operator returns the number of objects in the query range. Here AVG can be computed as SUM/AVG. Thus we focus on the other four aggregate operators.

Since the B+-tree efficiently supports the range query, it makes sense to utilize it to answer the aggregation query as well. Let's first look at some concepts.

Associated with each aggregate operator, there exists a *init_value* and an *aggregate* function. The *init_value* is the aggregate for an empty set of objects. For instance, the *init_value* for the COUNT operator is 0. The *aggregate* function computes the aggregate value. There are two versions. One version takes two aggregate values of object set S_1 and S_2 , and computes the aggregate value of set $S_1 \cup S_2$. Another version takes one aggregate value of set S_1 and an object o and computes the aggregate value of $S_1 \cup \{o\}$. For instance, if we know $COUNT_1$ and $COUNT_2$ of two sets, the COUNT for the whole set is $COUNT_1 + COUNT_2$. The COUNT of subset 1 added with an object o is $COUNT_1 + 1$. The *init_value* and the *aggregate* functions for COUNT, SUM, MIN, and MAX are shown below.

- COUNT operator:
 - $init_value = 0$
 - $aggregate(COUNT_1, COUNT_2) = COUNT_1 + COUNT_2$
 - $aggregate(COUNT_1, object) = COUNT_1 + 1$
- SUM operator:
 - $init_value = 0$
 - $aggregate(SUM_1, SUM_2) = SUM_1 + SUM_2$
 - $aggregate(SUM_1, object) = SUM_1 + object.value$
- MIN operator:
 - $init_value = +\infty$
 - $aggregate(MIN_1, MIN_2) = \min\{MIN_1, MIN_2\}$
 - $aggregate(MIN_1, object) = \min\{MIN_1, object.value\}$
- MAX operator:
 - $init_value = -\infty$
 - $aggregate(MAX_1, MAX_2) = \max\{MAX_1, MAX_2\}$
 - $aggregate(MAX_1, object) = \max\{MAX_1, object.value\}$

The B+-tree can support the aggregation query in the following way. We keep a temporary aggregate value, which is initially set to be *init_value*. A range search is performed on the B+-tree. For each object found, its value is aggregated with the temporary aggregate value on-the-fly. When all objects whose keys are in the query range are processed, this temporary aggregate value is returned.

However, this approach is not efficient, as the I/O cost is $O(\log_B n + t/B)$, which is linear to the number of objects divided by B . If the query range is large, the algorithm needs to access too many disk pages. It is ideal to find some approach whose query performance is independent to the size of the objects in the query range.

A better way is to store the local aggregate values in the tree. In more detail, along with each child pointer, we store the aggregate value of all objects in the corresponding sub-tree. By doing so, if the query range fully contains the key range of a sub-tree, we take the associated local aggregate value and avoid browsing the sub-tree. We call such a B+-tree with extra aggregate information the **aggregation B+-tree**. The algorithm to perform a aggregation query using the **aggregation B+-tree** is shown below.

Algorithm Aggregation(x, R)

Input: a node x of an aggregation B+-tree, the query key range R .

Action: Among objects in the sub-tree rooted by x , compute the aggregate value of objects whose keys belong to R .

1. Initialize the temporary aggregation value v as *init_value*.
2. **if** x is a leaf node
 - a. For every object o in x where $o.value \in R$, $v = aggr(v, o)$.
3. **else**
 - a. **for** every child pointer $x.child[i]$
 - i. **if** the key range of $x.child[i]$ is contained in R
 $v = aggregate(v, x.child[i].aggr)$
 - ii. **else if** the key range of $x.child[i]$ intersects R
 $y = DiskRead(x.child[i])$
 $v = aggregate(v, Aggregation(y, R))$
 - iii. **end if**
 - b. **end for**
4. **return** v .

The algorithm starts with examining the root node. Here the child pointers are divided into three groups. (1) There are at most two child pointers whose key ranges intersect the query range R . (2) The child pointers between them have key ranges fully contained in R . (3) The child pointers outside of them have key ranges non-intersecting with R .

For child pointers in group (2), the local aggregate stored at the child pointer (represented by $x.child[i].aggr$) is aggregated to the temporary aggregate value and the examination of the sub-tree is avoided. This is shown in step 3(a)i of the algorithm. For child pointers in group (3), no object in the sub-trees will contribute to the query and the examination of the sub-trees are also avoided.

For each of the two child pointers whose key ranges intersect R , a recursive call to *Aggregation* is performed. This is shown in step 3(a)ii of the algorithm. If we go one level down, in each of the two child nodes, there can be at most one child pointer whose key range intersects R . Take the left child node as an example. If there is a child pointer whose key range intersect R , all child pointers to the left of it will be outside of R and all child pointers to the right of it will be fully contained in R . Thus the algorithm examines two paths from root to leaf.

Theorem: *The I/O cost of the Aggregation query algorithm is $O(\log_B n)$.*

The above theorem shows that the aggregation query performance is independent of the number of objects in the query range.

University of Maryland at College Park

17.1 Introduction

The representation of multidimensional data is an important issue in applications in diverse fields that include database management systems (see [Chapter 62](#)), computer graphics (see [Chapter 55](#)), computer vision, computational geometry (see [Chapters 65, 66](#) and [67](#)), image processing (see [Chapter 58](#)), geographic information systems (GIS) (see [Chapter 56](#)), pattern recognition, VLSI design ([Chapter 53](#)), and others. The most common definition of multidimensional data is a collection of points in a higher dimensional space. These points can represent locations and objects in space as well as more general records where only some, or even none, of the attributes are locational. As an example of nonlocational point data, consider an employee record which has attributes corresponding to the employee's name, address, sex, age, height, weight, and social security number. Such records arise in database management systems and can be treated as points in, for this example, a seven-dimensional space (i.e., there is one dimension for each attribute) albeit the different dimensions have different type units (i.e., name and address are strings of characters, sex is binary; while age, height, weight, and social security number are numbers).

When multidimensional data corresponds to locational data, we have the additional property that all of the attributes have the same unit which is distance in space. In this case, we can combine the distance-denominated attributes and pose queries that involve proximity. For example, we may wish to find the closest city to Chicago within the two-dimensional space from which the locations of the cities are drawn. Another query seeks to find all cities within 50 miles of Chicago. In contrast, such queries are not very meaningful when the attributes do not have the same type.

When multidimensional data spans a continuous physical space (i.e., an infinite collection of locations), the issues become more interesting. In particular, we are no longer just interested in the locations of objects, but, in addition, we are also interested in the space that they occupy (i.e., their extent). Some example objects include lines (e.g., roads, rivers), regions (e.g., lakes, counties, buildings, crop maps, polygons, polyhedra), rectangles, and surfaces. The objects may be disjoint or could even overlap. One way to deal with such data is to store it explicitly by parameterizing it and thereby reduce it to a point in a higher dimensional space. For example, a line in two-dimensional space can be represented by the coordinate values of its endpoints (i.e., a pair of x and a pair of y coordinate values) and then stored as a point in a four-dimensional space [1]. Thus, in effect, we have constructed a transformation (i.e., mapping) from a two-dimensional space (i.e., the space from which the lines are drawn) to a four-dimensional space (i.e., the space containing the representative point corresponding to the line).

The transformation (also known as parameterization) approach is fine if we are just interested in retrieving the data. It is appropriate for queries about the objects (e.g., determining all lines that pass through a given point or that share an endpoint, etc.) and the immediate space that they occupy. However, the drawback of the transformation approach is that it ignores the

* All figures © 2017 by Hanan Samet.

geometry inherent in the data (e.g., the fact that a line passes through a particular region) and its relationship to the space in which it is embedded.

For example, suppose that we want to detect if two lines are near each other, or, alternatively, to find the nearest line to a given line. This is difficult to do in the four-dimensional space, regardless of how the data in it is organized, since proximity in the two-dimensional space from which the lines are drawn is not necessarily preserved in the four-dimensional space into which the lines have been transformed. In other words, although the two lines may be very close to each other, the Euclidean distance between their representative points may be quite large, unless the lines are approximately the same size, in which case proximity is preserved [2].

Of course, we could overcome these problems by projecting the lines back to the original space from which they were drawn, but in such a case, we may ask what was the point of using the transformation in the first place? In other words, at the least, the representation that we choose for the data should facilitate the performance of operations on the data. Thus when the multidimensional spatial data is nondiscrete, we need representations besides those that are designed for point data. The most common solution, and the one that we focus on in the rest of this chapter, is to use data structures that are based on spatial occupancy. Such methods decompose the space from which the spatial data is drawn (e.g., the two-dimensional space containing the lines) into regions that are usually called *buckets* because they often contain more than just one element. They are also commonly known as *bucketing methods*.

In this chapter, we explore a number of different representations of multidimensional data bearing the above issues in mind. While we cannot give exhaustive details of all of the data structures, we try to explain the intuition behind their development as well as to give literature pointers to where more information can be found. Many of these representations are described in greater detail in References 3–5 including an extensive bibliography. Our approach is primarily a descriptive one. Most of our examples are of two-dimensional spatial data although the representations are applicable to higher dimensional spaces as well.

At times, we discuss bounds on execution time and space requirements. Nevertheless, this information is presented in an inconsistent manner. The problem is that such analyses are very difficult to perform for many of the data structures that we present. This is especially true for the data structures that are based on spatial occupancy (e.g., quadtree [see Chapter 20 for more details] and R-tree [see Chapter 22 for more details] variants). In particular, such methods have good observable average-case behavior but may have very bad worst cases which may only arise rarely in practice. Their analysis is beyond the scope of this chapter and usually we do not say anything about it. Nevertheless, these representations find frequent use in applications where their behavior is deemed acceptable, and is often found to be better than that of solutions whose theoretical behavior would appear to be superior. The problem is primarily attributed to the presence of large constant factors which are usually ignored in the *big O* and Ω analyses [6].

The rest of this chapter is organized as follows. Section 17.2 reviews a number of representations of point data of arbitrary dimensionality. Section 17.3 describes bucketing methods that organize collections of spatial objects (as well as multidimensional point data) by aggregating the space that they occupy. The remaining sections focus on representations of nonpoint objects of different types. Section 17.4 covers representations of region data, while Section 17.5 discusses a subcase of region data which consists of collections of rectangles. Section 17.6 deals with curvilinear data which also includes polygonal subdivisions and collections of line segments. Section 17.7 contains a summary and a brief indication of some research issues and directions for future work.

17.2 Point Data

The simplest way to store point data of arbitrary dimension is in a sequential list. Accesses to the list can be sped up by forming sorted lists for the various attributes which are known as *inverted lists* [7]. There is one list for each attribute. This enables pruning the search with respect to the value of one of the attributes. It should be clear that the inverted list is not particularly useful for multidimensional range searches. The problem is that it can only speed up the search for one of the attributes (termed the *primary* attribute). A widely used solution is exemplified by the *fixed-grid* method [7,8]. It partitions the space from which the data is drawn into rectangular cells by overlaying it with a grid. Each grid cell c contains a pointer to another structure (e.g., a list) which contains the set of points that lie in c . Associated with the grid is an access structure to enable the determination of the grid cell associated with a particular point p . This access structure acts like a directory and is usually in the form of a d -dimensional array with one entry per grid cell or a tree with one leaf node per grid cell.

There are two ways to build a fixed grid. We can either subdivide the space into equal-sized intervals along each of the attributes (resulting in congruent grid cells) or place the subdivision lines at arbitrary positions that are dependent on the underlying data. In essence, the distinction is between organizing the data to be stored and organizing the embedding space from which the data is drawn [9]. In particular, when the grid cells are congruent (i.e., equal-sized when all of the attributes are locational with the same range and termed a *uniform grid*), use of an array access structure is quite simple and has the desirable property that the grid

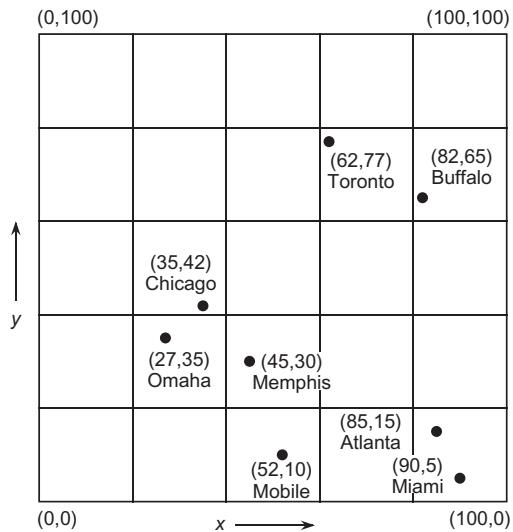

FIGURE 17.1 Uniform-grid representation corresponding to a set of points with a search radius of 20.

cell associated with point p can be determined in constant time. Moreover, in this case, if the width of each grid cell is twice the search radius for a rectangular range query, then the average search time is $O(F \cdot 2^d)$ where F is the number of points that have been found [10]. Figure 17.1 is an example of a uniform-grid representation for a search radius equal to 10 (i.e., a square of size 20×20).

The use of an array access structure when the grid cells are not congruent requires us to have a way of keeping track of their size so that we can determine the entry of the array access structure corresponding to the grid cell associated with point p . One way to do this is to make use of what are termed *linear scales* which indicate the positions of the grid lines (or partitioning hyperplanes in $d > 2$ dimensions). Given a point p , we determine the grid cell in which p lies by finding the “coordinate values” of the appropriate grid cell. The linear scales are usually implemented as one-dimensional trees containing ranges of values.

The array access structure is fine as long as the data is static. When the data is dynamic, it is likely that some of the grid cells become too full while other grid cells are empty. This means that we need to rebuild the grid (i.e., further partition the grid or reposition the grid partition lines or hyperplanes) so that the various grid cells are not too full. However, this creates many more empty grid cells as a result of repartitioning the grid (i.e., empty grid cells are split into more empty grid cells). The number of empty grid cells can be reduced by merging spatially adjacent empty grid cells into larger empty grid cells, while splitting grid cells that are too full, thereby making the grid adaptive. The result is that we can no longer make use of an array access structure to retrieve the grid cell that contains query point p . Instead, we make use of a tree access structure in the form of a k -ary tree where k is usually 2^d . Thus what we have done is marry a k -ary tree with the fixed-grid method. This is the basis of the point quadtree [11] and the PR quadtree [4,12] which are multidimensional generalizations of binary trees.

The difference between the point quadtree and the PR quadtree is the same as the difference between *trees* and *tries* [13], respectively. The binary search tree [7] is an example of the former since the boundaries of different regions in the search space are determined by the data being stored. Address computation methods such as radix searching [7] (also known as digital searching) are examples of the latter, since region boundaries are chosen from among locations that are fixed regardless of the content of the data set. The process is usually a recursive halving process in one dimension, recursive quartering in two dimensions, and so on, and is known as *regular decomposition*.

In two dimensions, a point quadtree is just a two-dimensional binary search tree. The first point that is inserted serves as the root, while the second point is inserted into the relevant quadrant of the tree rooted at the first point. Clearly, the shape of the tree depends on the order in which the points were inserted. For example, Figure 17.2 is the point quadtree corresponding to the data of Figure 17.1 inserted in the order Chicago, Mobile, Toronto, Buffalo, Memphis, Omaha, Atlanta, and Miami.

In two dimensions, the PR quadtree is based on a recursive decomposition of the underlying space into four congruent (usually square in the case of locational attributes) cells until each cell contains no more than one point. For example, Figure 17.3a is the partition of the underlying space induced by the PR quadtree corresponding to the data of Figure 17.1, while Figure 17.3b is its tree representation. The shape of the PR quadtree is independent of the order in which data points are inserted into it. The disadvantage of the PR quadtree is that the maximum level of decomposition depends on the minimum separation between two points. In particular, if two points are very close, then the decomposition can be very deep. This can be overcome by viewing the cells or nodes as buckets with capacity c and only decomposing a cell when it contains more than c points.

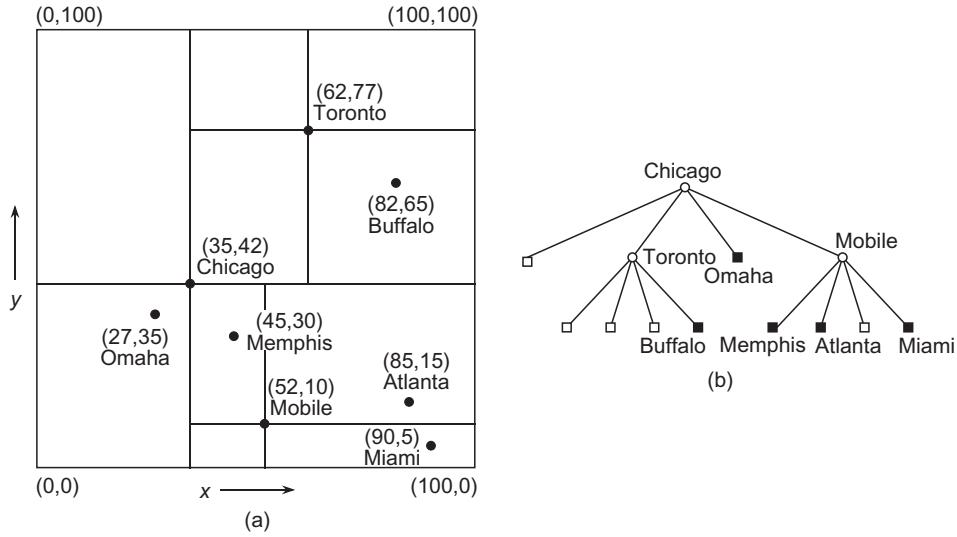

FIGURE 17.2 A point quadtree and the records it represents corresponding to Figure 17.1: (a) the resulting partition of space and (b) the tree representation.

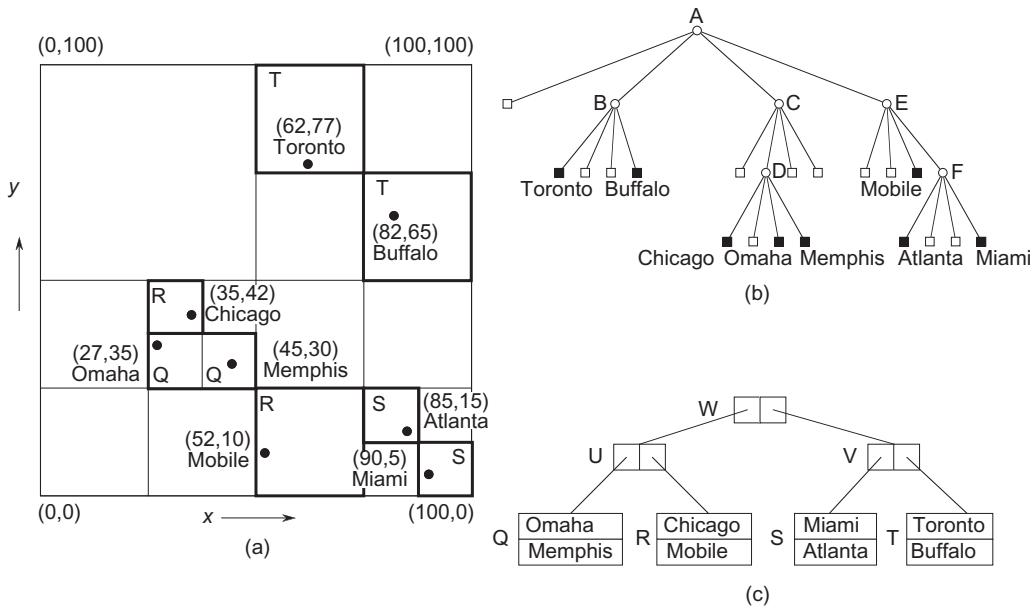

FIGURE 17.3 A PR quadtree and the points it represents corresponding to Figure 17.1: (a) the resulting partition of space, (b) the tree representation, and (c) one possible B⁺-tree for the nonempty grid cells where each node has a minimum of 2 and a maximum of 3 entries. The nonempty grid cells in (a) have been labeled with the name of the B⁺-tree leaf node in which they are a member.

As the dimensionality of the space increases, each level of decomposition of the quadtree results in many new cells as the fanout value of the tree is high (i.e., 2^d). This is alleviated by making use of a k-d tree [14]. The k-d tree is a binary tree where at each level of the tree, we subdivide along a different attribute so that, assuming d locational attributes, if the first split is along the x -axis, then after d levels, we cycle back and again split along the x -axis. It is applicable to both the point quadtree and the PR quadtree (in which case we have a PR k-d tree, or a bintree in the case of region data).

At times, in the dynamic situation, the data volume becomes so large that a tree access structure such as the one used in the point and PR quadtrees is inefficient. In particular, the grid cells can become so numerous that they cannot all fit into memory thereby causing them to be grouped into sets (termed *buckets*) corresponding to physical storage units (i.e., pages) in secondary storage. The problem is that, depending on the implementation of the tree access structure, each time we must follow a pointer, we may need to make a disk access. Below, we discuss two possible solutions: one making use of an array access structure and one

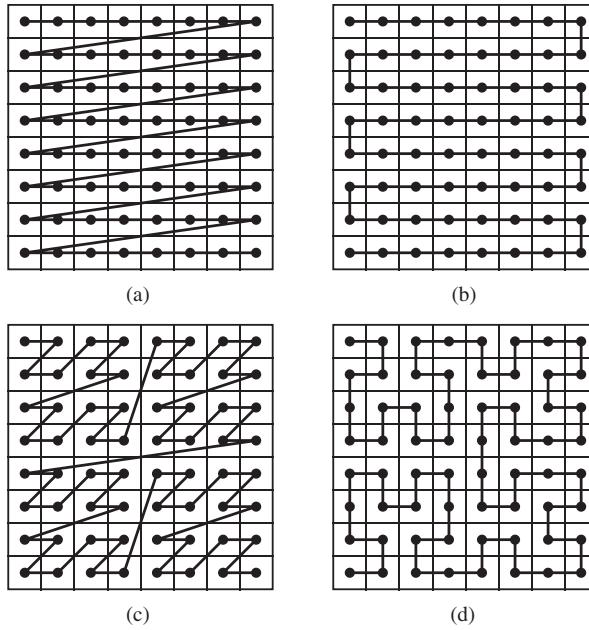

FIGURE 17.4 The result of applying four common different space-ordering methods to an 8×8 collection of pixels whose first element is in the upper left corner: (a) row order, (b) row-prime order, (c) Morton order, and (d) Peano–Hilbert order.

making use of an alternative tree access structure with a much larger fanout. We assume that the original decomposition process is such that the data is only associated with the leaf nodes of the original tree structure.

The difference from the array access structure used with the static fixed-grid method described earlier is that the array access structure (termed *grid directory*) may be so large (e.g., when d gets large) that it resides on disk as well, and the fact that the structure of the grid directory can change as the data volume grows or contracts. Each grid cell (i.e., an element of the grid directory) stores the address of a bucket (i.e., page) that contains the points associated with the grid cell. Notice that a bucket can correspond to more than one grid cell. Thus any page can be accessed by two disk operations: one to access the grid cell and one more to access the actual bucket.

This results in EXCELL [15] when the grid cells are congruent (i.e., equal-sized for locational data), and *grid file* [9] when the grid cells need not be congruent. The difference between these methods is most evident when a grid partition is necessary (i.e., when a bucket becomes too full and the bucket is not shared among several grid cells). In particular, a grid partition in the grid file only splits one interval in two thereby resulting in the insertion of a $(d - 1)$ -dimensional cross-section. On the other hand, a grid partition in EXCELL means that all intervals must be split in two thereby doubling the size of the grid directory.

An alternative to the array access structure is to assign an ordering to the grid cells resulting from the adaptive grid, and then to impose a tree access structure on the elements of the ordering that correspond to the nonempty grid cells. The ordering is analogous to using a mapping from d dimensions to one dimension. There are many possible orderings (e.g., see chapter 2 in Reference 5) with the most popular shown in Figure 17.4.

The domain of these mappings is the set of locations of the smallest possible grid cells (termed *pixels*) in the underlying space and thus we need to use some easily identifiable pixel in each grid cell such as the one in the grid cell's lower left corner. Of course, we also need to know the size of each grid cell. One mapping simply concatenates the result of interleaving the binary representations of the coordinate values of the lower left corner (e.g., (a, b) in two dimensions) and i of each grid cell of size 2^i so that i is at the right. The resulting number is termed a *locational code* and is a variant of the Morton order (Figure 17.4c). Assuming such a mapping and sorting the locational codes in increasing order yields an ordering equivalent to that which would be obtained by traversing the leaf nodes (i.e., grid cells) of the tree representation (e.g., Figure 17.8b) in the order SW, SE, NW, NE. It is also known as the Z-order on account of the Z-like pattern formed by the ordering. The Morton order (as well as the Peano–Hilbert order shown in Figure 17.4d) is particularly attractive for quadtree-like decompositions because all pixels within a grid cell appear in consecutive positions in the order. Alternatively, these two orders exhaust a grid cell before exiting it.

For example, Figure 17.3c shows the result of imposing a B^+ -tree [16] access structure on the nonempty grid cells of the PR quadtree given in Figure 17.3b. Each node of the B^+ -tree in our example has a minimum of 2 and a maximum of 3 entries. Figure 17.3c does not contain the values resulting from applying the mapping to the individual grid cells nor does it show the discriminator values that are stored in the nonleaf nodes of the B^+ -tree. The nonempty grid cells of the PR quadtree in Figure

[17.3a](#) are marked with the label of the leaf node of the B^+ -tree of which they are a member (e.g., the grid cell containing Chicago is in leaf node Q of the B^+ -tree).

It is important to observe that the above combination of the PR quadtree and the B^+ -tree has the property that the tree structure of the partition process of the underlying space has been decoupled [17] from that of the node hierarchy (i.e., the grouping process of the nodes resulting from the partition process) that makes up the original tree directory. More precisely, the grouping process is based on proximity in the ordering of the locational codes and on the minimum and maximum capacity of the nodes of the B^+ -tree. Unfortunately, the resulting structure has the property that the space that is spanned by a leaf node of the B^+ -tree (i.e., the grid cells spanned by it) has an arbitrary shape and, in fact, does not usually correspond to a k -dimensional hyperrectangle. In particular, the space spanned by the nonempty leaf node may have the shape of a staircase (e.g., the nonempty grid cells in [Figure 17.3a](#) that comprise leaf nodes S and T of the B^+ -tree in [Figure 17.3c](#)) or may not even be connected in the sense that it corresponds to regions that are not contiguous (e.g., the nonempty grid cells in [Figure 17.3a](#) that comprise the leaf node R of the B^+ -tree in [Figure 17.3c](#)). The PK-tree [18] is an alternative decoupling method which overcomes these drawbacks by basing the grouping process on k -instantiation which stipulates that each node of the grouping process contains a minimum of k objects or nonempty grid cells. The result is that all of the nonempty grid cells of the grouping process are congruent at the cost that the result is not balanced although use of relatively large values of k ensures that the resulting trees are relatively shallow or of a limited number of shapes. It can be shown that when the partition process has a fanout of f , then k -instantiation means that the number of objects in each node of the grouping process is bounded by $f \cdot (k - 1)$. Note that k -instantiation is different from bucketing where we only have an upper bound on the number of objects in the node.

Fixed-grids, quadtrees, k -d trees, grid file, EXCELL, as well as other hierarchical representations are good for range searching queries such as finding all cities within 80 miles of St. Louis. In particular, they act as pruning devices on the amount of search that will be performed as many points will not be examined since their containing cells lie outside the query range. These representations are generally very easy to implement and have good expected execution times, although they are quite difficult to analyze from a mathematical standpoint. However, their worst cases, despite being rare, can be quite bad. These worst cases can be avoided by making use of variants of range trees [19] and priority search trees [20]. For more details about these data structures, see [Chapter 19](#).

17.3 Bucketing Methods

There are four principal approaches to decomposing the space from which the objects are drawn. The first approach makes use of an object hierarchy and the space decomposition is obtained in an indirect manner as the method propagates the space occupied by the objects up the hierarchy with the identity of the propagated objects being implicit to the hierarchy. In particular, associated with each object is an object description (e.g., for region data, it is the set of locations in space corresponding to the cells that make up the object). Actually, since this information may be rather voluminous, it is often the case that an approximation of the space occupied by the object is propagated up the hierarchy rather than the collection of individual cells that are spanned by the object. For spatial data, the approximation is usually the minimum bounding rectangle formally known as the minimum axis-aligned bounding box (AABB) for the object, while for nonspatial data it is simply the hyperrectangle whose sides have lengths equal to the ranges of the values of the attributes. Therefore, associated with each element in the hierarchy is a bounding rectangle corresponding to the union of the bounding rectangles associated with the elements immediately below it.

The R-tree [21,22] (also sometimes referenced as an AABB tree) is an example of an object hierarchy which finds use especially in database applications. Note that other bounding objects can be used such as spheres (e.g., the SS-tree [23]), and the intersection of the minimum bounding sphere and the minimum bounding rectangle (e.g., the SR-tree [24]). Moreover, the minimum bounding rectangles need not be axis-aligned (e.g., the OBB-tree [25]). The number of objects or bounding rectangles that are aggregated in each node is permitted to range between a minimum of m where $m \leq \lceil M/2 \rceil$ and a maximum of M . The root node in an R-tree has at least two entries unless it is a leaf node in which case it has just one entry corresponding to the bounding rectangle of an object. The R-tree is usually built dynamically as the objects are encountered rather than waiting until all objects have been input (dynamically). The hierarchy is implemented as a tree structure with grouping being based, in part, on proximity of the objects or bounding rectangles.

For example, consider the collection of line segment objects given in [Figure 17.5](#) shown embedded in a 4×4 grid. [Figure 17.6a](#) is an example R-tree for this collection with $m = 2$ and $M = 3$. [Figure 17.6b](#) shows the spatial extent of the bounding rectangles of the nodes in [Figure 17.6a](#), with heavy lines denoting the bounding rectangles corresponding to the leaf nodes, and broken lines denoting the bounding rectangles corresponding to the subtrees rooted at the nonleaf nodes. Note that the R-tree is not unique. Its structure depends heavily on the order in which the individual objects were inserted into (and possibly deleted from) the tree.

Given that each R-tree node can contain a varying number of objects or bounding rectangles, it is not surprising that the R-tree was inspired by the B-tree [26]. Therefore, nodes are viewed as analogous to disk pages. Thus the parameters defining the tree

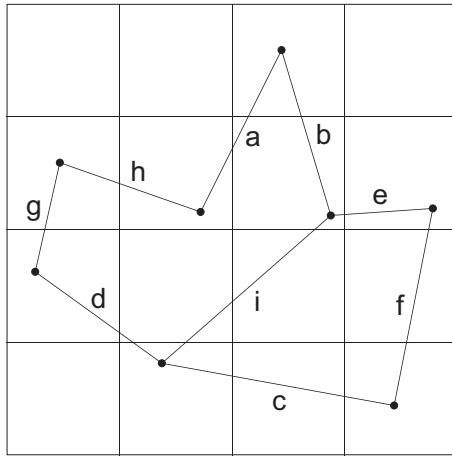

FIGURE 17.5 Example collection of line segments embedded in a 4×4 grid.

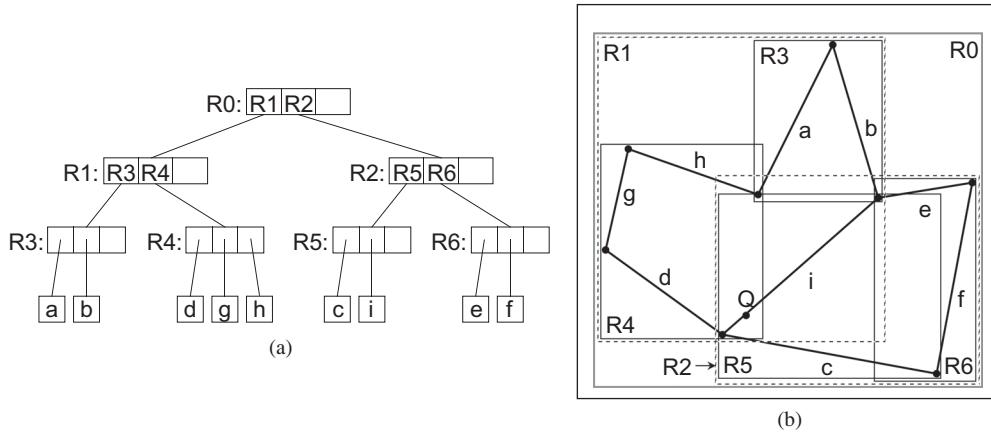

FIGURE 17.6 (a) R-tree for the collection of line segments with $m = 2$ and $M = 3$, in Figure 17.5, and (b) the spatial extents of the bounding rectangles. Notice that the leaf nodes in the index also store bounding rectangles although this is only shown for the nonleaf nodes.

(i.e., m and M) are chosen so that a small number of nodes is visited during a spatial query (i.e., point and range queries), which means that m and M are usually quite large. The actual implementation of the R-tree is really a B^+ -tree [16] as the objects are restricted to the leaf nodes.

The efficiency of the R-tree for search operations depends on its ability to distinguish between occupied space and unoccupied space (i.e., coverage), and to prevent a node from being examined needlessly due to a false overlap with other nodes. In other words, we want to minimize coverage and overlap. These goals guide the initial R-tree creation process as well, subject to the previously mentioned constraint that the R-tree is usually built as the objects are encountered rather than waiting until all objects have been input (i.e., dynamically).

The drawback of the R-tree (and any representation based on an object hierarchy) is that it does not result in a disjoint decomposition of space. The problem is that an object is only associated with one bounding rectangle (e.g., line segment i in Figure 17.6 is associated with bounding rectangle R5, yet it passes through R1, R2, R4, and R5, as well as through R0 as do all the line segments). In the worst case, this means that if we wish to determine which object (e.g., an intersecting line in a collection of line segment objects or a containing rectangle in a collection of rectangle objects) is associated with a particular point in the two-dimensional space from which the objects are drawn, then we may have to search the entire collection. For example, in Figure 17.6, when searching for the line segment that passes through point Q, we need to examine bounding rectangles R0, R1, R4, R2, and R5, rather than just R0, R2, and R5.

This drawback can be overcome by using one of three other approaches which are based on a decomposition of space into disjoint cells. Their common property is that the objects are decomposed into disjoint subobjects such that each of the subobjects is associated with a different cell. They differ in the degree of regularity imposed by their underlying decomposition rules and by the way in which the cells are aggregated into buckets.

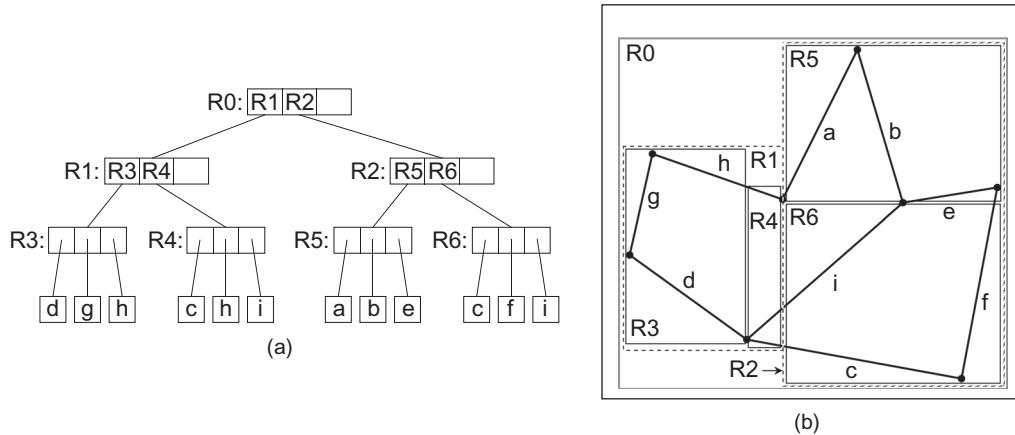

FIGURE 17.7 (a) R^+ -tree for the collection of line segments in Figure 17.5 with $m = 2$ and $M = 3$ and (b) the spatial extents of the bounding rectangles. Notice that the leaf nodes in the index also store bounding rectangles although this is only shown for the nonleaf nodes.

The price paid for the disjointness is that in order to determine the area covered by a particular object, we have to retrieve all the cells that it occupies. This price is also paid when we want to delete an object. Fortunately, deletion is not so common in such applications. A related costly consequence of disjointness is that when we wish to determine all the objects that occur in a particular region, we often need to retrieve some of the objects more than once [27–29]. This is particularly troublesome when the result of the operation serves as input to another operation via composition of functions. For example, suppose we wish to compute the perimeter of all the objects in a given region. Clearly, each object's perimeter should only be computed once. Avoiding reporting some of the objects more than once is a serious issue (see Reference 27 for a discussion of how to deal with this problem for a collection of line segment objects and Reference 28 for a collection of rectangle objects; see also Reference 29).

The first method based on disjointness partitions the embedding space into disjoint subspaces, and hence the individual objects into subobjects, so that each subspace consists of disjoint subobjects. The subspaces are then aggregated and grouped in another structure, such as a B-tree, so that all subsequent groupings are disjoint at each level of the structure. The result is termed as k -d-B-tree [30]. The R^+ -tree [31,32] is a modification of the k -d-B-tree where at each level we replace the subspace by the minimum bounding rectangle of the subobjects or subtrees that it contains. The cell tree [33] is based on the same principle as the R^+ -tree except that the collections of objects are bounded by minimum convex polyhedra instead of minimum axis-aligned bounding rectangles.

The R^+ -tree (as well as the other related representations) is motivated by a desire to avoid overlap among the bounding rectangles. Each object is associated with all the bounding rectangles that it intersects. All bounding rectangles in the tree (with the exception of the bounding rectangles for the objects at the leaf nodes) are nonoverlapping.* The result is that there may be several paths starting at the root to the same object. This may lead to an increase in the height of the tree. However, retrieval time is sped up.

Figure 17.7 is an example of one possible R^+ -tree for the collection of line segments in Figure 17.5. This particular tree is of order (2,3) although in general it is not possible to guarantee that all nodes will always have a minimum of two entries. In particular, the expected B-tree performance guarantees are not valid (i.e., pages are not guaranteed to be m/M full) unless we are willing to perform very complicated record insertion and deletion procedures. Notice that line segment objects c, h , and i appear in two different nodes. Of course, other variants are possible since the R^+ -tree is not unique.

The problem with representations such as the k -d-B-tree and the R^+ -tree is that overflow in a leaf node may cause overflow of nodes at shallower depths in the tree whose subsequent partitioning may cause repartitioning at deeper levels in the tree. There are several ways of overcoming the repartitioning problem. One approach is to use the LSD-tree [34] at the cost of poorer storage utilization. An alternative approach is to use representations such as the hB-tree [35] and the BANG file [36] which remove the requirement that each block be a hyperrectangle at the cost of multiple postings. This has a similar effect as that obtained when decomposing an object into several subobjects in order to overcome the nondisjoint decomposition problem when using an object hierarchy. The multiple posting problem is overcome by the BV-tree [37] which decouples the partitioning and grouping processes at the cost that the resulting tree is no longer balanced although as in the PK-tree [18] (which we point

* From a theoretical viewpoint, the bounding rectangles for the objects at the leaf nodes should also be disjoint. However, this may be impossible (e.g., when the objects are line segments and if many of the line segments intersect at a point).

out in Section 17.2 is also based on decoupling), use of relatively large fanout values ensure that the resulting trees are relatively shallow.

Methods such as the R⁺-tree (as well as the R-tree) also have the drawback that the decomposition is data dependent. This means that it is difficult to perform tasks that require composition of different operations and data sets (e.g., set-theoretic operations such as overlay). This drawback means that although these methods are good at distinguishing between occupied and unoccupied space in the underlying space (termed *image* in much of the subsequent discussion) under consideration, they are unable to correlate occupied space in two distinct images, and likewise for unoccupied space in the two images.

In contrast, the remaining two approaches to the decomposition of space into disjoint cells have a greater degree of data independence. They are based on a regular decomposition. The space can be decomposed either into blocks of uniform size (e.g., the uniform grid [38]) or adapt the decomposition to the distribution of the data (e.g., a quadtree-based approach [39]). In the former case, all the blocks are congruent (e.g., the 4×4 grid in Figure 17.5). In the latter case, the widths of the blocks are restricted to be powers of two and their positions are also restricted. Since the positions of the subdivision lines are restricted, and essentially the same for all images of the same size, it is easy to correlate occupied and unoccupied space in different images.

The uniform grid is ideal for uniformly distributed data, while quadtree-based approaches are suited for arbitrarily distributed data. In the case of uniformly distributed data, quadtree-based approaches degenerate to a uniform grid, albeit they have a higher overhead. Both the uniform grid and the quadtree-based approaches lend themselves to set-theoretic operations and thus they are ideal for tasks which require the composition of different operations and data sets. In general, since spatial data is not usually uniformly distributed, the quadtree-based regular decomposition approach is more flexible. The drawback of quadtree-like methods is their sensitivity to positioning in the sense that the placement of the objects relative to the decomposition lines of the space in which they are embedded effects their storage costs and the amount of decomposition that takes place. This is overcome to a large extent by using a bucketing adaptation that decomposes a block only if it contains more than b objects.

17.4 Region Data

There are many ways of representing region data. We can represent a region either by its boundary (termed a *boundary-based* representation) or by its interior (termed an *interior-based* representation). In this section, we focus on representations of collections of regions by their interior. In some applications, regions are really objects that are composed of smaller primitive objects by use of geometric transformations and Boolean set operations. *Constructive Solid Geometry* (CSG) [40] is a term usually used to describe such representations. They are beyond the scope of this chapter although algorithms do exist for converting between them and the quadtree and octree representations discussed in this chapter [41,42]. Instead, unless noted otherwise, our discussion is restricted to regions consisting of congruent cells of unit area (volume) with sides (faces) of unit size that are orthogonal to the coordinate axes.

Regions with arbitrary boundaries are usually represented by either using approximating bounding rectangles or more general boundary-based representations that are applicable to collections of line segments that do not necessarily form regions. In that case, we do not restrict the line segments to be parallel to the coordinate axes. Such representations are discussed in Section 17.6. It should be clear that although our presentation and examples in this section deal primarily with two-dimensional data, they are valid for regions of any dimensionality.

The region data is assumed to be uniform in the sense that all the cells that comprise each region are of the same type. In other words, each region is homogeneous. Of course, an image may consist of several distinct regions. Perhaps the best definition of a region is as a set of four-connected cells (i.e., in two dimensions, the cells are adjacent along an edge rather than a vertex) each of which is of the same type. For example, we may have a crop map where the regions correspond to the four-connected cells on which the same crop is grown. Each region is represented by the collection of cells that comprise it. The set of collections of cells that make up all of the regions is often termed an *image array* because of the nature in which they are accessed when performing operations on them. In particular, the array serves as an access structure in determining the region associated with a location of a cell as well as all remaining cells that comprise the region.

When the region is represented by its interior, then often we can reduce the storage requirements by aggregating identically valued cells into blocks. In the rest of this section, we discuss different methods of aggregating the cells that comprise each region into blocks as well as the methods used to represent the collections of blocks that comprise each region in the image.

The collection of blocks is usually a result of a space decomposition process with a set of rules that guide it. There are many possible decompositions. When the decomposition is recursive, we have the situation that the decomposition occurs in stages and often, although not always, the results of the stages form a containment hierarchy. This means that a block b obtained in stage i is decomposed into a set of blocks b_j that span the same space. Blocks b_j are, in turn, decomposed in stage $i + 1$ using the same decomposition rule. Some decomposition rules restrict the possible sizes and shapes of the blocks as well as their placement in space. Some examples include:

- Congruent blocks at each stage
- Similar blocks at all stages
- All sides of a block are of equal size
- All sides of each block are powers of 2 and so on.

Other decomposition rules dispense with the requirement that the blocks be rectangular (i.e., there exist decompositions using other shapes like triangles, etc.), while still others do not require that they be orthogonal, although, as stated before, we do make these assumptions here. In addition, the blocks may be disjoint or be allowed to overlap. Moreover, we can also constrain the centers of the blocks while letting them span a larger area so long as they cover all of the regions but they need not be disjoint (e.g., the quadtree medial axis transform, QMAT) [43,44]. Clearly, the choice is large. In the following, we briefly explore some of these decomposition processes. We restrict ourselves to disjoint decompositions, although this need not be the case (e.g., the field tree [45]).

The most general decomposition permits aggregation along all dimensions. In other words, the decomposition is arbitrary. The blocks need not be uniform or similar. The only requirement is that the blocks span the space of the environment. The drawback of arbitrary decompositions is that there is little structure associated with them. This means that it is difficult to answer queries such as determining the region associated with a given point, besides exhaustive search through the blocks. Thus we need an additional data structure known as an index or an access structure. A very simple decomposition rule that lends itself to such an index in the form of an array is one that partitions a d -dimensional space having coordinate axes x_i into d -dimensional blocks by use of h_i hyperplanes that are parallel to the hyperplane formed by $x_i = 0$ ($1 \leq i \leq d$). The result is a collection of $\prod_{i=1}^d (h_i + 1)$ blocks. These blocks form a grid of irregular-sized blocks rather than congruent blocks. There is no recursion involved in the decomposition process. We term the resulting decomposition an *irregular grid* as the partition lines are at arbitrary positions in contrast to a *uniform grid* [38] where the partition lines are positioned so that all of the resulting grid cells are congruent.

Although the blocks in the irregular grid are not congruent, we can still impose an array access structure by adding d access structures termed *linear scales*. The linear scales indicate the position of the partitioning hyperplanes that are parallel to the hyperplane formed by $x_i = 0$ ($1 \leq i \leq d$). Thus given a location l in space, say (a, b) in two-dimensional space, the linear scales for the x and y coordinate values indicate the column and row, respectively, of the array access structure entry which corresponds to the block that contains l . The linear scales are usually represented as one-dimensional arrays although they can be implemented using tree access structures such as binary search trees, range trees, segment trees, and so on.

Perhaps the most widely known decompositions into blocks are those referred to by the general terms *quadtree* and *octree* [3–5]. They are usually used to describe a class of representations for two- and three-dimensional data (and higher as well), respectively, that are the result of a recursive decomposition of the environment (i.e., space) containing the regions into blocks (not necessarily rectangular) until the data in each block satisfies some condition (e.g., with respect to its size, the nature of the regions that comprise it, the number of regions in it, etc.). The positions and/or sizes of the blocks may be restricted or arbitrary. It is interesting to note that quadtrees and octrees may be used with both interior-based and boundary-based representations although only the former are discussed in this section.

There are many variants of quadtrees and octrees (see also Sections 17.2, 17.5, and 17.6), and they are used in numerous application areas including high energy physics, VLSI, finite element analysis, and many others. Below, we focus on *region quadtrees* [46] and to a lesser extent on *region octrees* [47,48]. They are specific examples of interior-based representations for two- and three-dimensional region data (variants for data of higher dimension also exist), respectively, that permit further aggregation of identically valued cells.

Region quadtrees and region octrees are instances of a restricted decomposition rule where the environment containing the regions is recursively decomposed into four or eight, respectively, rectangular congruent blocks until each block is either completely occupied by a region or is empty (such a decomposition process is termed *regular*). For example, Figure 17.8a is the block decomposition for the region quadtree corresponding to three regions A, B, and C. Notice that in this case, all the blocks are square, have sides whose size is a power of 2, and are located at specific positions. In particular, assuming an origin at the lower left corner of the image containing the regions, then the coordinate values of the lower left corner of each block (e.g., (a, b) in two dimensions) of size $2^i \times 2^i$ satisfy the property that $a \bmod 2^i = 0$ and $b \bmod 2^i = 0$.

The traditional, and most natural, access structure for a region quadtree corresponding to a d -dimensional image is a tree with a fanout of 2^d (e.g., Figure 17.8b). Each leaf node in the tree corresponds to a different block b and contains the identity of the region associated with b . Each nonleaf node f corresponds to a block whose volume is the union of the blocks corresponding to the 2^d sons of f . In this case, the tree is a containment hierarchy and closely parallels the decomposition in the sense that they are both recursive processes and the blocks corresponding to nodes at different depths of the tree are similar in shape. Of course, the region quadtree could also be represented by using a mapping from the domain of the blocks to a subset of the integers and then imposing a tree access structure such as a B^+ -tree on the result of the mapping as was described in Section 17.2 for point data stored in a PR quadtree.

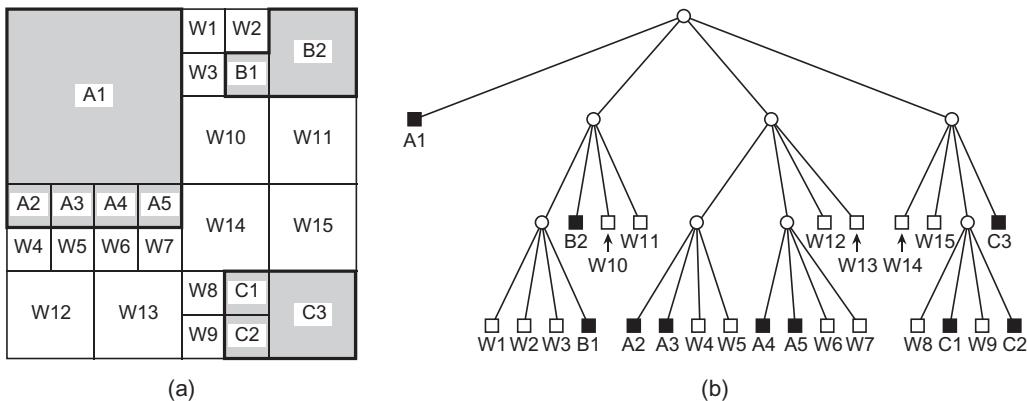

FIGURE 17.8 (a) Block decomposition and (b) its tree representation for the region quadtree corresponding to a collection of three regions A, B, and C.

As the dimensionality of the space (i.e., d) increases, each level of decomposition in the region quadtree results in many new blocks as the fanout value 2^d is high. In particular, it is too large for a practical implementation of the tree access structure. In this case, an access structure termed a *bintree* [49–51] with a fanout value of 2 is used. The bintree is defined in a manner analogous to the region quadtree except that at each subdivision stage, the space is decomposed into two equal-sized parts. In two dimensions, at odd stages we partition along the y -axis and at even stages we partition along the x -axis. In general, in the case of d dimensions, we cycle through the different axes every d levels in the bintree.

The region quadtree, as well as the bintree, is a regular decomposition. This means that the blocks are congruent—that is, at each level of decomposition, all of the resulting blocks are of the same shape and size. We can also use decompositions where the sizes of the blocks are not restricted in the sense that the only restriction is that they be rectangular and be a result of a recursive decomposition process. In this case, the representations that we described must be modified so that the sizes of the individual blocks can be obtained. An example of such a structure is an adaptation of the point quadtree [11] to regions. Although the point quadtree was designed to represent points in a higher dimensional space, the blocks resulting from its use to decompose space do correspond to regions. The difference from the region quadtree is that in the point quadtree, the positions of the partitions are arbitrary, whereas they are a result of a partitioning process into 2^d congruent blocks (e.g., quartering in two dimensions) in the case of the region quadtree.

As in the case of the region quadtree, as the dimensionality d of the space increases, each level of decomposition in the point quadtree results in many new blocks since the fanout value 2^d is high. In particular, it is too large for a practical implementation of the tree access structure. In this case, we can adapt the k -d tree [14], which has a fanout value of 2, to regions. As in the point quadtree, although the k -d tree was designed to represent points in a higher dimensional space, the blocks resulting from its use to decompose space do correspond to regions. Thus the relationship of the k -d tree to the point quadtree is the same as the relationship of the bintree to the region quadtree. In fact, the k -d tree is the precursor of the bintree and its adaptation to regions is defined in a similar manner in the sense that for d -dimensional data we cycle through the d -axes every d levels in the k -d tree. The difference is that in the k -d tree, the positions of the partitions are arbitrary, whereas they are a result of a halving process in the case of the bintree.

The k -d tree can be further generalized so that the partitions take place on the various axes at an arbitrary order, and, in fact, the partitions need not be made on every coordinate axis. The k -d tree is a special case of the *BSP tree* (denoting *Binary Space Partitioning*) [52] where the partitioning hyperplanes are restricted to be parallel to the axes, whereas in the BSP tree they have an arbitrary orientation. The BSP tree is a binary tree. In order to be able to assign regions to the left and right subtrees, we need to associate a direction with each subdivision line. In particular, the subdivision lines are treated as separators between two half-spaces.* Let the subdivision line have the equation $a \cdot x + b \cdot y + c = 0$. We say that the right subtree is the “positive” side and contains all subdivision lines formed by separators that satisfy $a \cdot x + b \cdot y + c \geq 0$. Similarly, we say that the left subtree is “negative” and contains all subdivision lines formed by separators that satisfy $a \cdot x + b \cdot y + c < 0$. As an example, consider Figure 17.9a which is an arbitrary space decomposition whose BSP tree is given in Figure 17.9b. Notice the use of arrows to indicate

* A (linear) *half-space* in d -dimensional space is defined by the inequality $\sum_{i=0}^d a_i \cdot x_i \geq 0$ on the $d+1$ homogeneous coordinates ($x_0 = 1$). The half-space is represented by a column vector a . In vector notation, the inequality is written as $a \cdot x \geq 0$. In the case of equality, it defines a hyperplane with a as its normal. It is important to note that half-spaces are volume elements; they are not boundary elements.

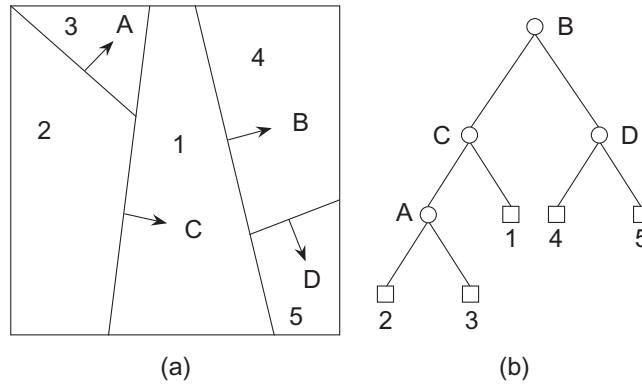

FIGURE 17.9 (a) An arbitrary space decomposition and (b) its BSP tree. The arrows indicate the direction of the positive half-spaces.

the direction of the positive half-spaces. The BSP tree is used in computer graphics to facilitate viewing. It is discussed in greater detail in [Chapter 21](#).

As mentioned before, the various hierarchical data structures that we described can also be used to represent regions in three dimensions and higher. As an example, we briefly describe the region octree which is the three-dimensional analog of the region quadtree. It is constructed in the following manner. We start with an image in the form of a cubical volume and recursively subdivide it into eight congruent disjoint cubes (called octants) until blocks are obtained of a uniform color or a predetermined level of decomposition is reached. [Figure 17.10a](#) is an example of a simple three-dimensional object whose region octree block decomposition is given in [Figure 17.10b](#) and whose tree representation is given in [Figure 17.10c](#).

The aggregation of cells into blocks in region quadtrees and region octrees is motivated, in part, by a desire to save space. Some of the decompositions have quite a bit of structure thereby leading to inflexibility in choosing partition lines, and so on. In fact, at times, maintaining the original image with an array access structure may be more effective from the standpoint of storage requirements. In the following, we point out some important implications of the use of these aggregations. In particular, we focus on the region quadtree and region octree. Similar results could also be obtained for the remaining block decompositions.

The aggregation of similarly valued cells into blocks has an important effect on the execution time of the algorithms that make use of the region quadtree. In particular, most algorithms that operate on images represented by a region quadtree are implemented by a preorder traversal of the quadtree and, thus, their execution time is generally a linear function of the number of nodes in the quadtree. A key to the analysis of the execution time of quadtree algorithms is the *Quadtree Complexity Theorem* [47] which states that the number of nodes in a region quadtree representation for a simple polygon (i.e., with nonintersecting edges and without holes) is $O(p + q)$ for a $2^q \times 2^q$ image with perimeter p measured in terms of the width of unit-sized cells (i.e., pixels). In all but the most pathological cases (e.g., a small square of unit width centered in a large image), the q factor is negligible and thus the number of nodes is $O(p)$.

The Quadtree Complexity Theorem also holds for three-dimensional data [53] (i.e., represented by a region octree) where perimeter is replaced by surface area, as well as for objects of higher dimensions d for which it is proportional to the size of the $(d - 1)$ -dimensional interfaces between these objects. The most important consequence of the Quadtree Complexity Theorem is that it means that most algorithms that execute on a region quadtree representation of an image, instead of one that simply

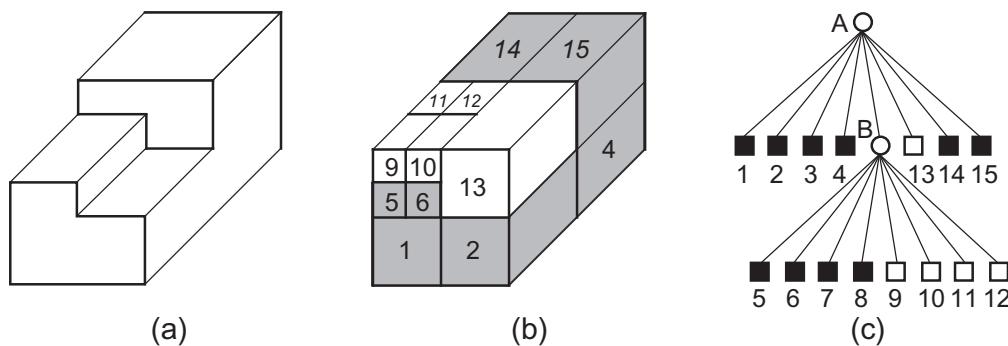

FIGURE 17.10 (a) Example three-dimensional object, (b) its region octree block decomposition, and (c) its tree representation.

imposes an array access structure on the original collection of cells, usually have an execution time that is proportional to the number of blocks in the image rather than the number of unit-sized cells. Some examples of such algorithms include perimeter computation [54], connected component labeling [55], Euler number [56], and quadtree to raster conversion [57]. Other related ramifications are illustrated by algorithms to compute spatial range queries which related to image dilation (i.e., region expansion and corridor or buffer computation in GIS) [58] which have been observed to execute in time that is independent of the radius of expansion when the regions to be expanded are represented using region quadtrees [59].

In its most general case, the above means that the use of the region quadtree, with an appropriate access structure, in solving a problem in d -dimensional space will lead to a solution whose execution time is proportional to the $(d - 1)$ -dimensional space of the surface of the original d -dimensional image. On the other hand, use of the array access structure on the original collection of cells results in a solution whose execution time is proportional to the number of cells that comprise the image. Therefore, region quadtrees and region octrees act like dimension-reducing devices.

Using a tree access structure captures the characterization of the region quadtree as being of variable resolution in that the underlying space is subdivided recursively until the underlying region satisfies some type of a homogeneity criterion. This is in contrast to a pyramid structure [60,61], which is a family of representations that make use of multiple resolution. This means that the underlying space is subdivided up to the smallest unit (i.e., a pixel) thereby resulting in a complete quadtree, where each leaf node is at the maximum depth and the nonleaf nodes contain information summarizing the contents of their subtrees. The pyramid facilitates feature-based queries [60], which given a feature, identify where it is in space, while the quadtree is more suited for location-based queries, which given a location, identify the features that are associated with it. Feature-based queries have become known as spatial data mining and the pyramid is used to implement them [60,62,63].

17.5 Rectangle Data

The rectangle data type lies somewhere between the point and region data types. It can also be viewed as a special case of the region data type in the sense that it is a region with only four sides. Rectangles are often used to approximate other objects in an image for which they serve as the minimum rectilinear enclosing object. For example, bounding rectangles are used in cartographic applications to approximate objects such as lakes, forests, hills, and so on. In such a case, the approximation gives an indication of the existence of an object. Of course, the exact boundaries of the object are also stored, but they are only accessed if greater precision is needed. For such applications, the number of elements in the collection is usually small, and most often the sizes of the rectangles are of the same order of magnitude as the space from which they are drawn.

Rectangles are also used in VLSI design rule checking as a model of chip components for the analysis of their proper placement. Again, the rectangles serve as minimum enclosing objects. In this application, the size of the collection is quite large (e.g., millions of components) and the sizes of the rectangles are several orders of magnitude smaller than the space from which they are drawn.

It should be clear that the actual representation that is used depends heavily on the problem environment. At times, the rectangle is treated as the Cartesian product of two one-dimensional intervals with the horizontal intervals being treated in a different manner than the vertical intervals. In fact, the representation issue is often reduced to one of representing intervals. For example, this is the case in the use of the plane-sweep paradigm [64] in the solution of rectangle problems such as determining all pairs of intersecting rectangles. In this case, each interval is represented by its left and right endpoints. The solution makes use of two passes.

The first pass sorts the rectangles in ascending order on the basis of their left and right sides (i.e., x coordinate values) and forms a list. The second pass sweeps a vertical scan line through the sorted list from left to right halting at each one of these points, say p . At any instant, all rectangles that intersect the scan line are considered *active* and are the only ones whose intersection needs to be checked with the rectangle associated with p . This means that each time the sweep line halts, a rectangle either becomes active (causing it to be inserted in the set of active rectangles) or ceases to be active (causing it to be deleted from the set of active rectangles). Thus the key to the algorithm is its ability to keep track of the active rectangles (actually just their vertical sides) as well as to perform the actual one-dimensional intersection test.

Data structures such as the segment tree [65], interval tree [66], and the priority search tree [20] can be used to organize the vertical sides of the active rectangles so that, for N rectangles and F intersecting pairs of rectangles, the problem can be solved in $O(N \cdot \log_2 N + F)$ time. All three data structures enable intersection detection, insertion, and deletion to be executed in $O(\log_2 N)$ time. The difference between them is that the segment tree requires $O(N \cdot \log_2 N)$ space while the interval tree and the priority search tree only need $O(N)$ space. These algorithms require that the set of rectangles be known in advance. However, they work even when the size of the set of active rectangles exceeds the amount of available memory, in which case multiple passes are made over the data [67]. For more details about these data structures, see Chapter 19.

In this chapter, we are primarily interested in dynamic problems (i.e., the set of rectangles is constantly changing). The data structures that are chosen for the collection of the rectangles are differentiated by the way in which each rectangle is represented.

One representation discussed in Section 17.1 reduces each rectangle to a point in a higher dimensional space, and then treats the problem as if we have a collection of points [1]. Again, each rectangle is a Cartesian product of two one-dimensional intervals where the difference from its use with the plane-sweep paradigm is that each interval is represented by its centroid and extent. Each set of intervals in a particular dimension is, in turn, represented by a grid file [9] which is described in Section 17.2.

The second representation is region-based in the sense that the subdivision of the space from which the rectangles are drawn depends on the physical extent of the rectangle—not just one point. Representing the collection of rectangles, in turn, with a tree-like data structure has the advantage for some of the representations that there is a relation between the depth of node in the tree and the size of the rectangle(s) that is (are) associated with it. Interestingly, some of the region-based solutions make use of the same data structures that are used in the solutions based on the plane-sweep paradigm.

There are three types of region-based solutions currently in use. The first two solutions use the R-tree and the R^+ -tree (discussed in Section 17.3) to store rectangle data (in this case the objects are rectangles instead of arbitrary objects). The third is a quadtree-based approach and uses the MX-CIF quadtree [68] (see also Reference 69 for a related variant).

In the *MX-CIF quadtree*, each rectangle is associated with the quadtree node corresponding to the smallest block which contains it in its entirety. Subdivision ceases whenever a node's block contains no rectangles. Alternatively, subdivision can also cease once a quadtree block is smaller than a predetermined threshold size. This threshold is often chosen to be equal to the expected size of the rectangle [68]. For example, Figure 17.11b is the MX-CIF quadtree for a collection of rectangles given in Figure 17.11a. Rectangles can be associated with both leaf and nonleaf nodes.

It should be clear that more than one rectangle can be associated with a given enclosing block and, thus, often we find it useful to be able to differentiate between them. This is done in the following manner [68]. Let P be a quadtree node with centroid (CX, CY) , and let S be the set of rectangles that are associated with P . Members of S are organized into two sets according to their intersection (or collinearity of their sides) with the lines passing through the centroid of P 's block—that is, all members of S that intersect the line $x = CX$ form one set and all members of S that intersect the line $y = CY$ form the other set.

If a rectangle intersects both lines (i.e., it contains the centroid of P 's block), then we adopt the convention that it is stored with the set associated with the line through $x = CX$. These subsets are implemented as binary trees (really tries), which in actuality are one-dimensional analogs of the MX-CIF quadtree. For example, Figures 17.11c and d illustrate the binary trees associated with the y -axes passing through the root and the NE son of the root, respectively, of the MX-CIF quadtree of Figure 17.11b. Interestingly, the MX-CIF quadtree is a two-dimensional analog of the interval tree described earlier. More precisely, the MX-CIF quadtree is a two-dimensional analog of the tile tree [70] which is a regular decomposition version of the interval tree. In fact, the tile tree and the one-dimensional MX-CIF quadtree are identical when rectangles are not allowed to overlap.

The drawback of the MX-CIF quadtree is that the size of the minimum enclosing quadtree cells depends on the position of the centroids of the objects and is independent of the size of the objects, subject to a minimum which is the size of the object. In fact, it may be as large as the entire space from which the objects are drawn. This has bad ramifications for applications where the objects move including games, traffic monitoring, and streaming. In particular, if the objects are moved even slightly, then they usually need to be reinserted in the structure.

The cover fieldtree [45,71] and the more commonly known loose quadtree (octree) [72] are designed to overcome this independence of the size of the minimum enclosing quadtree cell and the size of the object (see also the expanded MX-CIF quadtree [73], multiple shifted quadtree methods [74–76], and the partition fieldtree [45,71]). This is done by expanding the size of the space that is spanned by each quadtree cell c of width w by a cell expansion factor p ($p > 0$) so that the expanded cell is of width $(1 + p) \cdot w$ and an object is associated with its minimum enclosing expanded quadtree (octree) cell. The notion of an expanded quadtree cell can also be seen in the QMAT [43,44]. For example, letting $p = 1$, Figure 17.12 is the loose quadtree corresponding to the

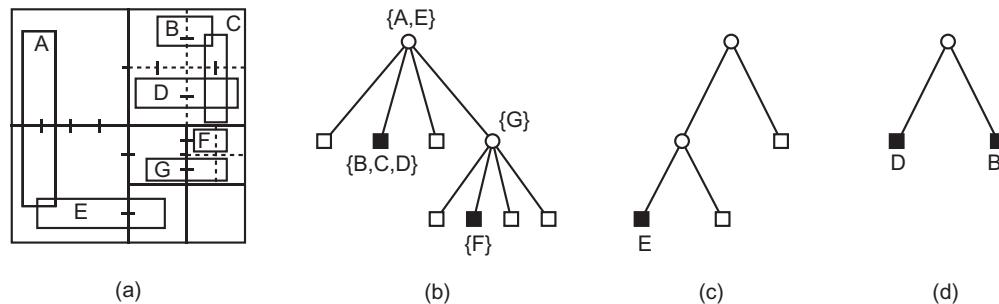

FIGURE 17.11 (a) Collection of rectangles and the block decomposition induced by the MX-CIF quadtree; (b) the tree representation of (a); the binary trees for the y -axes passing through the root of the tree in (b), and (d) the NE son of the root of the tree in (b).

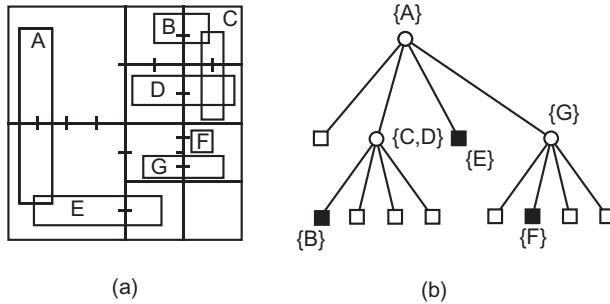

FIGURE 17.12 (a) Cell decomposition induced by the loose quadtree for a collection of rectangle objects identical to those in [Figure 17.11a](#) and (b) its tree representation.

collection of objects in [Figure 17.11a](#) and its MX-CIF quadtree in [Figure 17.11b](#). In this example, there are only two differences between the loose and MX-CIF quadtrees:

1. Rectangle object E is associated with the SW child of the root of the loose quadtree instead of with the root of the MX-CIF quadtree.
2. Rectangle object B is associated with the NW child of the NE child of the root of the loose quadtree instead of with the NE child of the root of the MX-CIF quadtree.

Ulrich [72] has shown that given a loose quadtree cell c of width w and cell expansion factor p , the radius r of the minimum bounding hypercube box b of the smallest object o that could possibly be associated with c must be greater than $pw/4$. Samet et al. [77] point out that the real utility of the loose quadtree is best evaluated in terms of the inverse of the above relation as we are interested in minimizing the maximum possible width w of c given an object o with minimum bounding hypercube box b of radius r (i.e., half the length of a side of the hypercube). This is because reducing w is the real motivation and goal for the development of the loose quadtree as an alternative to the MX-CIF quadtree for which, as we pointed out, w can be as large as the width of the underlying space. This was done by examining the range of the relative widths of c and b as this provides a way of taking into account the constraints imposed by the fact that the range of values of w is limited to powers of 2. In particular, they showed that this range is just a function of p , and hence independent of the position of o . Moreover, they prove that for $p \geq 0.5$, the relative widths of c and b take on at most two values, and usually just one value for $p \geq 1$. This makes updating the index very simple when objects are moving as there are at most two possible new cells associated with a moved object, instead of \log_2 of the width of the space in which the objects are embedded (e.g., as large as 16 assuming a $2^{16} \times 2^{16}$ embedding space). In other words, they have shown how to update in $O(1)$ time for $p \geq 0.5$ which is of great importance as there is no longer a need to perform a search for the appropriate quadtree cell.

17.6 Line Data and Boundaries of Regions

Section 17.4 was devoted to variations on hierarchical decompositions of regions into blocks, an approach to region representation that is based on a description of the region's interior. In this section, we focus on representations that enable the specification of the boundaries of regions, as well as curvilinear data and collections of line segments. The representations are usually based on a series of approximations which provide successively closer fits to the data, often with the aid of bounding rectangles. When the boundaries or line segments have a constant slope (i.e., linear and termed *line segments* in the rest of this discussion), then an exact representation is possible.

There are several ways of approximating a curvilinear line segment. The first is by digitizing it and then marking the unit-sized cells (i.e., pixels) through which it passes. The second is to approximate it by a set of straight line segments termed a *polyline*. Assuming a boundary consisting of straight lines (or polylines after the first stage of approximation), the simplest representation of the boundary of a region is the polygon. It consists of vectors which are usually specified in the form of lists of pairs of x and y coordinate values corresponding to their start and end points. The vectors are usually ordered according to their connectivity. One of the most common representations is the chain code [78] which is an approximation of a polygon's boundary by use of a sequence of unit vectors in the four (and sometimes eight) principal directions.

Chain codes, and other polygon representations, break down for data in three dimensions and higher. This is primarily due to the difficulty in ordering their boundaries by connectivity. The problem is that in two dimensions connectivity is determined by ordering the boundary elements $e_{i,j}$ of boundary b_i of object o so that the end vertex of the vector v_j corresponding to $e_{i,j}$

is the start vertex of the vector v_{j+1} corresponding to $e_{i,j+1}$. Unfortunately, such an implicit ordering does not exist in higher dimensions as the relationship between the boundary elements associated with a particular object is more complex.

Instead, we must make use of data structures which capture the topology of the object in terms of its faces, edges, and vertices. The winged-edge data structure is one such representation which serves as the basis of the boundary model (also known as *BRep* [79]). For more details about these data structures, see [Chapter 18](#).

Polygon representations are very local. In particular, if we are at one position on the boundary, we don't know anything about the rest of the boundary without traversing it element by element. Thus, using such representations, given a random point in space, it is very difficult to find the nearest line to it as the lines are not sorted. This is in contrast to hierarchical representations which are global in nature. They are primarily based on rectangular approximations to the data as well as on a regular decomposition in two dimensions. In the rest of this section, we discuss a number of such representations.

In Section 17.3, we already examined two hierarchical representations (i.e., the R-tree and the R^+ -tree) that propagate object approximations in the form of bounding rectangles. In this case, the sides of the bounding rectangles had to be parallel to the coordinate axes of the space from which the objects are drawn. In contrast, the *strip tree* [80] is a hierarchical representation of a single curve that successively approximates segments of it with bounding rectangles that does not require that the sides be parallel to the coordinate axes. The only requirement is that the curve be continuous; it need not be differentiable.

The strip tree data structure consists of a binary tree whose root represents the bounding rectangle of the entire curve. The rectangle associated with the root corresponds to a rectangular strip, that encloses the curve, whose sides are parallel to the line joining the endpoints of the curve. The curve is then partitioned in two at one of the locations where it touches the bounding rectangle (these are not tangent points as the curve only needs to be continuous; it need not be differentiable). Each subcurve is then surrounded by a bounding rectangle and the partitioning process is applied recursively. This process stops when the width of each strip is less than a predetermined value.

In order to be able to cope with more complex curves such as those that arise in the case of object boundaries, the notion of a strip tree must be extended. In particular, closed curves and curves that extend past their endpoints require some special treatment. The general idea is that these curves are enclosed by rectangles which are split into two rectangular strips, and from now on the strip tree is used as before.

The strip tree is similar to the point quadtree in the sense that the points at which the curve is decomposed depend on the data. In contrast, a representation based on the region quadtree has fixed decomposition points. Similarly, strip tree methods approximate curvilinear data with rectangles of arbitrary orientation, while methods based on the region quadtree achieve analogous results by use of a collection of disjoint squares having sides of length power of two. In the following, we discuss a number of adaptations of the region quadtree for representing curvilinear data.

The simplest adaptation of the region quadtree is the MX quadtree [47,81]. It is built by digitizing the line segments and labeling each unit-sized cell (i.e., pixel) through which the line segments pass as of type `boundary`. The remaining pixels are marked `WHITE` and are merged, if possible, into larger and larger quadtree blocks. [Figure 17.13a](#) is the MX quadtree for the collection of line segment objects in [Figure 17.5](#). A drawback of the MX quadtree is that it associates a thickness with a line. Also, it is difficult to detect the presence of a vertex whenever five or more line segments meet.

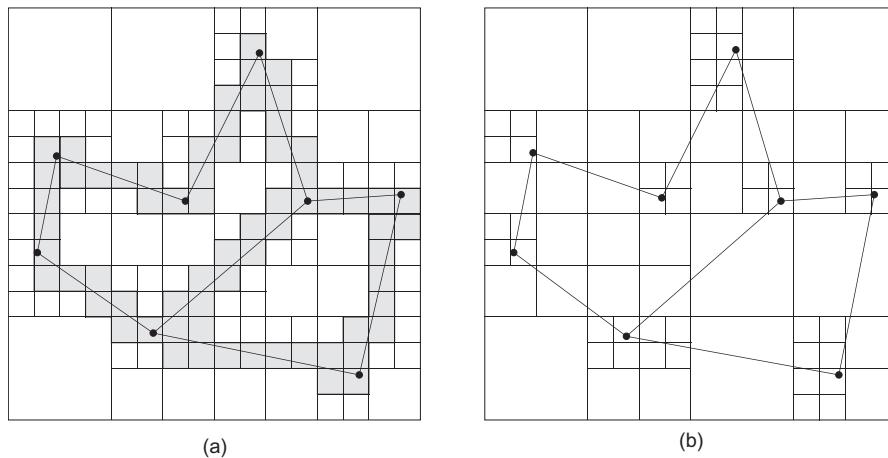

FIGURE 17.13 (a) MX quadtree and (b) edge quadtree for the collection of line segments of [Figure 17.5](#).

The edge quadtree [82,83] is a refinement of the MX quadtree based on the observation that the number of squares in the decomposition can be reduced by terminating the subdivision whenever the square contains a single curve that can be approximated by a single straight line. For example, Figure 17.13b is the edge quadtree for the collection of line segment objects in Figure 17.5. Applying this process leads to quadtrees in which long edges are represented by large blocks or a sequence of large blocks. However, small blocks are required in the vicinity of corners or intersecting edges. Of course, many blocks will contain no edge information at all.

The PM quadtree family [39,84] (see also edge-EXCELL [15]) represents an attempt to overcome some of the problems associated with the edge quadtree in the representation of collections of polygons (termed *polygonal maps*). In particular, the edge quadtree is an approximation because vertices are represented by pixels. There are a number of variants of the PM quadtree. These variants are either vertex-based or edge-based. They are all built by applying the principle of repeatedly breaking up the collection of vertices and edges (forming the polygonal map) until obtaining a subset that is sufficiently simple so that it can be organized by some other data structure.

The PM₁ quadtree [39] is an example of a vertex-based PM quadtree. Its decomposition rule stipulates that partitioning occurs as long as a block contains more than one line segment unless the line segments are all incident at the same vertex which is also in the same block (e.g., Figure 17.14a). Given a polygonal map whose vertices are drawn from a grid (say $2^m \times 2^m$), and where edges are not permitted to intersect at points other than the grid points (i.e., vertices), it can be shown that the maximum depth of any leaf node in the PM₁ quadtree is bounded from above by $4m + 1$ [85]. This enables a determination of the maximum amount of storage that will be necessary for each node. The PM₂ quadtree is another vertex-based member of the PM quadtree family that is similar to the PM₁ quadtree with the difference that the partitioning of a block b is halted when the line segments in b are all incident at the same vertex v but v need not be in the same block b as is the case for the PM₁ quadtree. For example, this means that in the PM₂ quadtree there is no need to partition the block corresponding to the NE child of the SW quadrant as in the PM₁ quadtree in Figure 17.14a that corresponds to the polygonal map formed by the collection of line segments of Figure 17.5. The PM₂ quadtree is particularly useful for polygonal maps that correspond to triangulations where it has been empirically observed to be relatively insensitive to movement of vertices and edges (L. De Floriani, personal communication, 2004).

A similar representation to the PM₁ quadtree has been devised for polyhedral (i.e., three-dimensional) objects (e.g., see Reference 86 and the references cited in Reference 4). The decomposition criteria are such that no node contains more than one face, edge, or vertex unless the faces all meet at the same vertex or are adjacent to the same edge. This representation is quite useful since its space requirements for polyhedral objects are significantly smaller than those of a region octree.

The PMR quadtree [84] is an edge-based variant of the PM quadtree. It makes use of a probabilistic splitting rule. A node is permitted to contain a variable number of line segments. A line segment is stored in a PMR quadtree by inserting it into the nodes corresponding to all the blocks that it intersects. During this process, the occupancy of each node that is intersected by the line segment is checked to see if the insertion causes it to exceed a predetermined *splitting threshold*. If the splitting threshold is exceeded, then the node's block is split *once*, and only once, into four equal quadrants.

For example, Figure 17.14b is the PMR quadtree for the collection of line segment objects in Figure 17.5 with a splitting threshold value of 2. The line segments are inserted in alphabetic order (i.e., a-i). It should be clear that the shape of the PMR quadtree depends on the order in which the line segments are inserted. Note the difference from the PM₁ quadtree in Figure

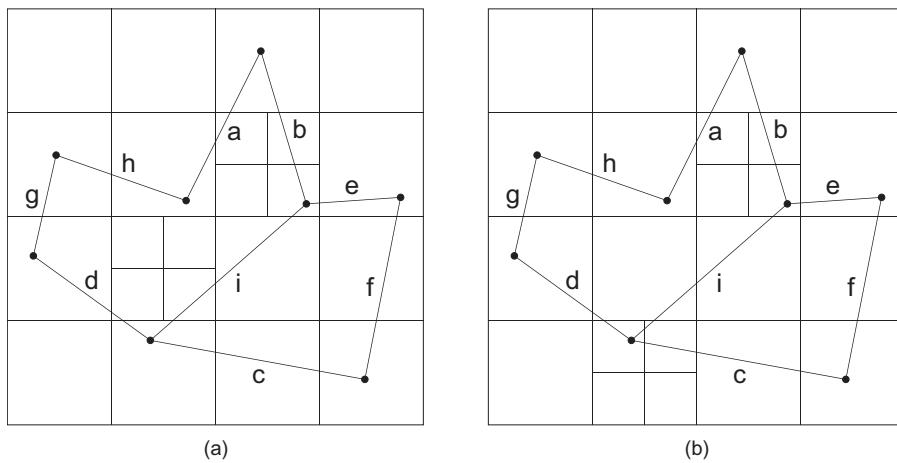

FIGURE 17.14 (a) PM₁ quadtree and (b) PMR quadtree for the collection of line segments of Figure 17.5.

17.14a—that is, the **NE** block of the **SW** quadrant is decomposed in the PM_1 quadtree while the **SE** block of the **SW** quadrant is not decomposed in the PM_1 quadtree.

On the other hand, a line segment is deleted from a PMR quadtree by removing it from the nodes corresponding to all the blocks that it intersects. During this process, the occupancy of the node and its siblings is checked to see if the deletion causes the total number of line segments in them to be less than the predetermined splitting threshold. If the splitting threshold exceeds the occupancy of the node and its siblings, then they are merged and the merging process is reapplied to the resulting node and its siblings. Notice the asymmetry between the splitting and merging rules.

The PMR quadtree is very good for answering queries such as finding the nearest line to a given point [87–90] (see Reference 91 for an empirical comparison with hierarchical object representations such as the R-tree and R^+ -tree). It is preferred over the PM_1 quadtree (as well as the MX and edge quadtrees) as it results in far fewer subdivisions. In particular, in the PMR quadtree there is no need to subdivide in order to separate line segments that are very “close” or whose vertices are very “close,” which is the case for the PM_1 quadtree. This is important since four blocks are created at each subdivision step. Thus when many subdivision steps that occur in the PM_1 quadtree result in creating many empty blocks, the storage requirements of the PM_1 quadtree will be considerably higher than those of the PMR quadtree. Generally, as the splitting threshold is increased, the storage requirements of the PMR quadtree decrease while the time necessary to perform operations on it will increase.

Using a random image model and geometric probability, it has been shown [92], theoretically and empirically using both random and real map data, that for sufficiently high values of the splitting threshold (i.e., ≥ 4), the number of nodes in a PMR quadtree is asymptotically proportional to the number of line segments and is independent of the maximum depth of the tree. In contrast, using the same model, the number of nodes in the PM_1 quadtree is a product of the number of lines and the maximal depth of the tree (i.e., n for a $2^n \times 2^n$ image). The same experiments and analysis for the MX quadtree confirmed the results predicted by the Quadtree Complexity Theorem (see Section 17.4) which is that the number of nodes is proportional to the total length of the line segments. Observe that although a bucket in the PMR quadtree can contain more line segments than the splitting threshold, this is not a problem. In fact, it can be shown [4] that the maximum number of line segments in a bucket is bounded by the sum of the splitting threshold and the depth of the block (i.e., the number of times the original space has been decomposed to yield this block).

When the line segments that make up the polygonal map are orthogonal and parallel to the coordinate axes, then we can make use of the line quadtree [93,94] which is an enhancement of the region quadtree where the boundaries of the regions are coincident with the quadtree blocks and are also represented in a hierarchical manner. In particular, the line quadtree recursively partitions the underlying space until obtaining blocks (possibly single pixels) that have no boundary elements passing through their interior. Associated with each block is a four bit code which indicates which of its four sides forms a boundary (not a partial boundary) of any single object (including the underlying space). Thus instead of distinguishing blocks on the basis of whether they are part of the background, and of the identity of the object in which they lie, we use the nature of the boundary information. Note the distinction from the region quadtree where no information is associated with the nonleaf nodes. In this respect, it is more like the pyramid (see Section 17.4).

17.7 Research Issues and Summary

A review has been presented of a number of representations of multidimensional data. Our focus has been on multidimensional spatial data with extent rather than just multidimensional point data. There has been a particular emphasis on hierarchical representations. Such representations are based on the “divide-and-conquer” problem-solving paradigm. They are of interest because they enable focusing computational resources on the interesting subsets of data. Thus there is no need to expend work where the payoff is small. Although many of the operations for which they are used can often be performed equally as efficiently, or more so, with other data structures, hierarchical data structures are attractive because of their conceptual clarity and ease of implementation.

When the hierarchical data structures are based on the principle of regular decomposition, we have the added benefit that different data sets (often of differing types) are in registration. This means that they are partitioned in known positions which are often the same or subsets of one another for the different data sets. This is true for all the features including regions, points, rectangles, lines, volumes, and so on. The result is that a query such as “finding all cities with more than 20,000 inhabitants in wheat-growing regions within 30 miles of the Mississippi River” can be executed by simply overlaying the region (crops), point (i.e., cities), and river maps even though they represent data of different types. Alternatively, we may extract regions such as those within 30 miles of the Mississippi River. Such operations find use in applications involving spatial data such as GIS.

Current research in multidimensional representations is highly application dependent in the sense that the work is driven by the application. Many of the recent developments have been motivated by the interaction with databases. This is facilitated by

the existence of browsing (e.g., [95–98]) or manipulating (e.g., by what is termed a spatial spreadsheet [99]) capabilities. The choice of a proper representation plays a key role in the speed with which responses are provided to queries. Knowledge of the underlying data distribution is also a factor and research is ongoing to make use of this information in the process of making a choice. Most of the initial applications in which the representation of multidimensional data has been important have involved spatial data of the kind described in this chapter. Such data is intrinsically of low dimensionality (i.e., two and three).

Future applications involve higher dimensional data for applications such as image databases where the data are often points in feature space. Unfortunately, for such applications, the performance of most indexing methods that rely on a decomposition of the underlying space is often unsatisfactory when compared with not using an index at all [100]. The problem is that for uniformly distributed data, most of the data is found to be at or near the boundary of the space in which it lies [101]. The result means that the query region usually overlaps all of the leaf node regions that are created by the decomposition process and thus a sequential scan is preferable. This has led to a number of alternative representations that try to speed up the scan (e.g., VA-file [102], VA⁺-file [103], IQ-tree [104], etc.). Nevertheless, representations such as the pyramid technique [105] are based on the principle that most of the data lies near the surface and therefore subdivide the data space as if it is an onion by peeling off hypervolumes that are close to its boundary. This is achieved by first dividing the hypercube corresponding to the d -dimensional data space into $2d$ pyramids having the center of the data space as their top point and one of the faces of the hypercube as its base. These pyramids are subsequently cut into slices that are parallel to their base. Of course, the high-dimensional data is not necessarily uniformly distributed which has led to other data structures with good performance (e.g., the hybrid tree [106]). Clearly, more work needs to be done in this area.

It is interesting to observe that the rise of the use of the world wide web has made spatial multidimensional data such as locations much more common. The explicit specification of location has traditionally been geometric (e.g., as latitude-longitude pairs of numbers). Unfortunately, this is not easy as most people don't usually know of a location in this way. Even more important is the fact that they don't know where to obtain this information and are not used to communicate or receive it from others in this way. Instead, they are used to specify a location textually which includes verbally.

The principal drawback of the textual specification of location data is that it is potentially ambiguous. First of all, we must be sure that the textual entity actually corresponds to a location (termed a *toponym*) rather than the name of a person, an organization, or an object, to name a few of many possible alternative interpretations. The process of determining whether a textual entity is a toponym is termed *toponym recognition* [107]. Moreover, having identified the textual entity as a toponym such as “Alexandria,” there are many possible locations named “Alexandria” and they must be resolved. This process is known as *toponym resolution* [108,109]. Moreover, in some cases we are not even sure that the term “Lincoln” denotes a location as it could be a reference to the name of a person. Both of these issues can arise when processing documents such as newspaper articles [110–114], tweets [115–117], blogs, and so on. The process of understanding and converting location text to its geometric specification, known as *geotagging* [118–126], serves as a prerequisite to indexing the data and is the subject of much research.

18.1 Introduction

Graphs ([Chapter 4](#)) have found extensive applications in computer science as a modeling tool. In mathematical terms, a graph is simply a collection of vertices and edges. Indeed, a popular graph data structure is the adjacency lists representation [1] in which each vertex keeps a list of vertices connected to it by edges. In a typical application, the vertices model entities and an edge models a relation between the entities corresponding to the edge endpoints. For example, the transportation problem calls for a minimum cost shipping pattern from a set of origins to a set of destinations [2]. This can be modeled as a complete directed bipartite graph. The origins and destinations are represented by two columns of vertices. Each origin vertex is labeled with the amount of supply stored there. Each destination vertex is labeled with the amount of demand required there. The edges are directed from the origin vertices to the destination vertices and each edge is labeled with the unit cost of transportation. Only the adjacency information between vertices and edges are useful and captured, apart from the application dependent information.

In geometric computing, graphs are also useful for representing various diagrams. We restrict our attention to diagrams that are planar graphs embedded in the plane using straight edges without edge crossings. Such diagrams are called *planar straight line graphs* and denoted by PSLGs for short. Examples include Voronoi diagrams, arrangements, and triangulations. Their definitions can be found in standard computational geometry texts such as the book by de Berg et al. [3]. See also [Chapters 65, 66, and 67](#). For completeness, we also provide their definitions in Section 18.8. The straight edges in a PSLG partition the plane into regions with disjoint interior. We call these regions *faces*. The adjacency lists representation is usually inadequate for applications that manipulate PSLGs. Consider the problem of locating the face containing a query point in a Delaunay triangulation. One practical algorithm is to walk towards the query point from a randomly chosen starting vertex [4], see [Figure 18.1](#). To support this algorithm, one needs to know the first face that we enter as well as the next face that we step into whenever we cross an edge. Such information is not readily provided by an adjacency lists representation.

There are three well-known data structures for representing PSLGs: the winged-edge, halfedge, and quadedge data structures. In Sections 18.2 and 18.3, we discuss the PSLGs that we deal with in more details and the operations on PSLGs. Afterwards, we introduce the three data structures in Sections 18.4 through 18.6. We conclude in Section 18.7 with some further remarks.

18.2 Features of PSLGs

We assume that each face has exactly one boundary and we allow dangling edges on a face boundary. These assumptions are valid for many important classes of PSLGs such as triangulations, Voronoi diagrams, planar subdivisions with no holes, arrangements of lines, and some special arrangements of line segments (see [Figure 18.2](#)).

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

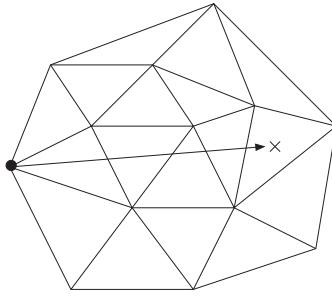

FIGURE 18.1 Locate the face containing the cross by walking from a randomly chosen vertex.

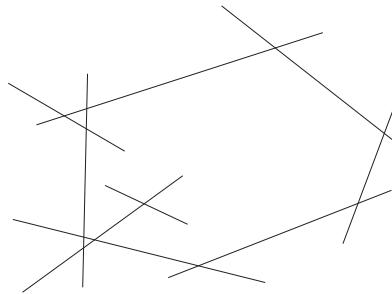

FIGURE 18.2 Dangling edges.

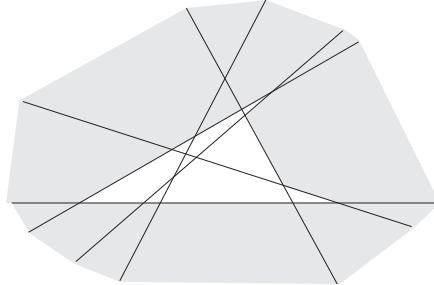

FIGURE 18.3 The shaded faces are the unbounded faces of the arrangement.

There is at least one unbounded face in a PSLG but there could be more than one, for example, in the arrangement of lines shown in [Figure 18.3](#).

The example also shows that there may be some infinite edges. To handle infinite edges like halflines and lines, we need a special vertex v_{inf} at infinity. One can imagine that the PSLG is placed in a small almost flat disk D at the north pole of a giant sphere S and v_{inf} is placed at the south pole. If an edge e is a halfline originating from a vertex u , then the endpoints of e are u and v_{inf} . One can view e as a curve on S from u near the north pole to v_{inf} at the south pole, but e behaves as a halfline inside the disk D . If an edge e is a line, then v_{inf} is the only endpoint of e . One can view e as a loop from v_{inf} to the north pole and back, but e behaves as a line inside the disk D .

We do not allow isolated vertices, except for v_{inf} . Planarity implies that the incident edges of each vertex are circularly ordered around that vertex. This applies to v_{inf} as well.

A PSLG data structure keeps three kinds of attributes: *vertex attributes*, *edge attributes*, and *face attributes*. The attributes of a vertex include its coordinates except for v_{inf} (we assume that v_{inf} is tagged to distinguish it from other vertices). The attributes of an edge include the equation of the support line of the edge (in the form of $Ax + By + C = 0$). The face attributes are useful for auxiliary information, for example, color.

18.3 Operations on PSLGs

The operations on a PSLG can be classified into *access functions* and *structural operations*. The access functions retrieve information without modifying the PSLG. Since the access functions partly depend on the data structure, we discuss them later when we introduce the data structures. In this section, we discuss four structural operations on PSLGs: *edge insertion*, *edge deletion*, *vertex split*, and *edge contraction*. We concentrate on the semantics of these four operations and discuss the implementation details later when we introduce the data structures. For vertex split and edge contraction, we assume further that each face in the PSLG is a simple polygon as these two operations are usually used under such circumstances.

18.3.1 Edge Insertion and Deletion

When a new edge e with endpoints u and v is inserted, we assume that e does not cross any existing edge. If u or v is not an existing vertex, the vertex will be created. If both u and v are new vertices, e is an isolated edge inside a face f . Since each face is assumed to have exactly one boundary, this case happens only when the PSLG is empty and f is the entire plane. Note that e becomes a new boundary of f . If either u or v is a new vertex, then the boundary of exactly one face gains the edge e . If both u and v already exist, then u and v lie on the boundary of a face which is split into two new faces by the insertion of e . These cases are illustrated in Figure 18.4.

The deletion of an edge e has the opposite effects. After the deletion of e , if any of its endpoint becomes an isolated vertex, it will be removed. The vertex v_{inf} is an exception and it is the only possible isolated vertex. The edge insertion is clearly needed to create a PSLG from scratch. Other effects can be achieved by combining edge insertions and deletions appropriately. For example, one can use the two operations to overlay two PSLGs in a plane sweep algorithm, see Figure 18.5.

18.3.2 Vertex Split and Edge Contraction

The splitting of a vertex v is best visualized as the continuous morphing of v into an edge e . Depending on the specification of the splitting, an incident face of v gains e on its boundary or an incident edge of v is split into a triangular face, see Figure 18.6. The incident edges of v are displaced and it is assumed that no self-intersection occurs within the PSLG during the splitting. The contraction of an edge e is the inverse of the vertex split. We also assume that no self-intersection occurs during the edge contraction. If e is incident on a triangular face, that face will disappear after the contraction of e .

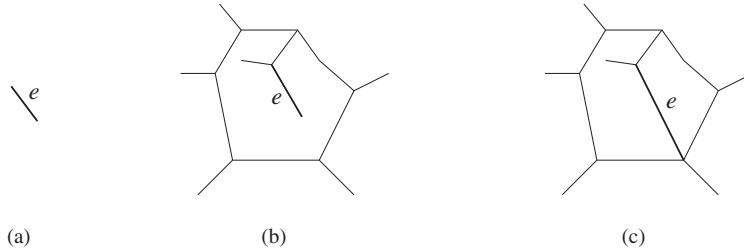

FIGURE 18.4 Cases in edge insertion.

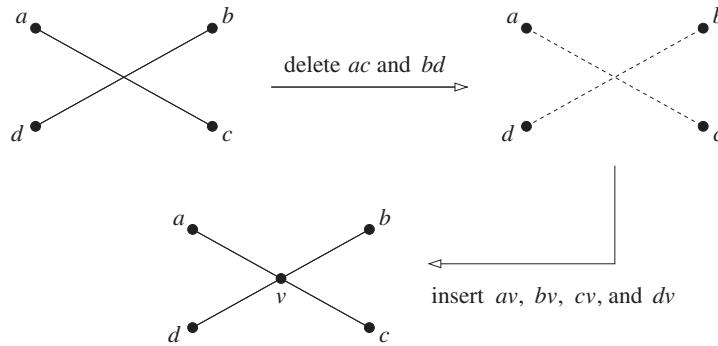

FIGURE 18.5 Intersecting two edges.

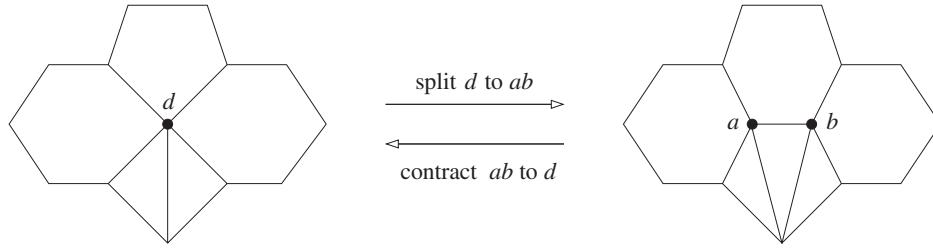

FIGURE 18.6 Vertex split and edge contraction.

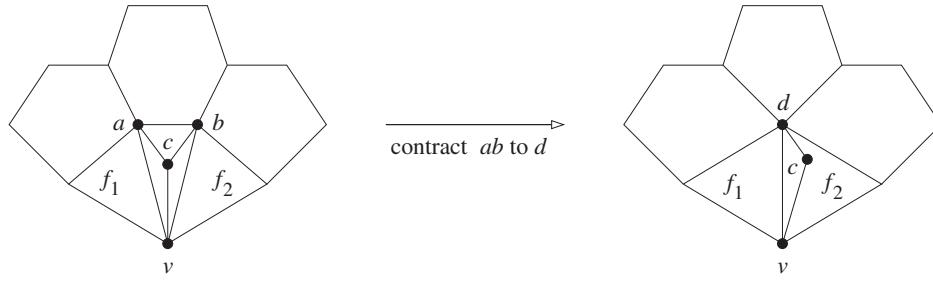

FIGURE 18.7 Non-contractible edge.

Not every edge can be contracted. Consider an edge ab . If the PSLG contains a cycle abv that is not the boundary of any face incident to ab , we call the edge ab *non-contractible* because its contraction is not cleanly defined. Figure 18.7 shows an example. In the figure, after the contraction, there is an ambiguity whether dv should be incident on the face f_1 or the face f_2 . In fact, one would expect the edge dv to behave like av and bv and be incident on both f_1 and f_2 after the contraction. However, this is impossible.

The vertex split and edge contraction have been used in clustering and hierarchical drawing of maximal planar graphs [5].

18.4 Winged-Edge

The winged-edge data structure was introduced by Baumgart [6] and it predates the halfedge and quadedge data structures. There are three kinds of records: *vertex records*, *edge records*, and *face records*. Each vertex record keeps a reference to one incident edge of the vertex. Each face record keeps a reference to one boundary edge of the face. Each edge e is stored as an oriented edge with the following references (see Figure 18.8):

- The *origin* endpoint $e.org$ and the *destination* endpoint $e.dest$ of e . The convention is that e is directed from $e.org$ to $e.dest$.
- The faces $e.left$ and $e.right$ on the left and right of e , respectively.
- The two edges $e.lcw$ and $e.lccw$ adjacent to e that bound the face $e.left$. The edge $e.lcw$ is incident to $e.org$ and the edge $e.lccw$ is incident to $e.dest$. Note that $e.lcw$ (resp. $e.lccw$) succeeds e if the boundary of $e.left$ is traversed in the clockwise (resp. anti-clockwise) direction from e .
- The two edges $e.rcw$ and $e.rccw$ adjacent to e that bound the face $e.right$. The edge $e.rcw$ is incident to $e.dest$ and the edge $e.rccw$ is incident to $e.org$. Note that $e.rcw$ (resp. $e.rccw$) succeeds e if the boundary of $e.right$ is traversed in the clockwise (resp. anti-clockwise) direction from e .

The information in each edge record can be retrieved in constant time. Given a vertex v , an edge e , and a face f , we can thus answer in constant time whether v is incident on e and e is incident on f . Given a vertex v , we can traverse the edges incident to v in clockwise order as follows. We output the edge e kept at the vertex record for v . We perform $e := e.rccw$ if $v = e.org$ and $e := e.lccw$ otherwise. Then we output e and repeat the above. Given a face f , we can traverse its boundary edges in clockwise order as follows. We output the edge e kept at the face record for f . We perform $e := e.lcw$ if $f = e.left$ and $e := e.rcw$ otherwise. Then we output e and repeat the above.

Note that an edge reference does not carry information about the orientation of the edge. Also, the orientations of the boundary edges of a face need not be consistent with either the clockwise or anti-clockwise traversal. Thus, the manipulation of the data structure is often complicated by case distinctions. We illustrate this with the insertion of an edge e . Assume that $e.org = u$,

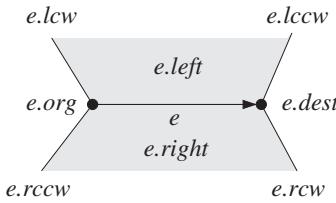

FIGURE 18.8 Winged-edge data structure.

$e.dest = v$, and both u and v already exist. The input also specifies two edges e_1 and e_2 incident to u and v , respectively. The new edge e is supposed to immediately succeed e_1 (resp. e_2) in the anti-clockwise ordering of edges around u (resp. v). The insertion routine works as follows.

1. If $u = v_{inf}$ and it is isolated, we need to store the reference to e in the vertex record for u . We update the vertex record for v similarly.
2. Let e_3 be the incident edge of u following e_1 such that e is to be inserted between e_1 and e_3 . Note that e_3 succeeds e_1 in anti-clockwise order. We insert e between e_1 and e_3 as follows.

```

 $e.rccw := e_1; e.lcw := e_3;$ 
if  $e.org = e_1.org$  then  $e_1.lcw := e$ ; else  $e_1.rcw := e$ ;
if  $e.org = e_3.org$  then  $e_3.rccw := e$ ; else  $e_3.lccw := e$ ;
```

3. Let e_4 be the incident edge of v following e_2 such that e is to be inserted between e_2 and e_4 . Note that e_4 succeeds e_2 in anti-clockwise order. We insert e between e_2 and e_4 as follows.

```

 $e.lccw := e_2; e.rcw := e_4;$ 
if  $e.dest = e_2.dest$  then  $e_2.rcw := e$ ; else  $e_2.lcw := e$ ;
if  $e.dest = e_4.dest$  then  $e_4.lccw := e$ ; else  $e_4.rccw := e$ ;
```

4. The insertion of e has split a face into two. So we create a new face f and make $e.left$ reference it. Also, we store a reference to e in the face record for f . There are further ramifications. First, we make $e.right$ reference the old face.

```
if  $e.org = e_1.org$  then  $e.right := e_1.left$ ; else  $e.right := e_1.right$ ;
```

Second, we make the *left* or *right* fields of the boundary edges of f reference f .

```

 $e' := e; w := e.org;$ 
repeat
if  $e'.org = w$  then  $e'.left := f$ ;  $w := e'.dest$ ;  $e' := e'.lccw$ 
else  $e'.right := f$ ;  $w := e'.org$ ;  $e' := e'.rccw$ 
until  $e' = e$ ;
```

Notice the inconvenient case distinctions needed in steps 2, 3, and 4. The halfedge data structure is designed to keep both orientations of the edges and link them properly. This eliminates most of these case distinctions as well as simplifies the storage scheme.

18.5 Halfedge

In the halfedge data structure, for each edge in the PSLG, there are two symmetric edge records for the two possible orientations of the edge [7]. This solves the orientation problem in the winged-edge data structure. The halfedge data structure is also known as the *doubly connected edge list* [3]. We remark that the name doubly connected edge list was first used to denote the variant of the winged-edge data structure in which the *lccw* and *rccw* fields are omitted [8,9].

There are three kinds of records: *vertex records*, *halfedge records*, and *face records*. Let e be a halfedge. The following information is kept at the record for e (see Figure 18.9).

- The reference $e.sym$ to the symmetric version of e .
- The *origin* endpoint $e.org$ of e . We do not need to store the destination endpoint of e since it can be accessed as $e.sym.org$. The convention is that e is directed from $e.org$ to $e.sym.org$.
- The face $e.left$ on the left of e .
- The next edge $e.succ$ and the previous edge $e.pred$ in the anti-clockwise traversal around the face $e.left$.

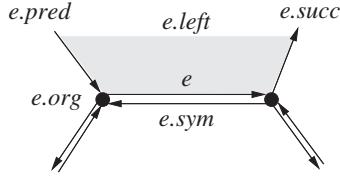

FIGURE 18.9 Halfedge data structure.

For each vertex v , its record keeps a reference to one halfedge $v.edge$ such that $v = v.edge.org$. For each face f , its record keeps a reference to one halfedge $f.edge$ such that $f = f.edge.left$.

We introduce two basic operations `make_halfedges` and `half_splice` which will be needed for implementing the operations on PSLGs. These two operations are motivated by the operations `make_edge` and `splice` introduced by Guibas and Stolfi [10] for the quadedge data structure. We can also do without `make_halfedges` and `half_splice`, but they make things simpler.

- `make_halfedges(u, v)`: Return two halfedges e and $e.sym$ connecting the points u and v . The halfedges e and $e.sym$ are initialized such that they represent a new PSLG with e and $e.sym$ as the only halfedges. That is, $e.succ = e.sym = e.pred$ and $e.sym.succ = e = e.sym.pred$. Also, e is the halfedge directed from u to v . If u and v are omitted, it means that the actual coordinates of $e.org$ and $e.sym.org$ are unimportant.
- `half_splice(e_1, e_2)`: Given two halfedges e_1 and e_2 , `half_splice` swaps the contents of $e_1.pred$ and $e_2.pred$ and the contents of $e_1.pred.succ$ and $e_2.pred.succ$. The effects are:
 - Let $v = e_2.org$. If $e_1.org \neq v$, the incident halfedges of $e_1.org$ and $e_2.org$ are merged into one circular list (see Figure 18.10a). The vertex v is now redundant and we finish the merging as follows.

```

 $e' := e_2;$ 
repeat
   $e'.org := e_1.org; e' := e'.sym.succ;$ 
until  $e' = e_2;$ 
delete the vertex record for  $v$ ;

```

- Let $v = e_2.org$. If $e_1.org = v$, the incident halfedges of v are separated into two circular lists (see Figure 18.10b). We create a new vertex u for $e_2.org$ with the coordinates of u left uninitialized. Then we finish the separation as follows.

```

 $u.edge := e_2; e' := e_2;$ 
repeat
   $e'.org := u; e' := e'.sym.succ;$ 
until  $e' = e_2$ .

```

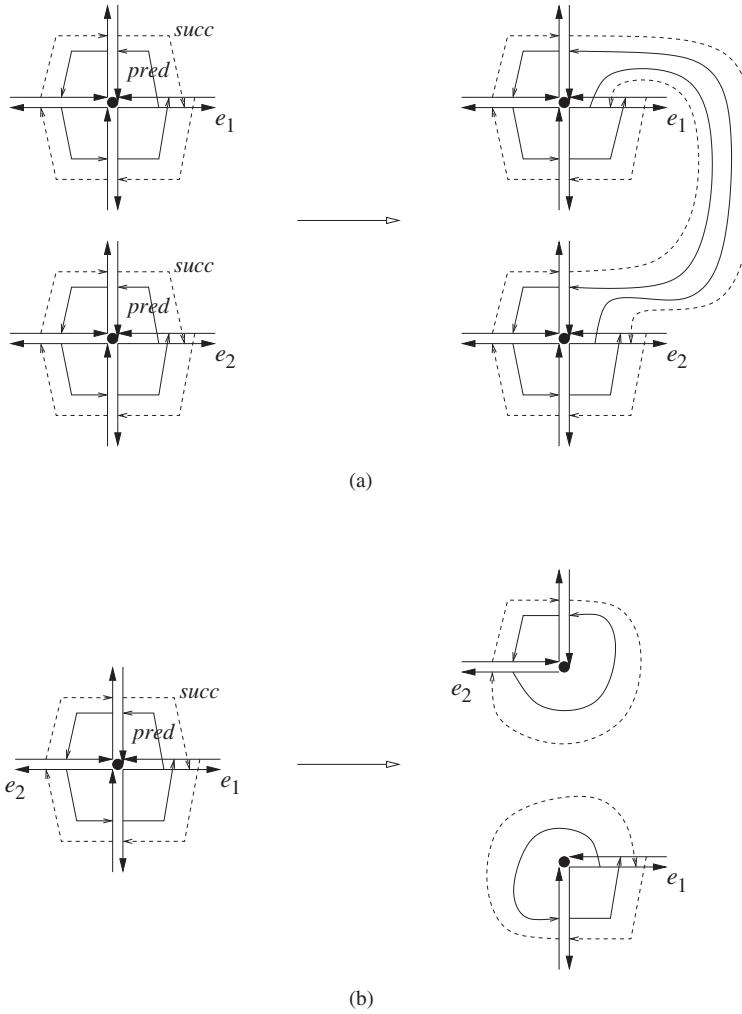

The behavior of `half_splice` is somewhat complex even in the following special cases. If e is an isolated halfedge, `half_splice(e_1, e)` deletes the vertex record for $e.org$ and makes e a halfedge incident to $e_1.org$ following e_1 in anti-clockwise order. If $e_1 = e.sym.succ$, `half_splice(e_1, e)` detaches e from the vertex $e_1.org$ and creates a new vertex record for $e.org$. If $e_1 = e$, `half_splice(e, e)` has no effect at all.

18.5.1 Access Functions

The information in each halfedge record can be retrieved in constant time. Given a vertex v , a halfedge e , and a face f , we can thus answer the following adjacency queries:

1. Is v incident on e ? This is done by checking if $v = e.org$ or $e.sym.org$.
2. Is e incident on f ? This is done by checking if $f = e.left$.
3. List the halfedges with origin v in clockwise order. Let $e = v.edge$. Output e , perform $e := e.sym.succ$, and then repeat until we return to $v.edge$.
4. List the boundary halfedges of f in anti-clockwise order. Let $e = f.edge$. Output e , perform $e := e.succ$, and then repeat until we return to $f.edge$.

Other adjacency queries (e.g., listing the boundary vertices of a face) can be answered similarly.

FIGURE 18.10 The effects of `half_splice`.

18.5.2 Edge Insertion and Deletion

The edge insertion routine takes two vertices u and v and two halfedges e_1 and e_2 . If u is a new vertex, e_1 is ignored; otherwise, we assume that $e_1.org = u$. Similarly, if v is a new vertex, e_2 is ignored; otherwise, we assume that $e_2.org = v$. The general case is that an edge connecting u and v is inserted between e_1 and $e_1.pred.sym$ and between e_2 and $e_2.pred.sym$. The two new halfedges e and $e.sym$ are returned with the convention that e is directed from u to v .

```
Algorithm insert( $u, v, e_1, e_2$ )
1.  $(e, e.sym) := \text{make\_halfedges}(u, v);$ 
2. if  $u$  is not new
3.   then half_splice( $e_1, e$ );
4.      $e.left := e_1.left;$ 
5.      $e.sym.left := e_1.left;$ 
6. if  $v$  is not new
7.   then half_splice( $e_2, e.sym$ );
8.      $e.left := e_2.left;$ 
9.      $e.sym.left := e_2.left;$ 
10. if neither  $u$  nor  $v$  is new
11.   then /* A face has been split */
12.      $e_2.left.edge := e;$ 
```

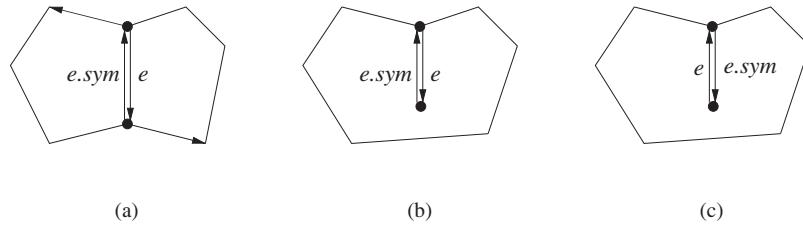

FIGURE 18.11 Cases in deletion.

```

13.      create a new face  $f$ ;
14.       $f.\text{edge} := e.\text{sym}$ ;
15.       $e' := e.\text{sym}$ ;
16.      repeat
17.           $e'.\text{left} := f$ ;
18.           $e' := e'.\text{succ}$ ;
19.      until  $e' = e.\text{sym}$ ;
20.      return  $(e, e.\text{sym})$ ;

```

The following deletion algorithm takes the two halfedges e and $e.\text{sym}$ corresponding to the edge to be deleted. If the edge to be deleted borders two adjacent faces, they have to be merged after the deletion.

Algorithm $\text{delete}(e, e.\text{sym})$

```

1.  if  $e.\text{left} \neq e.\text{sym}.\text{left}$ 
2.  then /* Figure 18.11a */
3.      /* the faces adjacent to  $e$  and  $e.\text{sym}$  are to be merged */
4.      delete the face record for  $e.\text{sym}.\text{left}$ ;
5.       $e' := e.\text{sym}$ ;
6.      repeat
7.           $e'.\text{left} := e.\text{left}$ ;
8.           $e' := e'.\text{succ}$ ;
9.      until  $e' = e.\text{sym}$ ;
10.      $e.\text{left}.\text{edge} := e.\text{succ}$ ;
11.      $\text{half\_splice}(e.\text{sym}.\text{succ}, e)$ ;
12.      $\text{half\_splice}(e.\text{succ}, e.\text{sym})$ ;
13.  else if  $e.\text{succ} = e.\text{sym}$ 
14.      then /* Figure 18.11b */
15.           $e.\text{left}.\text{edge} := e.\text{pred}$ ;
16.           $\text{half\_splice}(e.\text{sym}.\text{succ}, e)$ ;
17.      else /* Figure 18.11c */
18.           $e.\text{left}.\text{edge} := e.\text{succ}$ ;
19.           $\text{half\_splice}(e.\text{succ}, e.\text{sym})$ ;
20.  /*  $e$  becomes an isolated edge */
21.  delete the vertex record for  $e.\text{org}$  if  $e.\text{org} \neq v_{\text{inf}}$ ;
22.  delete the vertex record for  $e.\text{sym}.\text{org}$  if  $e.\text{sym}.\text{org} \neq v_{\text{inf}}$ ;
23.  delete the halfedges  $e$  and  $e.\text{sym}$ ;

```

18.5.3 Vertex Split and Edge Contraction

Recall that each face is assumed to be a simple polygon for the vertex split and edge contraction operations. The vertex split routine takes two points (p, q) and (x, y) and four halfedges e_1, e_2, e_3 , and e_4 in anti-clockwise order around the common origin v . It is required that either $e_1 = e_2$ or $e_1.\text{pred} = e_2.\text{sym}$ and either $e_3 = e_4$ or $e_3.\text{pred} = e_4.\text{sym}$. The routine splits v into an edge e connecting the points (p, q) and (x, y) . Also, e borders the faces bounded by e_1 and e_2 and by e_3 and e_4 . Note that if $e_1 = e_2$, we create a new face bounded by e_1, e_2 , and e . Similarly, a new face is created if $e_3 = e_4$. The following is the vertex split algorithm.

Algorithm $\text{split}(p, q, x, y, e_1, e_2, e_3, e_4)$

1. **if** $e_1 \neq e_2$ and $e_3 \neq e_4$

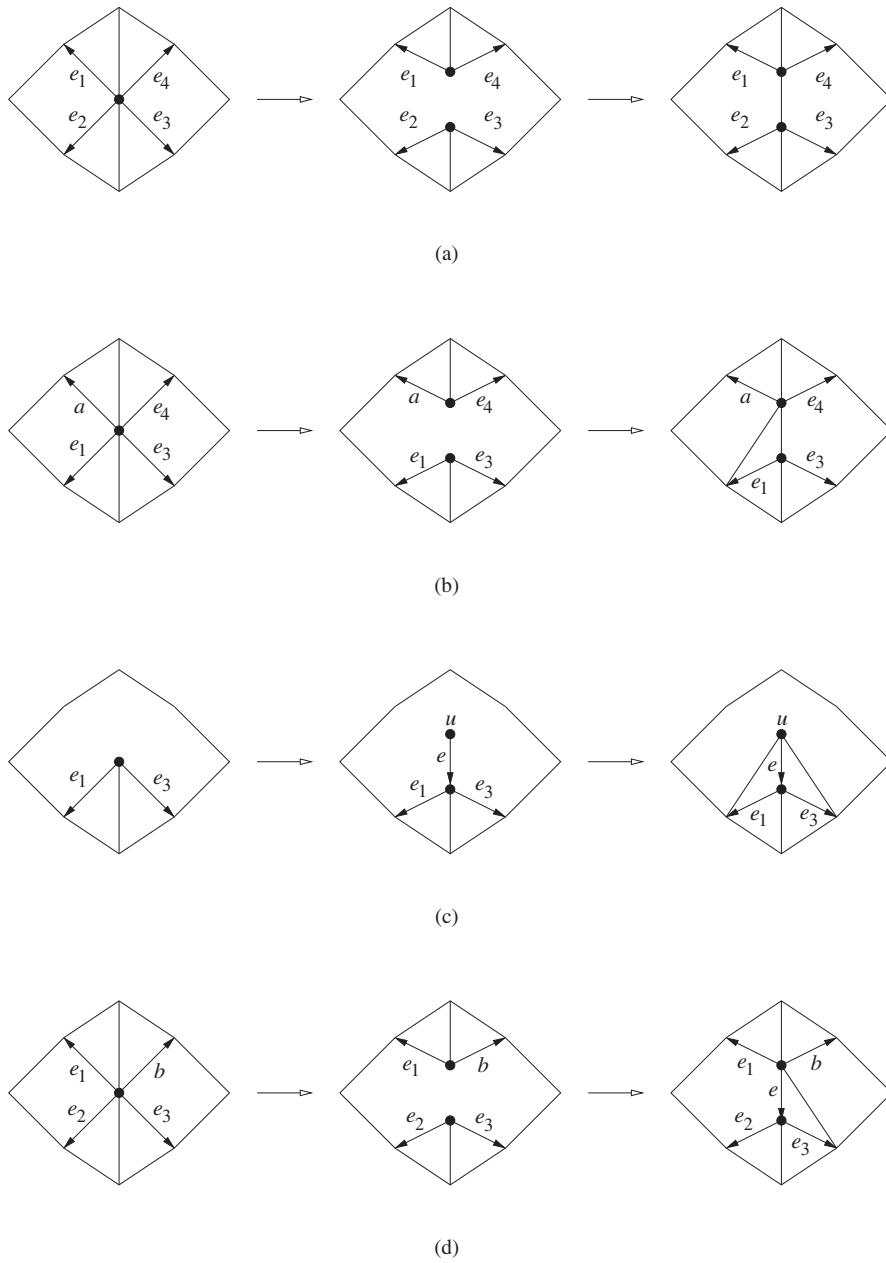

FIGURE 18.12 Cases for split.

```

2.   then /* Figure 18.12a */
3.     half_splice( $e_1, e_3$ );
4.     insert( $e_1.org, e_3.org, e_1, e_3$ );
5.     set the coordinates of  $e_3.org$  to  $(x, y)$ ;
6.     set the coordinates of  $e_1.org$  to  $(p, q)$ ;
7.   else if  $e_1 = e_2$ 
8.     then  $a := e_1.sym.succ$ ;
9.     if  $a \neq e_3$ 
10.    then /* Figure 18.12b */
11.      half_splice( $a, e_3$ );
12.      insert( $a.org, e_3.org, a, e_3$ );
13.      insert( $a.org, e_1.sym.org, a, e_1.sym$ );

```

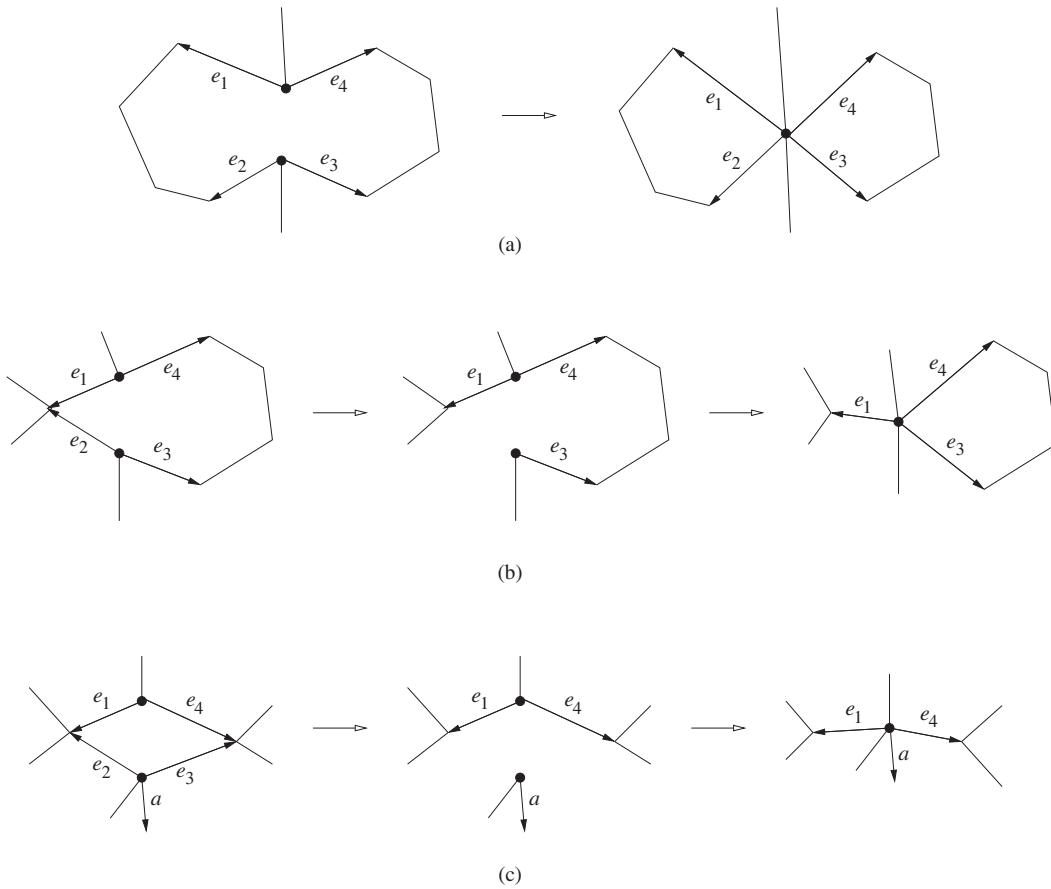

FIGURE 18.13 Cases for contract.

```

14.      set the coordinates of  $a.org$  to  $(x, y)$ ;
15.      else /* Figure 18.12c */
16.          let  $u$  be a new vertex at  $(x, y)$ ;
17.           $(e, e.sym) := \text{insert}(u, e_1.org, \cdot, e_3);$ 
18.           $\text{insert}(u, e_1.sym.org, e, e_1.sym);$ 
19.           $\text{insert}(u, e_3.sym.org, e, e_3.succ);$ 
20.      set the coordinates of  $e_1.org$  to  $(p, q)$ ;
21.      else  $b := e_3.pred.sym;$ 
22.          /* since  $e_1 \neq e_2$ ,  $b \neq e_2 */$ 
23.          /* Figure 18.12d */
24.           $\text{half\_splice}(e_1, e_3);$ 
25.           $(e, e.sym) := \text{insert}(b.org, e_3.org, e_1, e_3);$ 
26.           $\text{insert}(b.org, e_3.sym.org, e, e_3.succ);$ 
27.          set the coordinates of  $b.org$  to  $(x, y)$ ;
28.          set the coordinates of  $e_3.org$  to  $(p, q)$ ;

```

The following algorithm contracts an edge to a point (x, y) , assuming that the edge contractibility has been checked.

Algorithm $\text{contract}(e, e.sym, x, y)$

1. $e_1 := e.succ;$
2. $e_2 := e.pred.sym;$
3. $e_3 := e.sym.succ;$
4. $e_4 := e.sym.pred.sym;$
5. $\text{delete}(e, e.sym);$
6. **if** $e_1.succ \neq e_2.sym$ and $e_3.succ \neq e_4.sym$

```

7.   then /* Figure 18.13a */
8.     half_splice( $e_1, e_3$ );
9.   else if  $e_1.succ = e_2.sym$  and  $e_3.succ \neq e_4.sym$ 
10.    then /* Figure 18.13b */
11.      delete( $e_2, e_2.sym$ );
12.      half_splice( $e_1, e_3$ );
13.    else if  $e_1.succ \neq e_2.sym$  and  $e_3.succ = e_4.sym$ 
14.      then /* symmetric to Figure 18.13b */
15.        delete( $e_4, e_4.sym$ );
16.        half_splice( $e_1, e_3$ );
17.    else /* Figure 18.13c */
18.       $a := e_3.sym.succ$ ;
19.      delete( $e_3, e_3.sym$ );
20.      if  $a \neq e_2$ 
21.        then delete( $e_2, e_2.sym$ );
22.        half_splice( $e_1, a$ );
23.      else delete( $e_2, e_2.sym$ );
24. set the coordinates of  $e_1.org$  to  $(x, y)$ ;

```

18.6 Quadedge

The quadedge data structure was introduced by Guibas and Stolfi [10]. It represents the planar subdivision and its dual simultaneously. The dual S^* of a PSLG S is constructed as follows. For each face of S , put a dual vertex inside the face. For each edge of S bordering the faces f and f' , put a dual edge connecting the dual vertices of f and f' . The dual of a vertex v in S is a face and this face is bounded by the dual of the incident edges of v . Figure 18.14 shows an example. The dual may have loops and two vertices may be connected by more than one edge, so the dual may not be a PSLG. Nevertheless, the quadedge data structure is expressive enough to represent the dual. In fact, it is powerful enough to represent subdivisions of both orientable and non-orientable surfaces. We describe a simplified version sufficient for our purposes.

Each edge e in the PSLG is represented by four quadedges $e[i]$, where $i \in \{0, 1, 2, 3\}$. The quadedges $e[0]$ and $e[2]$ are the two oriented versions of e . The quadedges $e[1]$ and $e[3]$ are the two oriented versions of the dual of e . These four quadedges are best viewed as a cross such as $e[i+1]$ is obtained by rotating $e[i]$ for $\pi/2$ in the anti-clockwise direction. This is illustrated in Figure 18.15. The quadedge $e[i]$ has a *next* field referencing the quadedge that has the same origin as $e[i]$ and follows $e[i]$ in anti-clockwise order. In effect, the *next* fields form a circular linked list of quadedges with a common origin. This is called an *edge ring*. The following primitives are needed.

- $\text{rot}(e, i)$: Return $e[(i+1) \bmod 4]$.
- $\text{rot}^{-1}(e, i)$: Return $e[(i+3) \bmod 4]$.
- $\text{sym}(e, i)$: This function returns the quadedge with the opposite orientation of $e[i]$. This is done by returning $\text{rot}(\text{rot}(e, i))$.
- $\text{onext}(e, i)$: Return $e[i].next$.
- $\text{oprev}(e, i)$: This function gives the quadedge that has the same origin as $e[i]$ and follows $e[i]$ in clockwise order. This is done by returning $\text{rot}(e[(i+1) \bmod 4].next)$.

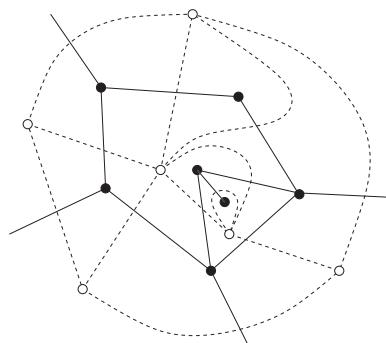

FIGURE 18.14 The solid lines and black dots show a PSLG and the dashed lines and the white dots denote the dual.

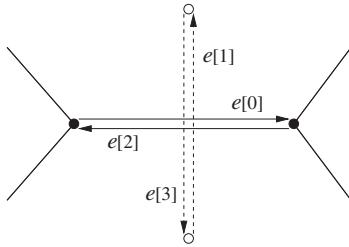

FIGURE 18.15 Quadedges.

The quadedge data structure is entirely edge based and there are no explicit vertex and face records.

The following two basic operations `make_edge` and `splice` are central to the operations on PSLGs supported by the quadedge data structure. Our presentation is slightly different from that in the original paper [10].

- `make_edge(u, v)`: Return an edge e connecting the points u and v . The quadedges $e[i]$ where $0 \leq i \leq 3$ are initialized such that they represent a new PSLG with e as the only edge. Also, $e[0]$ is the quadedge directed from u to v . If u and v are omitted, it means that the actual coordinates of the endpoints of are unimportant.
- `splice(a, i, b, j)`: Given two quadedges $a[i]$ and $b[j]$, let $(c, k) = \text{rot}(a[i].\text{next})$ and $(d, l) = \text{rot}(b[j].\text{next})$, `splice` swaps the contents of $a[i].\text{next}$ and $b[j].\text{next}$ and the contents of $c[k].\text{next}$ and $d[l].\text{next}$. The effects on the edge rings of the origins of $a[i]$ and $b[j]$ and the edge rings of the origins of $c[k]$ and $d[l]$ are:
 - If the two rings are different, they are merged into one (see Figure 18.16a).
 - If the two rings are the same, it will be split into two separate rings (see Figure 18.16b).

Notice that `make_edge` and `splice` are similar to the operations `make_halfedges` and `half_splice` introduced for the halfedge data structure in the previous section. As mentioned before, they inspire the definitions of `make_halfedges` and `half_splice`. Due to this similarity, one can easily adapt the edge insertion, edge deletion, vertex split, and edge contraction algorithms in the previous section for the quadedge data structure.

18.7 Further Remarks

We have assumed that each face in the PSLG has exactly one boundary. This requirement can be relaxed for the winged-edge and the halfedge data structures. One method works as follows. For each face f , pick one edge from each boundary and keep a list of references to these edges at the face record for f . Also, the edge that belongs to outer boundary of f is specially tagged. With this modification, one can traverse the boundaries of a face f consistently (e.g., keeping f on the left of traversal direction). The edge insertion and deletion algorithms also need to be enhanced. Since a face f may have several boundaries, inserting an edge may combine two boundaries without splitting f . If the insertion indeed splits f , one needs to distribute the other boundaries of f into the two faces resulting from the split. The reverse effects of edge deletion should be taken care of similarly.

The halfedge data structure has also been used for representing orientable polyhedral surfaces [11]. The full power of the quadedge data structure is only realized when one deals with both subdivisions of orientable and non-orientable surfaces. To this end, one needs to introduce a *flip bit* to allow viewing the surface from the above or below. The primitives need to be enhanced for this purpose. The correctness of the data structure is proven formally using *edge algebra*. The details are in the Guibas and Stolfi's original paper [10].

The vertex split and edge contraction are also applicable for polyhedral surfaces. The edge contractibility criteria carries over straightforwardly. Edge contraction is a popular primitive for surface simplification algorithms [12–14]. The edge contractibility criteria for non-manifolds has also been studied [15].

18.8 Glossary

Arrangements. Given a collection of lines, we split each line into edges by inserting a vertex at every intersection on the line. The resulting PSLG is called the *arrangement of lines*. The *arrangement of line segments* is similarly defined.

Voronoi diagram. Let S be a set of points in the plane. For each point $p \in S$, the Voronoi region of p is defined to be $\{x \in R^2 : \|p - x\| \leq \|q - x\|, \forall q \in S\}$. The *Voronoi diagram* of S is the collection of all Voronoi regions (including their boundaries).

Triangulation. Let S be a set of points in the plane. Any maximal PSLG with the points in S as vertices is a *triangulation* of S .

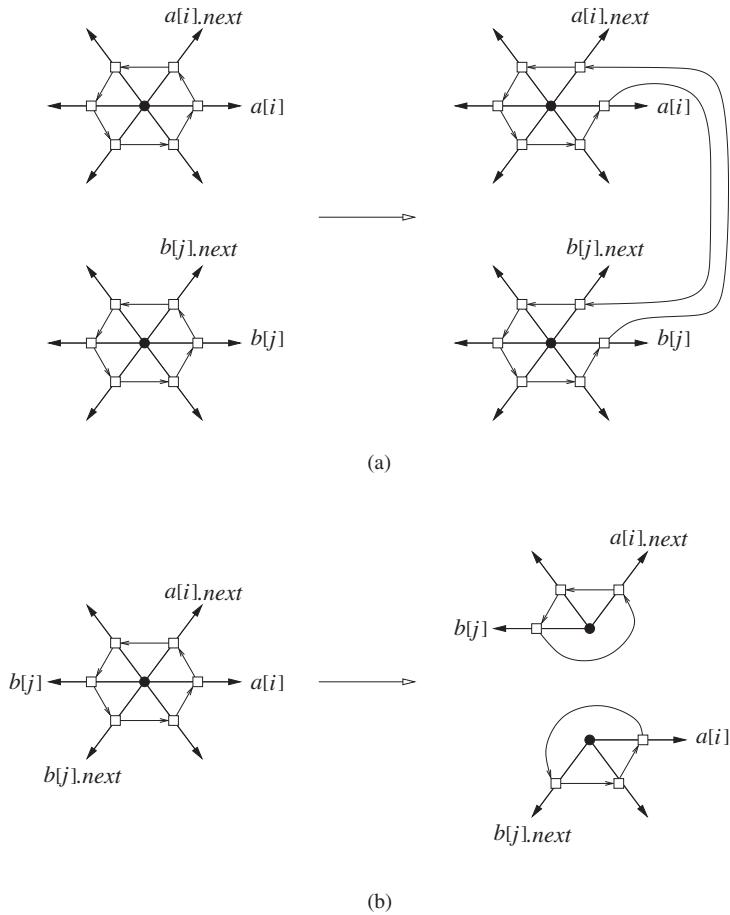

FIGURE 18.16 The effects of `splice`.

Delaunay triangulation. Let S be a set of points in the plane. For any three points p, q , and r in S , if the circumcircle of the triangle pqr does not strictly enclose any point in S , we call pqr a *Delaunay triangle*. The *Delaunay triangulation* of S is the collection of all Delaunay triangles (including their boundaries). The Delaunay triangulation of S is the dual of the Voronoi diagram of S .

19.1 Introduction

In this chapter, we introduce four basic data structures that are of fundamental importance and have many applications as we will briefly cover them in later sections. They are *interval trees*, *segment trees*, *range trees*, and *priority search trees*. Consider for example the following problems. Suppose we have a set of *iso-oriented rectangles* in the plane. A set of rectangles are said to be *iso-oriented* if their edges are parallel to the coordinate axes. The subset of iso-oriented rectangles defines a *clique*, if their common intersection is nonempty. The *largest* subset of rectangles whose common intersection is non-empty is called a *maximum clique*. The problem of finding this largest subset with a non-empty common intersection is referred to as the *maximum clique problem* for a rectangle intersection graph [1,2].^{*} The k -dimensional, $k \geq 1$, analog of this problem is defined similarly. In one-dimensional (1D) case, we will have a set of *intervals* on the real line, and an *interval intersection graph*, or simply *interval graph*. The maximum clique problem for interval graphs is to find a largest subset of intervals whose common intersection is non-empty. The cardinality of the maximum clique is sometimes referred to as the *density* of the set of intervals.

The problem of finding a subset of objects that satisfy a certain property is often referred to as the *searching problem*. For instance, given a set of numbers $S = \{x_1, x_2, \dots, x_n\}$, where $x_i \in \mathbb{R}$, $i = 1, 2, \dots, n$, the problem of finding the subset of numbers that lie between a range $[\ell, r]$, that is, $F = \{x \in S | \ell \leq x \leq r\}$, is called an (1D) *range search problem* [3,4].

To deal with this kind of geometric searching problem, we need to have appropriate data structures to support efficient searching algorithms. The data structure is assumed to be *static*, that is, the input set of objects is given *a priori*, and *no* insertions or deletions of the objects are allowed. If the searching problem satisfies *decomposability property*, that is, if they are *decomposable*,[†] then there are general *dynamization* schemes available [7], that can be used to convert static data structures into *dynamic* ones, where *insertions* and *deletions* of objects are permitted. Examples of decomposable searching problems include the *membership* problem in which one queries if a point p lies in S . Let S be partitioned into two subsets S_1 and S_2 , and $\text{Member}(p, S)$ returns *yes*, if $p \in S$, and *no* otherwise. It is easy to see that $\text{Member}(p, S) = \text{OR}(\text{Member}(p, S_1), \text{Member}(p, S_2))$, where OR is a Boolean operator.

* A rectangle intersection graph is a graph $G = (V, E)$, in which each vertex in V corresponds to a rectangle, and two vertices are connected by an edge in E , if the corresponding rectangles intersect.

† A searching problem is said to be *decomposable* if and only if $\forall x \in T_1, A, B \in 2^{T_2}, Q(x, A \cup B) = \bigcirc(Q(x, A), Q(x, B))$ for some efficiently computable associative operator \bigcirc on the elements of T_3 , where Q is a mapping from $T_1 \times 2^{T_2}$ to T_3 [5,6].

19.2 Interval Trees

Consider a set S of intervals, $S = \{I_i | i = 1, 2, \dots, n\}$, each of which is specified by an ordered pair, $I_i = [\ell_i, r_i], \ell_i, r_i \in \mathfrak{N}, \ell_i \leq r_i, i = 1, 2, \dots, n$.

An *interval tree* [8,9], $\text{Interval_Tree}(S)$, for S is a rooted augmented binary search tree, in which each node v has a key value, $v.key$, two tree pointers $v.left$ and $v.right$ to the left and right subtrees, respectively, and an auxiliary pointer, $v.aux$ to an augmented data structure, and is recursively defined as follows:

- The root node v associated with the set S , denoted $\text{Interval_Tree}_\text{root}(S)$, has key value $v.key$ equal to the median of the $2 \times |S|$ endpoints. This key value $v.key$ divides S into three subsets S_ℓ , S_r , and S_m , consisting of sets of intervals lying totally to the *left* of $v.key$, lying totally to the *right* of $v.key$, and containing $v.key$, respectively. That is, $S_\ell = \{I_i | r_i < v.key\}$, $S_r = \{I_j | v.key < \ell_j\}$, and $S_m = \{I_k | \ell_k \leq v.key \leq r_k\}$.
- Tree pointer $v.left$ points to the left subtree rooted at $\text{Interval_Tree}_\text{root}(S_\ell)$, and tree pointer $v.right$ points to the right subtree rooted at $\text{Interval_Tree}_\text{root}(S_r)$.
- Auxiliary pointer $v.aux$ points to an augmented data structure consisting of two sorted arrays, $\text{SA}(S_m.\text{left})$ and $\text{SA}(S_m.\text{right})$ of the set of left endpoints of the intervals in S_m and the set of right endpoints of the intervals in S_m , respectively. That is, $S_m.\text{left} = \{\ell_i | I_i \in S_m\}$ and $S_m.\text{right} = \{r_i | I_i \in S_m\}$.

19.2.1 Construction of Interval Trees

The following is a pseudo code for the recursive construction of the interval tree of a set S of n intervals. Without loss of generality, we shall assume that the endpoints of these n intervals are all distinct. See Figure 19.1a for an illustration.

function $\text{Interval_Tree}(S)$

/* It returns a pointer v to the root, $\text{Interval_Tree}_\text{root}(S)$, of the interval tree for a set S of intervals. */

Input: A set S of n intervals, $S = \{I_i | i = 1, 2, \dots, n\}$ and each interval $I_i = [\ell_i, r_i]$, where ℓ_i and r_i are the left and right endpoints, respectively of I_i , $\ell_i, r_i \in \mathfrak{N}$, and $\ell_i \leq r_i, i = 1, 2, \dots, n$.

Output: An interval tree, rooted at $\text{Interval_Tree}_\text{root}(S)$.

Method:

1. **if** $S = \emptyset$ **return** nil.
2. Create a node v such that $v.key$ equals x , where x is the middle point of the set of endpoints so that there are exactly $|S|/2$ endpoints less than or equal to x and greater than x , respectively. Let $S_\ell = \{I_i | r_i < x\}$, $S_r = \{I_j | x < \ell_j\}$, and $S_m = \{I_k | \ell_k \leq x \leq r_k\}$.

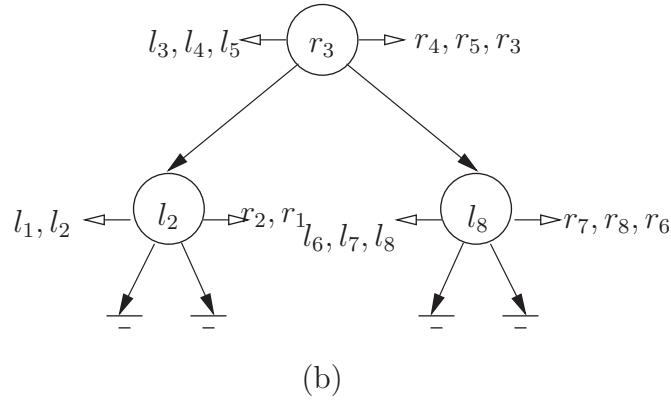

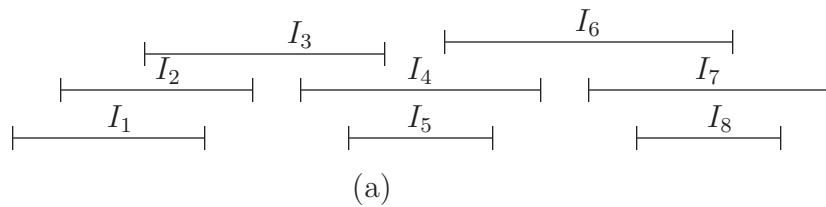

FIGURE 19.1 Interval tree for $S = \{I_1, I_2, \dots, I_8\}$ and its interval models.

3. Set $v.left$ equal to $\text{Interval_Tree}(S_\ell)$.
4. Set $v.right$ equal to $\text{Interval_Tree}(S_r)$.
5. Create a node w which is the root node of an auxiliary data structure associated with the set S_m of intervals, such that $w.left$ and $w.right$ point to two sorted arrays, $SA(S_m.left)$ and $SA(S_m.right)$, respectively. $SA(S_m.left)$ denotes an array of left endpoints of intervals in S_m in ascending order, and $SA(S_m.right)$ an array of right endpoints of intervals in S_m in descending order.
6. Set $v.aux$ equal to node w .

Note that this recursively built interval tree structure requires $O(n)$ space, where n is the cardinality of S , since each interval is either in the left subtree, the right subtree, or the middle augmented data structure.

19.2.2 Example and Its Applications

[Figure 19.1b](#) illustrates an example of an interval tree of a set of intervals, spread out as shown in [Figure 19.1a](#).

The interval trees can be used to handle quickly queries of the following forms.

Enclosing Interval Searching Problem [10,11]: Given a set S of n intervals and a query point q , report all those intervals containing q , that is, find a subset $F \subseteq S$ such that $F = \{I_i | \ell_i \leq q \leq r_i\}$.

Overlapping Interval Searching Problem [8,9,12]: Given a set S of n intervals and a query interval Q , report all those intervals in S overlapping Q , that is, find a subset $F \subseteq S$ such that $F = \{I_i | I_i \cap Q \neq \emptyset\}$.

The following pseudo code solves the **Overlapping Interval Searching Problem** in $O(\log n) + |F|$ time. It is invoked by a call to $\text{Overlapping_Interval_Search}(v, Q, F)$, where v is $\text{Interval_Tree_root}(S)$, and F , initially set to be \emptyset , will contain the set of intervals overlapping query interval Q .

procedure $\text{Overlapping_Interval_Search}(v, Q, F)$

Input: A set S of n intervals, $S = \{I_i | i = 1, 2, \dots, n\}$ and each interval $I_i = [\ell_i, r_i]$, where ℓ_i and r_i are the left and right endpoints, respectively of I_i , $\ell_i, r_i \in \mathbb{N}$, and $\ell_i \leq r_i, i = 1, 2, \dots, n$ and a query interval $Q = [\ell, r], \ell, r \in \mathbb{N}$, and $\ell \leq r$.

Output: A subset $F = \{I_i | I_i \cap Q \neq \emptyset\}$.

Method:

1. Set $F = \emptyset$ initially.
2. **if** v is nil **return**.
3. **if** $(v.key \in Q)$ **then**
 - for** each interval I_i in the augmented data structure pointed to by $v.aux$
 - do** $F = F \cup \{I_i\}$.
 - $\text{Overlapping_Interval_Search}(v.left, Q, F)$
 - $\text{Overlapping_Interval_Search}(v.right, Q, F)$
4. **if** $(r < v.key)$ **then**
 - for** each left endpoint ℓ_i in the sorted array pointed to by $v.aux.left$ such that $\ell_i < r$
 - do** $F = F \cup \{I_i\}$.
 - $\text{Overlapping_Interval_Search}(v.left, Q, F)$
5. **if** $(\ell > v.key)$ **then**
 - for** each right endpoint r_i in the sorted array pointed to by $v.aux.right$ such that $r_i > \ell$
 - do** $F = F \cup \{I_i\}$.
 - $\text{Overlapping_Interval_Search}(v.right, Q, F)$

It is obvious to see that an interval I in S overlaps a query interval $Q = [\ell, r]$ if (i) Q contains the left endpoint of I , (ii) Q contains the right endpoint of I , or (iii) Q is totally contained in I . Step 3 reports those intervals I that contain a point $v.key$ which is also contained in Q . The for-loop of Step 4 reports intervals in either case (i) or (iii) and the for-loop of Step 5 reports intervals in either case (ii) or (iii).

Note the special case of **procedure** $\text{Overlapping_Interval_Search}(v, Q, F)$ when we set the query interval $Q = [\ell, r]$ so that its left and right endpoints coincide, that is, $\ell = r$ will report all the intervals in S containing a query point, solving the **Enclosing Interval Searching Problem**.

However, if one is interested in the problem of finding a special type of overlapping intervals, for example, all intervals containing or contained in a given query interval [10,11], the interval tree data structure does not necessarily yield an efficient solution. Similarly, the interval tree does not provide an effective method to handle queries about the set of intervals, for example, the maximum clique, or the *measure*, the total length of the union of the intervals [13,14].

We conclude with the following theorem.

Theorem 19.1

The **Enclosing Interval Searching Problem** and **Overlapping Interval Searching Problem** for a set S of n intervals can both be solved in $O(\log n)$ time (plus time for output) and in linear space.

19.3 Segment Trees

The segment tree structure, originally introduced by Bentley [3,4], is a data structure for intervals whose endpoints are *fixed* or *known a priori*. The set $S = \{I_1, I_2, \dots, I_n\}$ of n intervals, each of which is represented by $I_i = [\ell_i, r_i]$, $\ell_i, r_i \in \mathbb{N}$, $\ell_i \leq r_i$, is represented by a data array, $\text{Data_Array}(S)$, whose entries correspond to the endpoints, ℓ_i or r_i , and are sorted in non-decreasing order. This sorted array is denoted $SA[1 \dots N]$, $N = 2n$. That is, $SA[1] \leq SA[2] \leq \dots \leq SA[N]$. We will in this section use the indexes in the range $[1, N]$ to refer to the entries in the sorted array $SA[1 \dots N]$. For convenience, we will be working in the transformed domain using indexes, and a comparison involving a point $q \in \mathbb{N}$ and an index $i \in \mathbb{N}$, unless otherwise specified, is performed in the original domain in \mathbb{N} . For instance, $q < i$ is interpreted as $q < SA[i]$.

The segment tree structure, as will be demonstrated later, can be useful in finding the *measure* of a set of intervals. That is, the length of the union of a set of intervals. It can also be used to find the maximum clique of a set of intervals. This structure can be generalized to higher dimensions.

19.3.1 Construction of Segment Trees

The segment tree, as the interval tree discussed in Section 19.2 is a rooted augmented binary search tree, in which each node v is associated with a range of integers $v.\text{range} = [v.B, v.E]$, $v.B, v.E \in \mathbb{N}$, $v.B < v.E$, representing a range of indexes from $v.B$ to $v.E$, a key $v.\text{key}$ that splits $v.\text{range}$ into two subranges, each of which is associated with each child of v , two tree pointers $v.\text{left}$ and $v.\text{right}$ to the left and right subtrees, respectively, and an auxiliary pointer, $v.\text{aux}$ to an augmented data structure. Given integers s and t , with $1 \leq s < t \leq N$, the segment tree, denoted $\text{Segment_Tree}(s, t)$, is recursively described as follows:

- The root node v , denoted $\text{Segment_Tree_root}(s, t)$, is associated with the range $[s, t]$, and $v.B = s$ and $v.E = t$.
- If $s + 1 = t$, then we have a leaf node v with $v.B = s$, $v.E = t$, and $v.\text{key} = \text{nil}$.
- Otherwise (i.e., $s + 1 < t$), let m be the mid-point of s and t , or $m = \lfloor (v.B + v.E)/2 \rfloor$. Set $v.\text{key} = m$.
- Tree pointer $v.\text{left}$ points to the left subtree rooted at $\text{Segment_Tree_root}(s, m)$, and tree pointer $v.\text{right}$ points to the right subtree rooted at $\text{Segment_Tree_root}(m, t)$.
- Auxiliary pointer $v.\text{aux}$ points to an augmented data structure, associated with the range $[s, t]$, whose content depends on the usage of the segment tree.

The following is a pseudo code for the construction of a segment tree for a range $[s, t]$ $s < t$, $s, t \in \mathbb{N}$, and the construction of a set of n intervals whose endpoints are indexed by an array of integers in the range $[1, N]$, $N = 2n$ can be done by a call to $\text{Segment_Tree}(1, N)$. See Figure 19.2b for an illustration.

function $\text{Segment_Tree}(s, t)$

/* It returns a pointer v to the root, $\text{Segment_Tree_root}(s, t)$, of the segment tree for the range $[s, t]$. */

Input: A set \mathcal{N} of integers, $\{s, s + 1, \dots, t\}$ representing the indexes of the endpoints of a subset of intervals.

Output: A segment tree, rooted at $\text{Segment_Tree_root}(s, t)$.

Method:

1. Let v be a node, $v.B = s$, $v.E = t$, $v.\text{left} = v.\text{right} = \text{nil}$, and $v.\text{aux}$ to be determined.
2. **if** $s + 1 = t$ **then return**.
3. Let $v.\text{key} = m = \lfloor (v.B + v.E)/2 \rfloor$.
4. $v.\text{left} = \text{Segment_Tree}(s, m)$
5. $v.\text{right} = \text{Segment_Tree}(m, t)$

The parameters $v.B$ and $v.E$ associated with node v define a range $[v.B, v.E]$, called a *standard range* associated with v . The standard range associated with a leaf node is also called an *elementary range*. It is straightforward to see that $\text{Segment_Tree}(s, t)$ constructed in **function** $\text{Segment_Tree}(s, t)$ described above is balanced, and has height, denoted $\text{Segment_Tree}(s, t).\text{height}$, equal to $\lceil \log_2(t - s) \rceil$.

We now introduce the notion of *canonical covering* of a range $[b, e]$, where $b, e \in \mathbb{N}$ and $1 \leq b < e \leq N$. A node v in $\text{Segment_Tree}(1, N)$ is said to be in the *canonical covering* of $[b, e]$ if its associated standard range satisfies this property $[v.B, v.E] \subseteq [b, e]$, while that of its parent node does not. It is obvious that if a node v is in the canonical covering, then its *sibling*

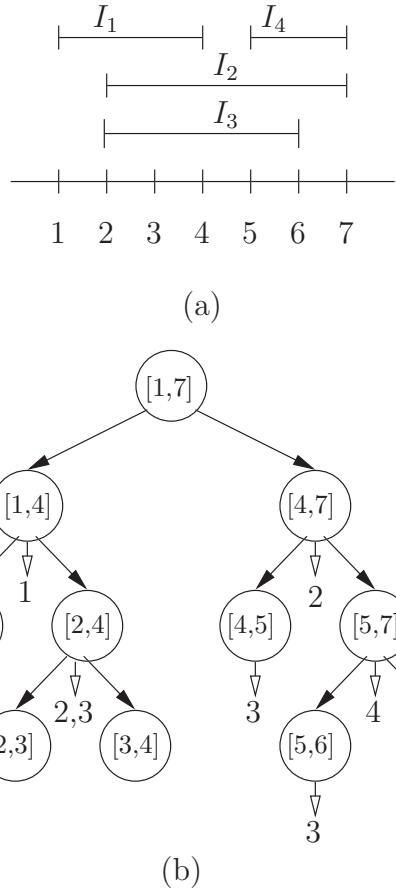

FIGURE 19.2 Segment tree of $S = \{I_1, I_2, I_3, I_4\}$ and its interval models.

node, that is, the node with the same parent node as the present one, is not, for otherwise the common parent node would have been in the canonical covering. Thus, at each level, there are *at most* two nodes that belong to the canonical covering of $[b, e]$.

Thus, for each range $[b, e]$, the number of nodes in its canonical covering is at most $\lceil \log_2(e - b) \rceil + \lfloor \log_2(e - b) \rfloor - 2$. In other words, a range $[b, e]$ (or respectively an interval $[b, e]$) can be decomposed into at most $\lceil \log_2(e - b) \rceil + \lfloor \log_2(e - b) \rfloor - 2$ standard ranges (or respectively subintervals) [3,4].

To identify the nodes in a segment tree T that are in the canonical covering of an interval $I = [b, e]$, representing a range $[b, e]$, we perform a call to `Interval_Insertion(v, b, e, Q)`, where v is `Segment_Tree_root(1, N)`. The procedure `Interval_Insertion(v, b, e, Q)` is defined below.

```

procedure Interval_Insertion( $v, b, e, Q$ )
/* It returns a queue  $Q$  of nodes  $q \in T$  such that  $[v.B, v.E] \subseteq [b, e]$  but  $[u.B, u.E] \subsetneq [b, e]$ , where  $u$  is the parent node of  $v$ . */
Input: A segment tree  $T$  pointed to by its root node,  $v = \text{Segment\_Tree\_root}(1, N)$ , for a set  $S$  of intervals.
Output: A queue  $Q$  of nodes in  $T$  that are in the canonical covering of  $[b, e]$ .
Method:
```

1. Initialize an output queue Q , which supports insertion ($\Rightarrow Q$) and deletion ($\Leftarrow Q$) in constant time.
2. **if** $([v.B, v.E] \subseteq [b, e])$ **then append** $[b, e]$ to v , $v \Rightarrow Q$ and **return**.
3. **if** $(b < v.key)$ **then** `Interval_Insertion(v.left, b, e, Q)`
4. **if** $(v.key < e)$ **then** `Interval_Insertion(v.right, b, e, Q)`

To **append** $[b, e]$ to a node v means to insert interval $I = [b, e]$ into the auxiliary structure associated with node v to indicate that node v whose standard range is totally contained in I is in the canonical covering of I . If the auxiliary structure $v.aux$ associated with node v is an array, the operation **append** $[b, e]$ to a node v can be implemented as $v.aux[j++] = I$.

procedure Interval_Insertion(v, b, e, Q) described above can be used to represent a set S of n intervals in a segment tree by performing the insertion operation n times, one for each interval. As each interval I can have at most $O(\log n)$ nodes in its canonical covering, and hence we perform at most $O(\log n)$ **append** operations for each insertion, the total amount of space required in the auxiliary data structures reflecting all the nodes in the canonical covering is $O(n \log n)$.

Deletion of an interval represented by a range $[b, e]$ can be done similarly, except that the **append** operation will be replaced by its corresponding inverse operation **remove** that removes the interval from the auxiliary structure associated with some canonical covering node.

Theorem 19.2

The segment tree for a set S of n intervals can be constructed in $O(n \log n)$ time, and if the auxiliary structure for each node v contains a list of intervals containing v in the canonical covering, then the space required is $O(n \log n)$.

To simplify the description, given a set S of intervals, we assume that the endpoints of the intervals are represented by the indexes of a sorted array $SA[1 \dots N]$, $N = 2|S|$, containing these endpoints, and the segment tree representing this set is abbreviated as Segment_Tree(S) in the remaining of this section.

19.3.2 Examples and Its Applications

Figure 19.2b illustrates an example of a segment tree of the set of intervals, as shown in Figure 19.2a. The integers, if any, under each node v represent the indexes of intervals that contain the node in its canonical covering. For example, Interval I_2 contains nodes labeled by standard ranges [2,4] and [4,7].

We now describe how segment trees can be used to solve the **Enclosing Interval Searching Problem** defined before, the **Maximum Clique Problem** of a set of intervals, and that of a set of rectangles, which are defined below.

Maximum Clique Size of a set of Intervals [2,15,16]: Given a set $S = \{I_1, I_2, \dots, I_n\}$ of n intervals, a *clique* is a subset $C_I \subseteq S$ such that the common intersection of intervals in C_I is non-empty, and a *maximum clique* is a clique of maximum size. That is, $\bigcap_{I_i \in C_I \subseteq S} I_i \neq \emptyset$ and $|C_I|$ is maximized. The problem is to find the maximum size $|C_I|$.

Maximum Clique Size of a set of Rectangles [2]: Given a set $S = \{R_1, R_2, \dots, R_n\}$ of n rectangles, a *clique* is a subset $C_R \subseteq S$ such that the common intersection of rectangles in C_R is non-empty, and a *maximum clique* is a clique of maximum size. That is, $\bigcap_{R_i \in C_R \subseteq S} R_i \neq \emptyset$ and $|C_R|$ is maximized. The problem is to find the maximum size $|C_R|$.

The following pseudo code solves the **Enclosing Interval Searching Problem** in $O(\log n) + |F|$ time, where F is the output set. It is invoked by a call Point_in_Interval_Search(v, q, F), where v is Segment_Tree_root(S), and F , initially set to be \emptyset , will contain the set of intervals containing a query point q .

procedure Point_in_Interval_Search(v, q, F)
/* It returns in F the list of intervals stored in the segment tree pointed to by v and containing query point q . */
Input: A segment tree representing a set S of n intervals, $S = \{I_i | i = 1, 2, \dots, n\}$ and a query point $q \in \mathbb{R}$. The auxiliary structure $v.aux$ associated with each node v is a list of intervals $I \in S$ that contain v in their canonical coverings.
Output: A subset $F = \{I_i | \ell_i \leq q \leq r_i\}$.
Method:

1. **if** v is nil **or** ($q < v.B$ **or** $q > v.E$) **then return.**
2. **if** ($v.B \leq q \leq v.E$) **then**
 - for** each interval I_i in the auxiliary data structure pointed to by $v.aux$ **do** $F = F \cup \{I_i\}$.
3. **if** ($q \leq v.key$) **then** Point_in_Interval_Search($v.left, q, F$)
4. **else** /* i.e., $q > v.key$ */ Point_in_Interval_Search($v.right, q, F$)

We now address the problem of finding the size of the maximum clique of a set S of intervals, $S = \{I_1, I_2, \dots, I_n\}$, where each interval $I_i = [\ell_i, r_i]$, and $\ell_i \leq r_i$, $\ell_i, r_i \in \mathbb{R}$, $i = 1, 2, \dots, n$. There are other approaches, such as plane-sweep [2,4,15,16], that solve this problem within the same complexity.

For this problem, we introduce an auxiliary data structure to be stored at each node v . $v.aux$ will contain two pieces of information: one is the *number* of intervals containing v in the canonical covering, denoted $v.\#\!$, and the other is the *clique size*, denoted $v.clq$. The *clique size* of a node v is the size of the maximum clique whose common intersection is contained in but not equal to the standard range associated with v . It is defined to be equal to the *larger* of the two numbers: $v.left.\#\!$ + $v.left.clq$ and $v.right.\#\!$ + $v.right.clq$. For a leaf node v , $v.clq = 0$. The size of the maximum clique for the set of intervals will then be stored at the root

node $r = \text{Segment_Tree_root}(S)$ and is equal to the sum of $r.\sharp$ and $r.clq$. It is obvious that the space needed for this segment tree is linear.

As this data structure supports insertion of intervals incrementally, it can be used to answer the maximum clique of the current set of intervals as the intervals are inserted into (or deleted from) the segment tree T . The following pseudo code finds the size of the maximum clique of a set of intervals.

function Interval_Maximum_Clique_Size(S)

/* It returns the size of the maximum clique of a set S of intervals. */

Input: A set S of n intervals and the segment tree T rooted at $r = \text{Segment_Tree_root}(S)$.

Output: An integer, which is the size of the maximum clique of S .

Method:

1. Initialize $v.clq = v.\sharp = 0$ for all nodes v in T .

2. **for** each interval $I_i = [\ell_i, r_i] \in S$, $i = 1, 2, \dots, n$ **do**

/* Insert I_i into the tree and update $v.\sharp$ and $v.clq$ for all visited nodes and those nodes in the canonical covering of I_i . */
 $clq_{S_i} = \text{Update_Segment_Tree_by_Weight}(r, \ell_i, r_i, +1)$ (see below).

3. **return** clq_{S_n} .

function Update_Segment_Tree_by_Weight(v, b, e, w)

/* Insert into/delete from the segment tree pointed to by v the interval $I = [b, e]$ and update $v.\sharp$ and $v.clq$ by w for all visited nodes and those nodes in the canonical covering of I . */

Input: A segment tree rooted at v containing a set of intervals, an interval $I = [b, e]$ to be inserted/deleted, $b, e \in \mathfrak{N}$, $b \leq e$, and a weight $w \in \{+1, -1\}$, where $+1$ corresponds to insertion and -1 to deletion.

Output: An integer, which is the size of the maximum clique of the set of intervals after update.

Method:

1. **if** ($[v.B, v.E] \subseteq [b, e]$) **then**

$v.\sharp = v.\sharp + w$

return $v.\sharp + v.clq$

2. **if** ($b < v.key$) **then** $\text{Update_Segment_Tree_by_Weight}(v.left, b, e, w)$

3. **if** ($v.key < e$) **then** $\text{Update_Segment_Tree_by_Weight}(v.right, b, e, w)$

4. $v.clq = \max\{v.left.\sharp + v.left.clq, v.right.\sharp + v.right.clq\}$

5. **return** $v.\sharp + v.clq$

Note that **function** $\text{Update_Segment_Tree_by_Weight}(v, b, e, w)$ visits at most $O(\log n)$ nodes in the canonical covering of I and takes $O(\log n)$ time. Since **function** $\text{Interval_Maximum_Clique_Size}(S)$ invokes the function n times, we obtain the following theorem.

Theorem 19.3

Given a set $S = \{I_1, I_2, \dots, I_n\}$ of n intervals, the size of the maximum clique of $S_i = \{I_1, I_2, \dots, I_i\}$ can be found in $O(i \log n)$ time and linear space, for each $i = 1, 2, \dots, n$, by using a segment tree.

Next, we extend the study of the maximum clique size problem to its 2D version, finding the size of the maximum clique of a set S of rectangles, $S = \{R_1, R_2, \dots, R_n\}$, where each rectangle $R_i = [x_{\ell,i}, x_{r,i}] \times [y_{\ell,i}, y_{r,i}]$, $x_{\ell,i}, x_{r,i}, y_{\ell,i}, y_{r,i} \in \mathfrak{N}^2$, $x_{\ell,i} \leq x_{r,i}$, $y_{\ell,i} \leq y_{r,i}$, $i = 1, 2, \dots, n$. We will describe a reduction of this problem to **Maximum Clique Size of a set of Intervals**, which can be easily generalized to higher dimensions.

For each rectangle R_j in S , let L_j denote the horizontal line $y = y_{\ell,j}$ through the bottom of R_j , and S_j denote the set of rectangles in S intersecting L_j , that is, $S_j = \{R_i | R_i \cap L_j \neq \emptyset, 1 \leq i \leq n\}$. It is not difficult to see that any non-empty common intersection of rectangles in S has to intersect a horizontal line L_j for some j , so does the common intersection of rectangles in the maximum clique of S . This implies that the maximum clique of S is equivalent to the maximum clique of some set S_j . Then, for any fixed S_j , finding the size of the maximum clique of S_j can be reduced to the problem **Maximum Clique Size of a set of Intervals** as follows. Consider L_j as a 1D real line. Each rectangle R_i intersecting L_j , that is, $y_{\ell,i} \leq y_{\ell,j} \leq y_{r,i}$, can be mapped to an interval $I_i = [x_{\ell,i}, x_{r,i}]$ on L_j . Let S_j^I denote the set of intervals I_i whose corresponding rectangles R_i intersect L_j . Obviously, the maximum clique of S_j is exactly the same (in terms of size) as that of S_j^I . Thus, the size of the maximum clique of S_j can be obtained by constructing S_j^I in $O(n)$ time and performing a call to $\text{Interval_Maximum_Clique_Size}(S_j^I)$ in $O(n \log n)$ time. It follows that we can solve **Maximum Clique Size of a Set of Rectangles** in $O(n^2 \log n)$ time by obtaining the size of the maximum clique for each S_j and taking the maximum.

However, by applying the plane-sweep technique, the above algorithm can be optimally implemented in $O(n \log n)$ time. Let $S^I = \{I_1, I_2, \dots, I_n\}$ denote the set of intervals $I_i = [x_{\ell,i}, x_{r,i}]$ corresponding to the x -ranges of all rectangles R_i in S . We create a sorted array $SA(S^I)$ containing the endpoints of intervals in S^I sorted in nondecreasing order, so that these endpoints can be represented by the indexes of $SA(S^I)$, and construct an empty segment tree T rooted at $r = \text{Segment_Tree_root}(S^I)$, in which each node contains two auxiliary values: interval number and clique size. Then, we scan the y -coordinates of all rectangles in S from bottom to top. If an *entry coordinate* $y_{\ell,j}$ of some rectangle R_j is met, the corresponding x -range I_j is inserted into T . Otherwise if an *exit coordinate* $y_{r,j}$ of R_j is met, I_j is removed from T . We can observe that, when I_j is inserted, the set of intervals stored in T is equivalent to S_j^I , and the size of the maximum clique of S_j^I (and the corresponding S_j) is equal to the sum of $r.\sharp$ and $r.clq$. Thus, for each S_j , the scanning checks its maximum clique and obtains its size in a more efficient way. The following pseudo code finds the size of the maximum clique of S in optimal $O(n \log n)$ time.

```
function Rectangle_Maximum_Clique_Size( $S$ )
/* It returns the size of the maximum clique of a set  $S$  of rectangles. */
Input: A set  $S$  of  $n$  rectangles.
Output: An integer, which is the size of the maximum clique of  $S$ .
Method:

1. Create the set  $S^I$ , the sorted array  $SA(S^I)$ , and the segment tree  $T$ , rooted at  $r = \text{Segment\_Tree\_root}(S^I)$ .
2. Initialize  $v.clq = v.\sharp = 0$  for all nodes  $v$  in  $T$ .
3. Create a sorted array  $SY$  containing the  $y$ -coordinates of all rectangles in  $S$ , that is,  $SY$  has  $\{y_{\ell,j}, y_{r,j} | R_j \in S\}$  in nondecreasing order (ties broken in favor of entry coordinates).
4.  $max\_clq = 0$ 
5. for each coordinate  $SY[k]$ ,  $k = 1, 2, \dots, N, N = 2n$  do
    /* Suppose that  $SY[k]$  corresponds to  $R_j = [x_{\ell,j}, x_{r,j}] \times [y_{\ell,j}, y_{r,j}]$ . */
    if  $SY[k]$  is the entry coordinate  $y_{\ell,j}$  of  $R_j$  then
        /* Insert  $I_j$  into  $T$  and update  $v.\sharp$  and  $v.clq$  for all visited nodes and those nodes in the canonical covering of  $I_j$ . */
         $clq_{-S_j} = \text{Update\_Segment\_Tree\_by\_Weight}(r, x_{\ell,j}, x_{r,j}, +1)$ 
        if  $clq_{-S_j} > max\_clq$  then  $max\_clq = clq_{-S_j}$ 
    else /*  $SY[k]$  is the exit coordinate  $y_{r,j}$  of  $R_j$  */
        /* Delete  $I_j$  from  $T$  and update  $v.\sharp$  and  $v.clq$  for all visited nodes and those nodes in the canonical covering of  $I_j$ . */
         $\text{Update\_Segment\_Tree\_by\_Weight}(r, x_{\ell,j}, x_{r,j}, -1)$ 
6. return  $max\_clq$ .
```

Similarly, each insertion or deletion of an interval updates at most $O(\log n)$ nodes in T and the scanning of y -coordinates takes $O(n \log n)$ time. We conclude that

Theorem 19.4

Given a set $S = \{R_1, R_2, \dots, R_n\}$ of n rectangles, the size of the maximum clique of S can be found in $O(n \log n)$ time and linear space by using a segment tree.

We note that the above reduction can be adapted to find the maximum clique of a set of *hyperrectangles* in k -dimensions for $k > 2$ in $O(n^{k-1} \log n)$ time [2].

19.4 Range Trees

Consider a set S of points in k -dimensional space \mathfrak{N}^k . A range tree for this set S of points is a data structure that supports general range queries of the form $[x_{\ell}^1, x_r^1] \times [x_{\ell}^2, x_r^2] \times \dots \times [x_{\ell}^k, x_r^k]$, where each range $[x_{\ell}^i, x_r^i]$, $x_{\ell}^i, x_r^i \in \mathfrak{N}$, $x_{\ell}^i \leq x_r^i$ for all $i = 1, 2, \dots, k$, denotes an interval in \mathfrak{N} . The Cartesian product of these k ranges is referred to as a k D-range. In two-dimensional space, a 2D-range is simply an axes-parallel rectangle in \mathfrak{N}^2 . The *range search problem* is to find all the points in S that satisfy any range query. In one-dimension, the range search problem can be easily solved in logarithmic time using a sorted array or a balanced binary search tree. The 1D-range is simply an interval $[x_{\ell}, x_r]$. We first do a binary search using x_{ℓ} as the search key to find the first node v whose key is no less than x_{ℓ} . Once v is located, the rest is simply to retrieve the nodes, one at a time, until the node u whose key is greater than x_r . We shall in this section describe an augmented binary search tree which is easily generalized to higher dimensions.

19.4.1 Construction of Range Trees

A range tree is primarily a binary search tree augmented with an auxiliary data structure. The root node v , denoted $\text{Range_Tree_root}(S)$, of a k D-range tree [3,4,17,18] for a set S of points in k -dimensional space \mathbb{R}^k , that is, $S = \{p_i = (x_i^1, x_i^2, \dots, x_i^k), i = 1, 2, \dots, n\}$, where $p_i.x^j = x_i^j \in \mathbb{R}$ is the j th coordinate value of point p_i , for $j = 1, 2, \dots, k$, is associated with the entire set S . The key stored in $v.key$ is to partition S into two approximately equal subsets S_ℓ and S_r , such that all the points in S_ℓ and in S_r lie to the left and to the right, respectively, of the hyperplane $H^k:x^k = v.key$. That is, we will store the median of the k th coordinate values of all the points in S in $v.key$ of the root node v , that is, $v.key = p_j.x^k$ for some point p_j such that S_ℓ contains points $p_\ell, p_\ell.x^k \leq v.key$, and S_r contains points $p_r, p_r.x^k > v.key$. Each node v in the k D-range tree, as before, has two tree pointers, $v.left$ and $v.right$, to the roots of its left and right subtrees, respectively. The node pointed to by $v.left$ will be associated with the set S_ℓ and the node pointed to by $v.right$ will be associated with the set S_r . The auxiliary pointer $v.aux$ will point to an augmented data structure, in our case a $(k-1)$ D-range tree.

A 1D-range tree is a sorted array of all the points $p_i \in S$ such that the entries are drawn from the set $\{x_i^1 | i = 1, 2, \dots, n\}$ sorted in nondecreasing order. This 1D-range tree supports the 1D-range search in logarithmic time.

The following is a pseudo code for a k D-range tree for a set S of n points in k -dimensional space. See Figure 19.3a and b for an illustration. Figure 19.4c is a schematic representation of a k D-range tree.

function $kD_Range_Tree(k, S)$

/* It returns a pointer v to the root, $kD_Range_Tree_root(k, S)$, of the k D-range tree for a set $S \subseteq \mathbb{R}^k$ of points, $k \geq 1$. */

Input: A set S of n points in \mathbb{R}^k , $S = \{p_i = (x_i^1, x_i^2, \dots, x_i^k), i = 1, 2, \dots, n\}$, where $x_i^j \in \mathbb{R}$ is the j th coordinate value of point p_i , for $j = 1, 2, \dots, k$.

Output: A k D-range tree, rooted at $kD_Range_Tree_root(k, S)$.

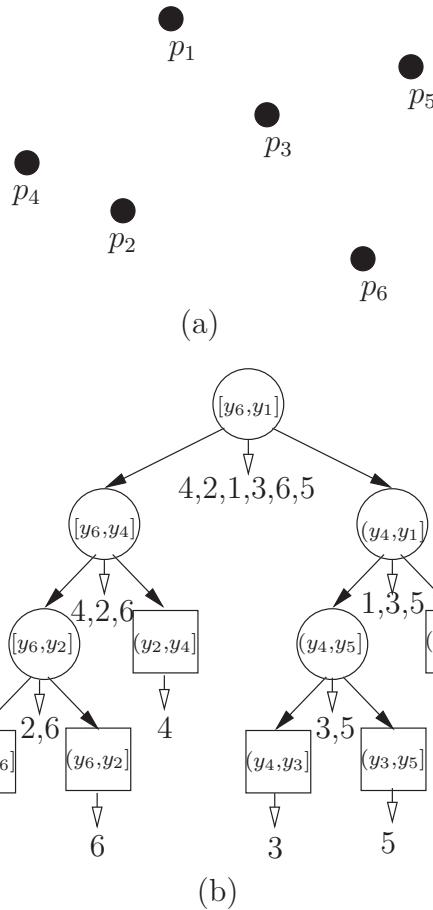

FIGURE 19.3 2D-range tree of $S = \{p_1, p_2, \dots, p_6\}$, where $p_i = (x_i, y_i)$.

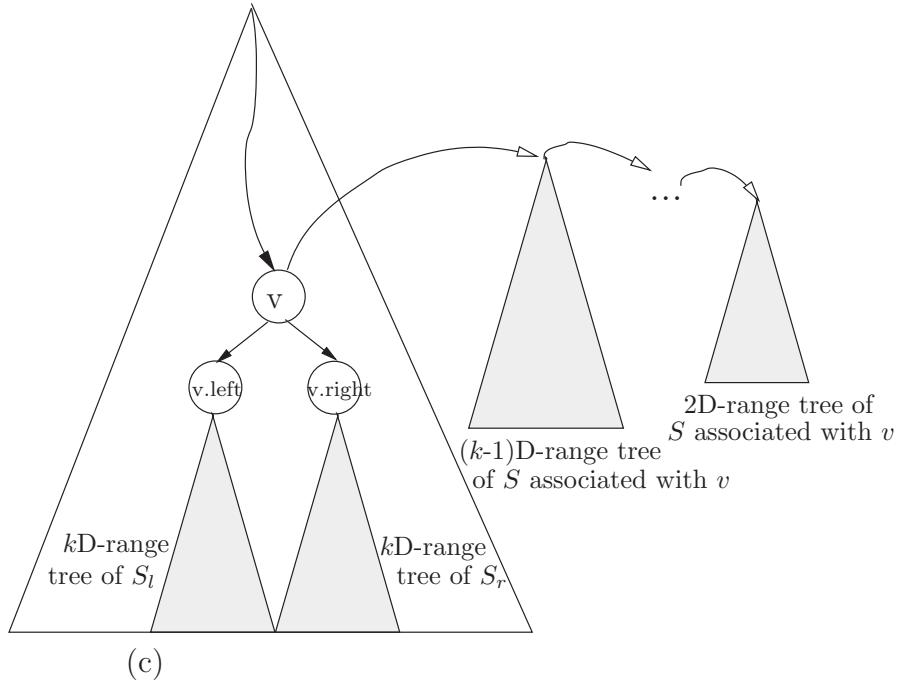

FIGURE 19.4 A schematic representation of a (layered) k D-range tree, where S is the set associated with node v .

Method:

1. **if** $S = \emptyset$, **return** nil.
2. **if** ($k = 1$) create a sorted array $SA(S)$ pointed to by a node v containing the set of the 1st coordinate values of all the points in S , that is, $SA(S)$ has $\{p_i.x^1 | i = 1, 2, \dots, n\}$ in nondecreasing order. **return** (v).
3. Create a node v such that $v.key$ equals the *median* of the set $\{p_i.x^k | k \text{th coordinate value of } p_i \in S, i = 1, 2, \dots, n\}$. Let S_ℓ and S_r denote the subset of points whose k th coordinate values are not greater than and are greater than $v.key$, respectively. That is, $S_\ell = \{p_i \in S | p_i.x^k \leq v.key\}$ and $S_r = \{p_j \in S | p_j.x^k > v.key\}$.
4. $v.left = kD_Range_Tree(k, S_\ell)$
5. $v.right = kD_Range_Tree(k, S_r)$
6. $v.aux = kD_Range_Tree(k - 1, S)$

As this is a recursive algorithm with two parameters, k and $|S|$, that determine the recursion depth, it is not immediately obvious how much time and how much space are needed to construct a k D-range tree for a set of n points in k -dimensional space.

Let $T(n, k)$ denote the time taken and $S(n, k)$ denote the space required to build a k D-range tree of a set of n points in \mathbb{R}^k . The following are recurrence relations for $T(n, k)$ and $S(n, k)$, respectively.

$$T(n, k) = \begin{cases} O(1) & \text{if } n = 1 \\ O(n \log n) & \text{if } k = 1 \\ 2T(n/2, k) + T(n, k - 1) + O(n) & \text{otherwise.} \end{cases}$$

$$S(n, k) = \begin{cases} O(1) & \text{if } n = 1 \\ O(n) & \text{if } k = 1 \\ 2S(n/2, k) + S(n, k - 1) + O(1) & \text{otherwise.} \end{cases}$$

Note that in one dimension, we need to have the points sorted and stored in a sorted array, and thus $T(n, 1) = O(n \log n)$ and $S(n, 1) = O(n)$. The solutions of $T(n, k)$ and $S(n, k)$ to the above recurrence relations are $T(n, k) = O(n \log^{k-1} n + n \log n)$ for $k \geq 1$ and $S(n, k) = O(n \log^{k-1} n)$ for $k \geq 1$. For a general multidimensional divide-and-conquer scheme, and solutions to the recurrence relation, please refer to Bentley [19] and Monier [20], respectively.

We conclude that

Theorem 19.5

The k D-range tree for a set of n points in k -dimensional space can be constructed in $O(n \log^{k-1} n + n \log n)$ time and $O(n \log^{k-1} n)$ space for $k \geq 1$.

19.4.2 Examples and Its Applications

[Figure 19.3b](#) illustrates an example of a range tree for a set of points in two dimensions, shown in [Figure 19.3a](#). This list of integers under each node represents the indexes of points in ascending x -coordinates. [Figure 19.4](#) illustrates a general schematic representation of a k D-range tree, which is a *layered* structure [3,4].

We now discuss how we make use of a range tree to solve the range search problem. We shall use 2D-range tree as an example for illustration purposes. It is rather obvious to generalize it to higher dimensions. Recall we have a set S of n points in the plane \Re^2 and 2D range query $Q = [x_\ell, x_r] \times [y_\ell, y_r]$. Let us assume that a 2D-range tree rooted at $2D_Range_Tree_root(S)$ is available. Besides, for each node v in the range tree, it is associated with a *standard range* for the set S_v of points represented in the subtree rooted at node v , in this case $[v.B, v.E]$ where $v.B = \min\{p_i.x\}$ and $v.E = \max\{p_i.x\}$ for all $p_i \in S_v$. $v.key$ will split the standard range into two standard subranges $[v.B, v.key]$ and $[v.key, v.E]$, each associated with the root nodes $v.left$ and $v.right$ of the left and right subtrees of v , respectively.

The following pseudo code reports in F the set of points in S that lie in the range $Q = [x_\ell, x_r] \times [y_\ell, y_r]$. It is invoked by $2D_Range_Search(v, x_\ell, x_r, y_\ell, y_r, F)$, where v is the root, $2D_Range_Tree_root(S)$, and F , initially empty, will return all the points in S that lie in the range $Q = [x_\ell, x_r] \times [y_\ell, y_r]$.

procedure $2D_Range_Search(v, x_\ell, x_r, y_\ell, y_r, F)$

/* It returns F containing all the points in the range tree rooted at node v that lie in $[x_\ell, x_r] \times [y_\ell, y_r]$. */

Input: A set S of n points in \Re^2 , $S = \{p_i | i = 1, 2, \dots, n\}$ and each point $p_i = (p_i.x, p_i.y)$, where $p_i.x$ and $p_i.y$ are the x - and y -coordinates of p_i , $p_i.x, p_i.y \in \Re$, $i = 1, 2, \dots, n$.

Output: A set F of points in S that lie in $[x_\ell, x_r] \times [y_\ell, y_r]$.

Method:

1. Start from the root node v to find the split node s , $s = Find_split-node(v, y_\ell, y_r)$ (see below), such that $s.key$ lies in $[y_\ell, y_r]$.
2. **if** s is a leaf **then** $1D_Range_Search(s.aux, x_\ell, x_r, F)$ that checks in the sorted array pointed to by $s.aux$, which contains just a point p , to see if its x -coordinate $p.x$ lies in the x -range $[x_\ell, x_r]$.
3. $v = s.left$.
4. **while** v is not a leaf **do**
 - if** $(y_\ell \leq v.key)$ **then**
 - $1D_Range_Search(v.right.aux, x_\ell, x_r, F)$
 - $v = v.left$
 - else** $v = v.right$
5. /* v is a leaf, and check node $v.aux$ directly */
 $1D_Range_Search(v.aux, x_\ell, x_r, F)$
6. $v = s.right$
7. **while** v is not a leaf **do**
 - if** $(y_r > v.key)$ **then**
 - $1D_Range_Search(v.left.aux, x_\ell, x_r, F)$
 - $v = v.right$
 - else** $v = v.left$
8. /* v is a leaf, and check node $v.aux$ directly */
 $1D_Range_Search(v.aux, x_\ell, x_r, F)$.

function $Find_split-node(v, b, e)$

/* Given a k D-range tree T rooted at v and an interval $I = [b, e] \subseteq [v.B, v.E]$, this procedure returns the *split-node* s such that either $[s.B, s.E] = [b, e]$ or $[s_\ell.B, s_\ell.E] \cap [b, e] \neq \emptyset$ and $[s_r.B, s_r.E] \cap [b, e] \neq \emptyset$, where s_ℓ and s_r are the left child and right child of s , respectively. */

1. **if** $[v.B, v.E] = [b, e]$ **then return** v
2. **if** $(b < v.key)$ **and** $(e > v.key)$ **then return** v
3. **if** $(e \leq v.key)$ **then return** $Find_split-node(v.left, b, e)$
4. **if** $(b \geq v.key)$ **then return** $Find_split-node(v.right, b, e)$

procedure 1D_Range_Search(v, x_ℓ, x_r, F) is very straightforward. v is a pointer to a sorted array SA. We first do a binary search in SA looking for the first element no less than x_ℓ and then start to report in F those elements no greater than x_r . It is obvious that **procedure** 2D_Range_Search finds all the points in Q in $O(\log^2 n)$ time. Note that there are $O(\log n)$ nodes for which we need to invoke 1D_Range_Search in their auxiliary sorted arrays. These nodes v are in the canonical covering* of the y -range $[y_\ell, y_r]$, since its associated standard range $[v.B, v.E]$ is totally contained in $[y_\ell, y_r]$, and the 2D-range search problem is now reduced to the 1D-range search problem.

This is not difficult to see that the 2D-range search problem can be answered in time $O(\log^2 n)$ plus time for output, as there are $O(\log n)$ nodes in the canonical covering of a given y -range and for each node in the canonical covering we spend $O(\log n)$ time for dealing with the 1D-range search problem.

However, with a modification to the auxiliary data structure, one can achieve an optimal query time of $O(\log n)$, instead of $O(\log^2 n)$ [18,21,22]. This is based on the observation that in each of the 1D-range search subproblem associated with each node in the canonical covering, we perform the same query, reporting points whose x -coordinates lie in the x -range $[x_\ell, x_r]$. More specifically, we are searching for the smallest element no less than x_ℓ .

The modification is performed on the sorted array associated with each of the node in the 2D_Range_Tree(S).

Consider the root node v . As it is associated with the entire set of points, $v.aux$ points to the sorted array containing the x -coordinates of *all* the points in S . Let this sorted array be denoted $SA(v)$ and the entries, $SA(v)_i, i = 1, 2, \dots, |S|$, are sorted in nondecreasing order of the x -coordinate values. In addition to the x -coordinate value, each entry also contains the index of the corresponding point. That is, $SA(v)_i.key$ and $SA(v)_i.index$ contain the x -coordinate and index of p_j , respectively, where $SA(v)_i.index = j$ and $SA(v)_i.key = p_j.x$.

We shall augment each entry $SA(v)_i$ with two pointers, $SA(v)_i.left$ and $SA(v)_i.right$. They are defined as follows. Let v_ℓ and v_r denote the roots of the left and right subtrees of v , that is, $v.left = v_\ell$ and $v.right = v_r$. $SA(v)_i.left$ points to the entry $SA(v_\ell)_j$ such that entry $SA(v_\ell)_j.key$ is the smallest among all key values $SA(v_\ell)_j.key \geq SA(v)_i.key$. Similarly, $SA(v)_i.right$ points to the entry $SA(v_r)_k$ such that entry $SA(v_r)_k.key$ is the smallest among all key values $SA(v_r)_k.key \geq SA(v)_i.key$.

These two augmented pointers, $SA(v)_i.left$ and $SA(v)_i.right$, possess the following property: if $SA(v)_i.key$ is the smallest key such that $SA(v)_i.key \geq x_\ell$, then $SA(v_\ell)_j.key$ is also the smallest key such that $SA(v_\ell)_j.key \geq x_\ell$. Similarly $SA(v_r)_k.key$ is the smallest key such that $SA(v_r)_k.key \geq x_\ell$.

Thus if we have performed a binary search in the auxiliary sorted array $SA(v)$ associated with node v locating the entry $SA(v)_i$ whose key $SA(v)_i.key$ is the smallest key such that $SA(v)_i.key \geq x_\ell$, then following the left (respectively right) pointer $SA(v)_i.left$ (respectively $SA(v)_i.right$) to $SA(v_\ell)_j$ (respectively $SA(v_r)_k$), the entry $SA(v_\ell)_j.key$ (respectively $SA(v_r)_k.key$) is also the smallest key such that $SA(v_\ell)_j.key \geq x_\ell$ (respectively $SA(v_r)_k.key \geq x_\ell$). Thus there is no need to perform an additional binary search in the auxiliary sorted array $SA(v.left)$ (respectively $SA(v.right)$).

With this additional modification, we obtain an *augmented* 2D-range tree and the following theorem.

Theorem 19.6

The 2D-range search problem for a set of n points in the two-dimensional space can be solved in time $O(\log n)$ plus time for output, using an augmented 2D-range tree that requires $O(n \log n)$ space.

The following procedure is generalized from **procedure** 2D_Range_Search($v, x_\ell, x_r, y_\ell, y_r, F$) discussed in Section 19.4.2 taken into account the augmented auxiliary data structure. It is invoked by $kD_Range_Search(k, v, Q, F)$, where v is the root $kD_Range_Tree_root(S)$ of the range tree, Q is the kD -range, $[x_\ell^1, x_r^1] \times [x_\ell^2, x_r^2] \times \dots \times [x_\ell^k, x_r^k]$, represented by a two dimensional array, such that $Q_i.\ell = x_\ell^i$ and $Q_i.r = x_r^i$, and F , initially empty, will contain all the points that lie in Q .

procedure $kD_Range_Search(k, v, Q, F)$.

/* It returns F containing all the points in the range tree rooted at node v that lie in kD -range, $[x_\ell^1, x_r^1] \times [x_\ell^2, x_r^2] \times \dots \times [x_\ell^k, x_r^k]$, where each range $[x_\ell^i, x_r^i]$, $x_\ell^i = Q_i.\ell$, $x_r^i = Q_i.r \in \mathfrak{N}$, $x_\ell^i \leq x_r^i$ for all $i = 1, 2, \dots, k$ denotes an interval in \mathfrak{N} . */

Input: A set S of n points in \mathfrak{N}^k , $S = \{p_i | i = 1, 2, \dots, n\}$ and each point $p_i = (p_i.x^1, p_i.x^2, \dots, p_i.x^k)$, where $p_i.x^j \in \mathfrak{N}$, are the j th coordinates of $p_i, j = 1, 2, \dots, k$.

Output: A set F of points in S that lie in $[x_\ell^1, x_r^1] \times [x_\ell^2, x_r^2] \times \dots \times [x_\ell^k, x_r^k]$.

Method:

1. **if** ($k > 2$) **then**

- Start from the root node v to find the split node s , $s = \text{Find_split-node}(v, Q_k.\ell, Q_k.r)$, such that $s.key$ lies in $[Q_k.\ell, Q_k.r]$.
- **if** the split node is not found **then return**

* See the definition of the canonical covering defined in Section 19.3.1.

- if s is a leaf **then** check in the sorted array pointed to by $s.aux$, which contains just a point p . $p \Rightarrow F$ if its coordinate values lie in Q . **return**
 - $v = s.left$
 - **while** v is not a leaf **do**
 - if** ($Q_k.\ell \leq v.key$)
 - then** $kD_Range_Search(k - 1, v.right.aux, Q, F)$
 - $v = v.left$
 - else** $v = v.right$
 - /* v is a leaf, and check node $v.aux$ directly */
Check in the sorted array pointed to by $v.aux$, which contains just a point p . $p \Rightarrow F$ if its coordinate values lie in Q .
 - $v = s.right$
 - **while** v is not a leaf **do**
 - if** ($Q_k.r > v.key$)
 - then** $kD_Range_Search(k - 1, v.left.aux, Q, F)$
 - $v = v.right$
 - else** $v = v.left$
 - /* v is a leaf, and check node $v.aux$ directly */
Check in the sorted array pointed to by $v.aux$, which contains just a point p . $p \Rightarrow F$ if its coordinate values lie in Q .
2. **else** /* $k \leq 2$ */
3. **if** $k = 2$ **then**
- Do binary search in sorted array $SA(v)$ associated with node v , using $Q_1.\ell$ (x_ℓ^1) as key to find entry o_v such that $SA(v)_{o_v}$'s key, $SA(v)_{o_v}.key$ is the smallest such that $SA(v)_{o_v}.key \geq Q_1.\ell$.
 - Find the split node s , $s = \text{Find_split-node}(v, Q_2.\ell, Q_2.r)$, such that $s.key$ lies in $[Q_2.\ell, Q_2.r]$. Record the root-to-split-node path from v to s , following *left* or *right* tree pointers.
 - **if** the split node is not found **then return**
 - Starting from entry o_v ($SA(v)_i$) follow pointers $SA(v)_{o_v}.left$ or $SA(v)_{o_v}.right$ according to the v -to- s path to point to entry $SA(s)_{o_s}$ associated with $SA(s)$.
 - **if** s is a leaf **then** check in the sorted array pointed to by $s.aux$, which contains just a point p . $p \Rightarrow F$ if its coordinate values lie in Q . **return**
 - $v = s.left$, $o_v = SA(s)_{o_s}.left$
 - **while** v is not a leaf **do**
 - if** ($Q_2.\ell \leq v.key$)
 - then** $\ell = SA(v)_{o_v}.right$
 - while** ($SA(v.right)_\ell.key \leq Q_1.r$) **do**
 - point $p_m \Rightarrow F$, where $m = SA(v.right)_\ell.index$
 - $\ell++$
 - $v = v.left$, $o_v = SA(v)_{o_v}.left$
 - else** $v = v.right$, $o_v = SA(v)_{o_v}.right$
 - /* v is a leaf, and check node $v.aux$ directly */
Check in the sorted array pointed to by $v.aux$, which contains just a point p . $p \Rightarrow F$ if its coordinate values lie in Q .
 - $v = s.right$, $o_v = SA(s)_{o_s}.right$
 - **while** v is not a leaf **do**
 - if** ($Q_2.r > v.key$)
 - then** $\ell = SA(v)_{o_v}.left$
 - while** ($SA(v.left)_\ell.key \leq Q_1.r$) **do**
 - point $p_m \Rightarrow F$, where $m = SA(v.left)_\ell.index$
 - $\ell++$
 - $v = v.right$, $o_v = SA(v)_{o_v}.right$
 - else** $v = v.left$, $o_v = SA(v)_{o_v}.left$
 - /* v is a leaf, and check node $v.aux$ directly */
Check in the sorted array pointed to by $v.aux$, which contains just a point p . $p \Rightarrow F$ if its coordinate values lie in Q .

The following recurrence relation for the query time $Q(n, k)$ of the kD -range search problem can be easily obtained:

$$Q(n, k) = \begin{cases} O(1) & \text{if } n = 1 \\ O(\log n) + \mathcal{F} & \text{if } k = 2 \\ \sum_{v \in CC} Q(n_v, k - 1) + O(\log n) & \text{otherwise} \end{cases}$$

where \mathcal{F} denotes the output size and n_v denotes the size of the subtree rooted at node v that belongs to the canonical covering CC of the query. The solution is $Q(n, k) = O(\log^{k-1} n) + \mathcal{F}$ [3,4].

We conclude with the following theorem.

Theorem 19.7

The k D-range search problem for a set of n points in the k -dimensional space can be solved in time $O(\log^{k-1} n)$ plus time for output, using an augmented k D-range tree that requires $O(n \log^{k-1} n)$ space for $k \geq 1$.

19.5 Priority Search Trees

The priority search tree was originally introduced by McCreight [23]. It is a hybrid of two data structures, binary search tree and a priority queue [24]. A *priority queue* is a queue and supports the following operations: insertion of an item and deletion of the minimum (highest priority) item, so called *delete_min* operation. Normally the *delete_min* operation takes constant time, while updating the queue so that the minimum element is readily accessible takes logarithmic time. However, searching for an element in a priority queue will normally take linear time. To support efficient searching, the priority queue is modified to be a priority search tree. We will give a formal definition and its construction later. As the priority search tree represents a set S of elements, each of which has two pieces of information, one being a key from a totally ordered set, say the set \mathfrak{N} of real numbers, and the other being a notion of priority, also from a totally ordered set, for each element, we can model this set S as a set of points in two-dimensional space. The x - and y -coordinates of a point p represent the key and the priority, respectively. For instance, consider a set of jobs $S = \{J_1, J_2, \dots, J_n\}$, each of which has a release time $r_i \in \mathfrak{N}$ and a priority $p_i \in \mathfrak{N}, i = 1, 2, \dots, n$. Then each job J_i can be represented as a point q such that $q.x = r_i, q.y = p_i$.

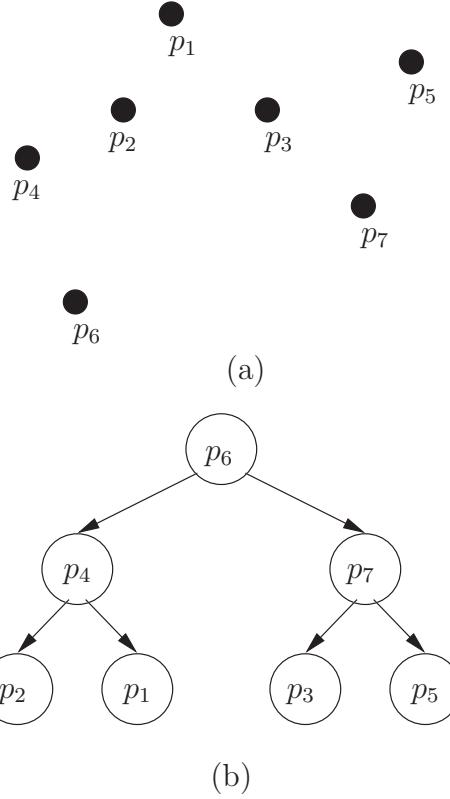

The priority search tree can be used to support queries of the form, find, among a set S of n points, the point p with minimum $p.y$ such that its x -coordinate lies in a given range $[\ell, r]$, that is, $\ell \leq p.x \leq r$. As can be shown later, this query can be answered in $O(\log n)$ time.

19.5.1 Construction of Priority Search Trees

As before, the root node, `Priority_Search_Tree_root(S)`, represents the entire set S of points. Each node v in the tree will have a key $v.key$, an auxiliary data $v.aux$ containing the index of the point, and two pointers $v.left$ and $v.right$ to its left and right subtrees, respectively, such that all the key values stored in the left subtree are less than $v.key$ and all the key values stored in the right subtree are greater than $v.key$. The following is a pseudo code for the recursive construction of the priority search tree of a set S of n points in \mathfrak{N}^2 . See [Figure 19.5a](#) for an illustration.

```
function Priority_Search_Tree( $S$ )
/* It returns a pointer  $v$  to the root, Priority_Search_Tree_root(S), of the priority search tree for a set  $S$  of points. */
Input: A set  $S$  of  $n$  points in  $\mathfrak{N}^2$ ,  $S = \{p_i | i = 1, 2, \dots, n\}$  and each point  $p_i = (p_i.x, p_i.y)$ , where  $p_i.x$  and  $p_i.y$  are the  $x$ - and  $y$ -coordinates of  $p_i$ ,  $p_i.x, p_i.y \in \mathfrak{N}, i = 1, 2, \dots, n$ .
Output: A priority search tree, rooted at Priority_Search_Tree_root(S).
Method:
1. if  $S = \emptyset$ , return nil.
2. Create a node  $v$  such that  $v.key$  equals the median of the set  $\{p.x | p \in S\}$ , and  $v.aux$  contains the index  $i$  of the point  $p_i$  whose  $y$ -coordinate is the minimum among all the  $y$ -coordinates of the set  $S$  of points, that is,  $p_i.y = \min\{p.y | p \in S\}$ .
3. Let  $S_\ell = \{p \in S \setminus \{p_{v.aux}\} | p.x \leq v.key\}$  and  $S_r = \{p \in S \setminus \{p_{v.aux}\} | p.x > v.key\}$  denote the set of points whose  $x$ -coordinates are less than or equal to  $v.key$  and greater than  $v.key$ , respectively.
4.  $v.left = \text{Priority\_Search\_Tree}(S_\ell)$ .
5.  $v.right = \text{Priority\_Search\_Tree}(S_r)$ .
6. return  $v$ .
```

Thus, `Priority_Search_Tree_root(S)` is a minimum heap data structure with respect to the y -coordinates, that is, the point with minimum y -coordinate can be accessed in constant time, and is a balanced binary search tree for the x -coordinates. Implicitly the root node v is associated with an x -range $[x_\ell, x_r]$ representing the span of the x -coordinate values of all the points in the whole set S . The root of the left subtree pointed to by $v.left$ is associated with the x -range $[x_\ell, v.key]$ representing the span of the x -coordinate values of all the points in the set S_ℓ and the root of the right subtree pointed to by $v.right$ is associated with the x -range $(v.key, x_r]$ representing the span of the x -coordinate values of all the points in the set S_r . It is obvious that this algorithm takes $O(n \log n)$ time and linear space. We summarize this in the following.

FIGURE 19.5 Priority search tree of $S = \{p_1, p_2, \dots, p_7\}$.

Theorem 19.8

The priority search tree for a set S of n points in \mathbb{R}^2 can be constructed in $O(n \log n)$ time and linear space.

19.5.2 Examples and Its Applications

Figure 19.5 illustrates an example of a priority search tree of the set of points. Note that the root node contains p_6 since its y -coordinate value is the minimum.

We now illustrate a usage of the priority search tree by an example. Consider a so-called *grounded 2D-range search problem* for a set of n points in the plane. As defined in Section 19.4.2, a 2D-range search problem is to find all the points $p \in S$ such that $p.x$ lies in an x -range $[x_\ell, x_r]$, $x_\ell \leq x_r$ and $p.y$ lies in a y -range $[y_\ell, y_r]$. When the y -range is of the form $[-\infty, y_r]$ then the 2D-range is referred to as *grounded 2D-range* or sometimes as 1.5D-range, and the 2D-range search problem as *grounded 2D-range search* or 1.5D-range search problem.

Grounded 2D-Range Search Problem: Given a set S of n points in the plane \mathbb{R}^2 , with preprocessing allowed, find the subset F of points whose x - and y -coordinates satisfy a grounded 2D-range query of the form $[x_\ell, x_r] \times [-\infty, y_r]$, $x_\ell, x_r, y_r \in \mathbb{R}$, $x_\ell \leq x_r$.

The following pseudo code solves this problem optimally. We assume that a priority search tree for S has been constructed via procedure `Priority_Search_Tree(S)`. The answer will be obtained in F via an invocation to `Priority_Search_Tree_Range_Search(v, x_ℓ, x_r, y_r, F)`, where v is `Priority_Search_Tree_root(S)`.

procedure `Priority_Search_Tree_Range_Search(v, x_ℓ, x_r, y_r, F)`

/ v points to the root of the tree, F is a queue and set to **nil** initially. */*

Input: A set S of n points, $\{p_1, p_2, \dots, p_n\}$, in \mathbb{R}^2 , stored in a priority search tree, `Priority_Search_Tree(S)` pointed to by `Priority_Search_Tree_root(S)`, and a grounded 2D-range $[x_\ell, x_r] \times [-\infty, y_r]$, $x_\ell, x_r, y_r \in \mathbb{R}$, $x_\ell \leq x_r$.

Output: A subset $F \subseteq S$ of points that lie in the grounded 2D-range, that is, $F = \{p \in S | x_\ell \leq p.x \leq x_r \text{ and } p.y \leq y_r\}$.

Method:

1. Start from the root v finding the first split node v_{split} such that $v_{split}.key$ lies in the x -range $[x_\ell, x_r]$.

2. For each node u on the path from node v to node v_{split} , if the point $p_{u.aux}$ lies in range $[x_\ell, x_r] \times [-\infty, y_r]$ then report it by $(p_{u.aux} \Rightarrow F)$.
3. For each node u on the path from $v_{split}.left$ to x_ℓ in the left subtree of v_{split} , do
if the path goes left at u then Priority_Search_Tree_1dRange_Search($u.right, y_r, F$)
4. For each node u on the path from $v_{split}.right$ to x_r in the right subtree of v_{split} , do
if the path goes right at u then Priority_Search_Tree_1dRange_Search($u.left, y_r, F$)

procedure Priority_Search_Tree_1dRange_Search(v, y_r, F)

/* Report in F all the points p_i , whose y -coordinate values are no greater than y_r , where $i = v.aux$. */

1. if v is nil, return.
2. if $p_{v.aux}.y \leq y_r$ then report it by $(p_{v.aux} \Rightarrow F)$.
3. Priority_Search_Tree_1dRange_Search($v.left, y_r, F$)
4. Priority_Search_Tree_1dRange_Search($v.right, y_r, F$)

procedure Priority_Search_Tree_1dRange_Search(v, y_r, F) basically retrieves all the points stored in the priority search tree rooted at v such that their y -coordinates are all less than or equal to y_r . The search terminates at the node u whose associated point has a y -coordinate greater than y_r , implying all the nodes in the subtree rooted at u satisfy this property. The amount of time required is proportional to the output size. Thus we conclude that

Theorem 19.9

The **Grounded 2D-Range Search Problem** for a set S of n points in the plane \mathbb{R}^2 can be solved in time $O(\log n)$ plus time for output, with a priority search tree structure for S that requires $O(n \log n)$ time and $O(n)$ space.

Note that the space requirement for the priority search tree is linear, compared to that of a 2D-range tree, which requires $O(n \log n)$ space. That is, the **Grounded 2D-Range Search Problem** for a set S of n points can be solved optimally using priority search tree structure.

20.1 Introduction

Quadtrees are hierarchical spatial tree data structures that are based on the principle of recursive decomposition of space. The term *quadtree* originated from representation of two dimensional data by recursive decomposition of space using separators parallel to the coordinate axis. The resulting split of a region into four regions corresponding to southwest, northwest, southeast and northeast quadrants is represented as four children of the node corresponding to the region, hence the term “quad” tree. In a three dimensional analogue, a region is split into eight regions using planes parallel to the coordinate planes. As each internal node can have eight children corresponding to the 8-way split of the region associated with it, the term *octree* is used to describe the resulting tree structure. Analogous data structures for representing spatial data in higher than three dimensions are called *hyperoctrees*. It is also common practice to use the term *quadtrees* in a generic way irrespective of the dimensionality of the spatial data. This is especially useful when describing algorithms that are applicable regardless of the specific dimensionality of the underlying data.

Several related spatial data structures are described under the common rubric of quadtrees. Common to these data structures is the representation of spatial data at various levels of granularity using a hierarchy of regular, geometrically similar regions (such as cubes, hyperrectangles etc.). The tree structure allows quick focusing on regions of interest, which facilitates the design of fast algorithms. As an example, consider the problem of finding all points in a data set that lie within a given distance from a query point, commonly known as the *spherical region query*. In the absence of any data organization, this requires checking the distance from the query point to each point in the data set. If a quadtree of the data is available, large regions that lie outside the spherical region of interest can be quickly discarded from consideration, resulting in great savings in execution time. Furthermore, the unit aspect ratio employed in most quadtree data structures allows geometric arguments useful in designing fast algorithms for certain classes of applications.

In constructing a quadtree, one starts with a square, cubic or hypercubic region (depending on the dimensionality) that encloses the spatial data under consideration. The different variants of the quadtree data structure are differentiated by the principle used in the recursive decomposition process. One important aspect of the decomposition process is if the decomposition is guided by input data or is based on the principle of equal subdivision of the space itself. The former results in a tree size proportional to the size of the input. If all the input data is available *a priori*, it is possible to make the data structure height balanced. These

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

attractive properties come at the expense of difficulty in making the data structure dynamic, typically in accommodating deletion of data. If the decomposition is based on equal subdivision of space, the resulting tree depends on the distribution of spatial data. As a result, the tree is height balanced and is linear in the size of input only when the distribution of the spatial data is uniform, and the height and size properties deteriorate with increase in nonuniformity of the distribution. The beneficial aspect is that the tree structure facilitates easy update operations and the regularity in the hierarchical representation of the regions facilitates geometric arguments helpful in designing algorithms.

Another important aspect of the decomposition process is the termination condition to stop the subdivision process. This identifies regions that will not be subdivided further, which will be represented by leaves in the quadtree. Quadtrees have been used as fixed resolution data structures, where the decomposition stops when a preset resolution is reached, or as variable resolution data structures, where the decomposition stops when a property based on input data present in the region is satisfied. They are also used in a hybrid manner, where the decomposition is stopped when either a resolution level is reached or when a property is satisfied.

Quadtrees are used to represent many types of spatial data including points, line segments, rectangles, polygons, curvilinear objects, surfaces, volumes and cartographic data. Their use is pervasive spanning many application areas including computational geometry, computer aided design ([Chapter 53](#)), computer graphics ([Chapter 55](#)), databases ([Chapter 62](#)), geographic information systems ([Chapter 56](#)), image processing ([Chapter 58](#)), pattern recognition, robotics and scientific computing. Introduction of the quadtree data structure and its use in applications involving spatial data dates back to the early 1970s and can be attributed to the work of Klinger [1], Finkel and Bentley [2], and Hunter [3]. Due to extensive research over the last three decades, a large body of literature is available on quadtrees and its myriad applications. For a detailed study on this topic, the reader is referred to the classic textbooks by Samet [4,5]. Development of quadtree like data structures, algorithms and applications continues to be an active research area with significant research developments in recent years. In this chapter, we attempt a coverage of some of the classical results together with some of the more recent developments in the design and analysis of algorithms using quadtrees and octrees.

20.2 Quadtrees for Point Data

We first explore quadtrees in the context of the simplest type of spatial data—multidimensional points. Consider a set of n points in d dimensional space. The principal reason a spatial data structure is used to organize multidimensional data is to facilitate queries requiring spatial information. A number of such queries can be identified for point data. For example:

1. *Range query*: Given a range of values for each dimension, find all the points that lie within the range. This is equivalent to retrieving the input points that lie within a specified hyperrectangular region. Such a query is often useful in database information retrieval.
2. *Spherical region query*: Given a query point p and a radius r , find all the points that lie within a distance of r from p . In a typical molecular dynamics application, spherical region queries centered around each of the input points is required.
3. *All nearest neighbor query*: Given n points, find the nearest neighbor of each point within the input set.

While quadtrees are used for efficient execution of such spatial queries, one must also design algorithms for the operations required of almost any data structure such as constructing the data structure itself, and accommodating searches, insertions and deletions. Though such algorithms will be covered first, it should be kept in mind that the motivation behind the data structure is its use in spatial queries. If all that were required was search, insertion and deletion operations, any one dimensional organization of the data using a data structure such as a binary search tree would be sufficient.

20.2.1 Point Quadtrees

The point quadtree is a natural generalization of the binary search tree data structure to multiple dimensions. For convenience, first consider the two dimensional case. Start with a square region that contains all of the input points. Each node in the point quadtree corresponds to an input point. To construct the tree, pick an arbitrary point and make it the root of the tree. Using lines parallel to the coordinate axis that intersect at the selected point (see [Figure 20.1](#)), divide the region into four subregions corresponding to the southwest, northwest, southeast and northeast quadrants, respectively. Each of the subregions is recursively decomposed in a similar manner to yield the point quadtree. For points that lie at the boundary of two adjacent regions, a convention can be adopted to treat the points as belonging to one of the regions. For instance, points lying on the left and bottom edges of a region may be considered included in the region, while points lying on the top and right edges are not. When a region corresponding to a node in the tree contains a single point, it is considered a leaf node. Note that point quadtrees are not unique and their structure depends on the selection of points used in region subdivisions. Irrespective of the choices made, the resulting tree will have n nodes, one corresponding to each input point.

If all the input points are known in advance, it is easy to choose the points for subdivision so as to construct a height balanced tree. A simple way to do this is to sort the points with one of the coordinates, say x , as the primary key and the other coordinate,

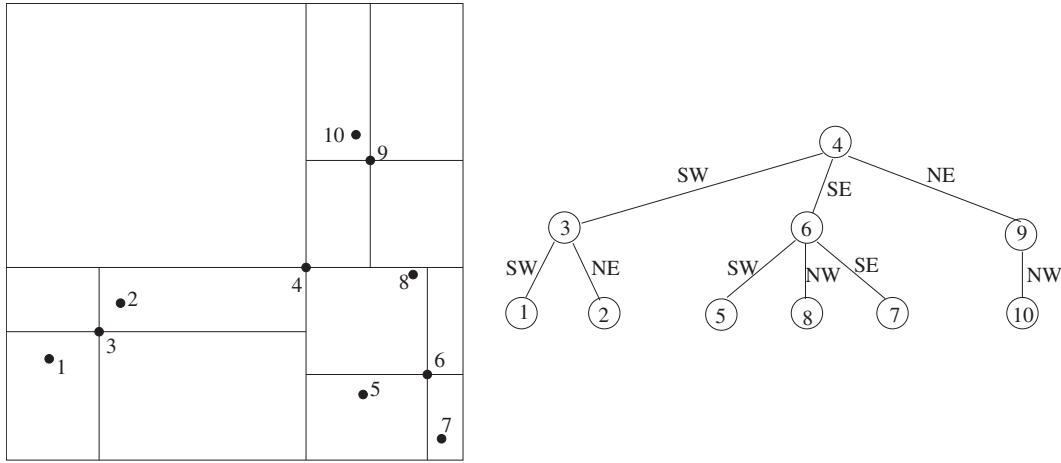

FIGURE 20.1 A two dimensional set of points and a corresponding point quadtree.

say y , as the secondary key. The first subdivision point is chosen to be the median of this sorted data. This will ensure that none of the children of the root node receives more than half the points. In $O(n)$ time, such a sorted list can be created for each of the four resulting subregions. As the total work at every level of the tree is bounded by $O(n)$, and there are at most $O(\log n)$ levels in the tree, a height balanced point quadtree can be built in $O(n \log n)$ time. Generalization to d dimensions is immediate, with $O(dn \log n)$ run time.

The recursive structure of a point quadtree immediately suggests an algorithm for searching. To search for a point, compare it with the point stored at the root. If they are different, the comparison immediately suggests the subregion containing the point. The search is directed to the corresponding child of the root node. Thus, search follows a path in the quadtree until either the point is discovered, or a leaf node is reached. The run time is bounded by $O(dh)$, where h is the height of the tree.

To insert a new point not already in the tree, first conduct a search for it which ends in a leaf node. The leaf node now corresponds to a region containing two points. One of them is chosen for subdividing the region and the other is inserted as a child of the node corresponding to the subregion it falls in. The run time for point insertion is also bounded by $O(dh)$, where h is the height of the tree after insertion. One can also construct the tree itself by repeated insertions using this procedure. Similar to binary search trees, the run time under a random sequence of insertions is expected to be $O(n \log n)$ [6]. Overmars and van Leeuwen [7] present algorithms for constructing and maintaining optimized point quadtrees irrespective of the order of insertions.

Deletion in point quadtrees is much more complex. The point to be deleted is easily identified by a search for it. The difficulty lies in identifying a point in its subtree to take the place of the deleted point. This may require nontrivial readjustments in the subtree underneath. The reader interested in deletion in point quadtrees is referred to [8]. An analysis of the expected cost of various types of searches in point quadtrees is presented by Flajolet *et al.* [9].

For the remainder of the chapter, we will focus on quadtree data structures that use equal subdivision of the underlying space, called *region quadtrees*. This is because we regard Bentley's multidimensional binary search trees [2], also called k - d trees, to be superior to point quadtrees. The k - d tree is a binary tree where a region is subdivided into two based only on one of the dimensions. If the dimension used for subdivision is cyclically rotated at consecutive levels in the tree, and the subdivision is chosen to be consistent with the point quadtree, then the resulting tree would be equivalent to the point quadtree but without the drawback of large degree (2^d in d dimensions). Thus, it can be argued that point quadtrees are contained in k - d trees. Furthermore, recent results on compressed region quadtrees indicate that it is possible to simultaneously achieve the advantages of both region and point quadtrees. In fact, region quadtrees are the most widely used form of quadtrees despite their dependence on the spatial distribution of the underlying data. While their use posed theoretical inconvenience—it is possible to create as large a worst-case tree as desired with as little as three points—they are widely acknowledged as the data structure of choice for practical applications. We will outline some of these recent developments and outline how good practical performance and theoretical performance guarantees can both be achieved using region quadtrees.

20.2.2 Region Quadtrees

The region quadtree for n points in d dimensions is defined as follows: Consider a hypercube large enough to enclose all the points. This region is represented by the root of the d -dimensional quadtree. The region is subdivided into 2^d subregions of equal

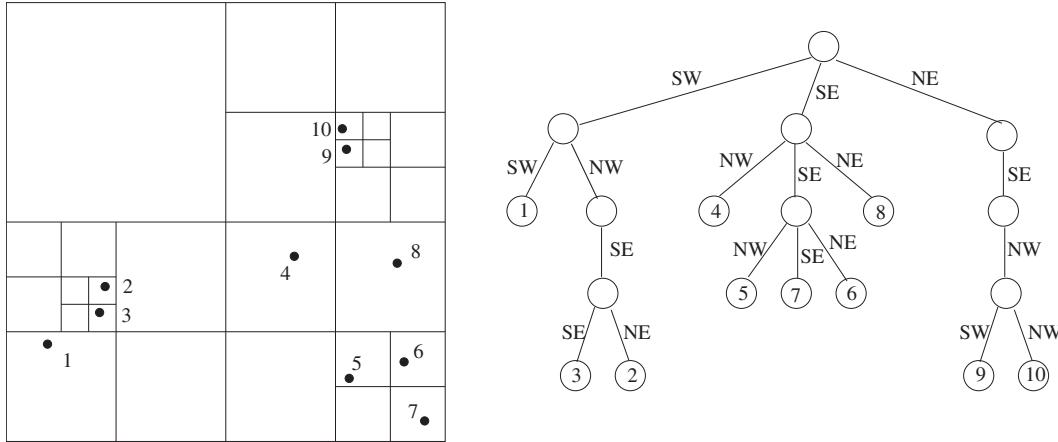

FIGURE 20.2 A two dimensional set of points and the corresponding region quadtree.

size by bisecting along each dimension. Each of these regions containing at least one point is represented as a child of the root node. The same procedure is recursively applied to each child of the root node. The process is terminated when a region contains only a single point. This data structure is also known as the *point region quadtree*, or *PR-quadtrees* for short [10]. At times, we will simply use the term *quadtree* when the tree implied is clear from the context. The region quadtree corresponding to a two dimensional set of points is shown in Figure 20.2. Once the enclosing cube is specified, the region quadtree is unique. The manner in which a region is subdivided is independent of the specific location of the points within the region. This makes the size of the quadtree sensitive to the spatial distribution of the points.

Before proceeding further, it is useful to establish a terminology to describe the type of regions that correspond to nodes in the quadtree. Call a hypercubic region containing all the points the *root cell*. Define a hierarchy of cells by the following: The root cell is in the hierarchy. If a cell is in the hierarchy, then the 2^d equal-sized cubic subregions obtained by bisecting along each dimension of the cell are also called *cells* and belong to the hierarchy (see Figure 20.3 for an illustration of the cell hierarchy in two dimensions). We use the term *subcell* to describe a cell that is completely contained in another. A cell containing the subcell is called a *supercell*. The subcells obtained by bisecting a cell along each dimension are called the *immediate subcells* with respect to the bisected cell. Also, a cell is the *immediate supercell* of any of its immediate subcells. We can treat a cell as a set of all points in space contained in the cell. Thus, we use $C \subseteq D$ to indicate that the cell C is a subcell of the cell D and $C \subset D$ to indicate that C is a subcell of D but $C \neq D$. Define the *length of a cell* C , denoted $\text{length}(C)$, to be the span of C along any dimension. An important property of the cell hierarchy is that, given two arbitrary cells, either one is completely contained in the other or they are disjoint. Cells are considered disjoint if they are adjacent to each other and share a boundary.

Each node in a quadtree corresponds to a subcell of the root cell. Leaf nodes correspond to largest cells that contain a single point. There are as many leaf nodes as the number of points, n . The size of the quadtree cannot be bounded as a function of n , as it depends on the spatial distribution. For example, consider a data set of 3 points consisting of two points very close to each other and a faraway point located such that the first subdivision of the root cell will separate the faraway point from the other two. Then, depending on the specific location and proximity of the other two points, a number of subdivisions may be necessary to separate them. In principle, the location and proximity of the two points can be adjusted to create as large a worst-case tree as desired. In practice, this is an unlikely scenario due to limits imposed by computer precision.

From this example, it is intuitively clear that a large number of recursive subdivisions may be required to separate points that are very close to each other. In the worst case, the recursive subdivision continues until the cell sizes are so small that a single cell cannot contain both the points irrespective of their location. Subdivision is never required beyond this point, but the points may be separated sooner depending on their actual location. Let s be the smallest distance between any pair of points and D be the length of the root cell. An upper bound on the height of the quadtree is obtained by considering the worst-case path needed to separate a pair of points which have the smallest pairwise distance. The length of the smallest cell that can contain two points s apart in d dimensions is $\frac{s}{\sqrt{d}}$ (see Figure 20.4 for a two and three dimensional illustration). The paths separating the closest points may contain recursive subdivisions until a cell of length smaller than $\frac{s}{\sqrt{d}}$ is reached. Since each subdivision halves the length of the cells, the maximum path length is given by the smallest k for which $\frac{D}{2^k} < \frac{s}{\sqrt{d}}$, or $k = \lceil \log \frac{\sqrt{d}D}{s} \rceil$. For a fixed number of dimensions, the worst-case path length is $O(\log \frac{D}{s})$. Since the tree has n leaves, the number of nodes in the tree is bounded by $O(n \log \frac{D}{s})$. In the worst case, D is proportional to the largest distance between any pair of points. Thus, the height of a quadtree

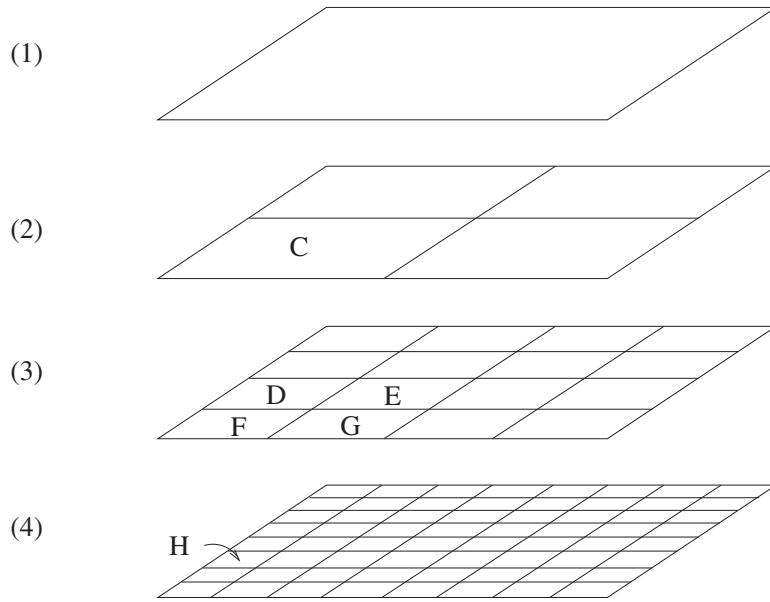

FIGURE 20.3 Illustration of hierarchy of cells in two dimensions. Cells D, E, F and G are immediate subcells of C. Cell H is an immediate subcell of D, and is a subcell of C.

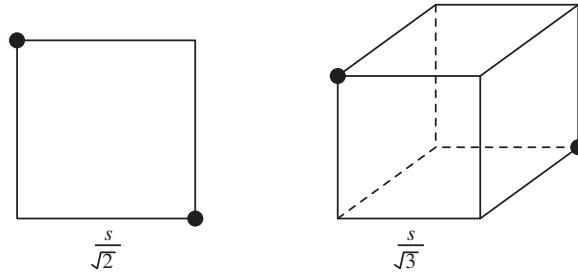

FIGURE 20.4 Smallest cells that could possibly contain two points that are a distance s apart in two and three dimensions.

is bounded by the logarithm of the ratio of the largest pairwise distance to the smallest pairwise distance. This ratio is a measure of the degree of nonuniformity of the distribution.

Search, insert and delete operations in region quadtrees are rather straightforward. To search for a point, traverse a path from root to a leaf such that each cell on the path encloses the point. If the leaf contains the point, it is in the quadtree. Otherwise, it is not. To insert a point not already in the tree, search for the point which terminates in a leaf. The leaf node corresponds to a region which originally had one point. To insert a new point which also falls within the region, the region is subdivided as many times as necessary until the two points are separated. This may create a chain of zero or more length below the leaf node followed by a branching to separate the two points. To delete a point present in the tree, conduct a search for the point which terminates in a leaf. Delete the leaf node. If deleting the node leaves its parent with a single child, traverse the path from the leaf to the root until a node with at least two children is encountered. Delete the path below the level of the child of this node. Each of the search, insert and delete operations takes $O(h)$ time, where h is the height of the tree. Construction of a quadtree can be done either through repeated insertions, or by constructing the tree level by level starting from the root. In either case, the worst case run time is $O(n \log \frac{D}{s})$. We will not explore these algorithms further in favor of superior algorithms to be described later.

20.2.3 Compressed Quadtrees and Octrees

In an n -leaf tree where each internal node has at least two children, the number of nodes is bounded by $2n - 1$. The size of quadtrees is distribution dependent because there can be internal nodes with only one child. In terms of the cell hierarchy, a cell may contain all its points in a small volume so that, recursively subdividing it may result in just one of the immediate subcells containing the points for an arbitrarily large number of steps. Note that the cells represented by nodes along such a path have

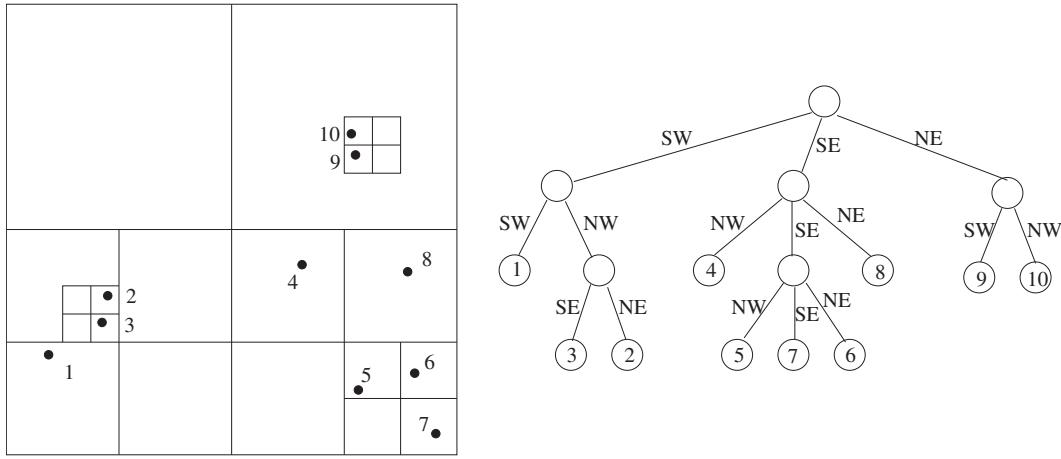

FIGURE 20.5 The two-dimensional set of points from Figure 20.2, and the corresponding compressed quadtree.

different sizes but they all enclose the same points. In many applications, all these nodes essentially contain the same information as the information depends only on the points the cell contains. This prompted the development of compressed quadtrees, which are obtained by compressing each such path into a single node. Therefore, each node in a compressed quadtree is either a leaf or has at least two children. The compressed quadtree corresponding to the quadtree of Figure 20.2 is depicted in Figure 20.5. Compressed quadtrees originated from the work of Clarkson [11] in the context of the all nearest neighbors problem and further studied by Aluru and Sevilgen [12].

A node v in the compressed quadtree is associated with two cells, *large cell of v* ($L(v)$) and *small cell of v* ($S(v)$). They are the largest and smallest cells that enclose the points in the subtree of the node, respectively. When $S(v)$ is subdivided, it results in at least two non-empty immediate subcells. For each such subcell C resulting from the subdivision, there is a child u such that $L(u) = C$. Therefore, $L(u)$ at a node u is an immediate subcell of $S(v)$ at its parent v . A node is a leaf if it contains a single point and the small cell of a leaf node is the hypothetical cell with zero length containing the point.

The size of a compressed quadtree is bounded by $O(n)$. The height of a compressed quadtree has a lower bound of $\Omega(\log n)$ and an upper bound of $O(n)$. Search, insert and delete operations on compressed quadtrees take $O(h)$ time. In practice, the height of a compressed quadtree is significantly smaller than suggested by the upper bound because (a) computer precision limits restrict the ratio of largest pairwise distance to smallest pairwise distance that can be represented, and (b) the ratio of length scales represented by a compressed quadtree of height h is at least $2^h : 1$. In most practical applications, the height of the tree is so small that practitioners use representation schemes that allow only trees of constant height [13,14] or even assume that the height is constant in algorithm analysis [15]. For instance, a compressed octree of height 20 allows potentially $8^{20} = 2^{60}$ leaf nodes and a length scale of $2^{20} : 1 \approx 10^6 : 1$.

Though compressed quadtrees are described as resulting from collapsing chains in quadtrees, such a procedure is not intended for compressed quadtree construction. Instead, algorithms for direct construction of compressed quadtrees in $O(dn \log n)$ time will be presented, which can be used to construct quadtrees efficiently if necessary. To obtain a quadtree from its compressed version, identify each node whose small cell is not identical to its large cell and replace it by a chain of nodes corresponding to the hierarchy of cells that lead from the large cell to the small cell.

20.2.4 Cell Orderings and Space-Filling Curves

We explore a suitable one dimensional ordering of cells and use it in conjunction with spatial ordering to develop efficient algorithms for compressed quadtrees. First, define an ordering for the immediate subcells of a cell. In two dimensions, we use the order SW, NW, SE and NE. The same ordering has been used to order the children of a node in a two dimensional quadtree (Figures 20.2 and 20.5). Now consider ordering two arbitrary cells. If one of the cells is contained in the other, the subcell precedes the supercell. If the two cells are disjoint, the smallest supercell enclosing both the cells contains them in different immediate subcells of it. Order the cells according to the order of the immediate subcells containing them. This defines a total order on any collection of cells with a common root cell. It follows that the order of leaf regions in a quadtree corresponds to the left-or-right order in which the regions appear in our drawing scheme. Similarly, the ordering of all regions in a quadtree corresponds to the postorder traversal of the quadtree. These concepts naturally extend to higher dimensions. Note that any ordering of the immediate subcells of a cell can be used as foundation for cell orderings.

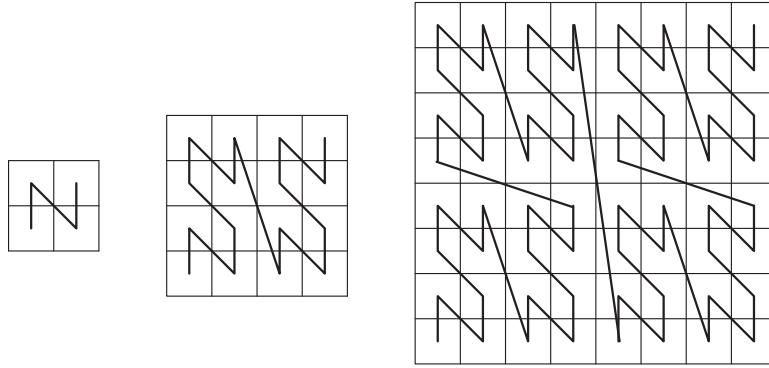

FIGURE 20.6 Z-curve for 2×2 , 4×4 and 8×8 cell decompositions.

Ordering of cells at a particular resolution in the manner described above can be related to space filling curves. Space filling curves are proximity preserving mappings from a multidimensional uniform cell decomposition to a one dimensional ordering. The path implied in the multidimensional space by the linear ordering, that is, the sequence in which the multidimensional cells are visited according to the linear ordering, forms a non-intersecting curve. Of particular interest is Morton ordering, also known as the Z-space filling curve [16]. The Z-curves for 2×2 , 4×4 and 8×8 cell decompositions are shown in Figure 20.6. Consider a square two dimensional region and its $2^k \times 2^k$ cell decomposition. The curve is considered to originate in the lower left corner and terminate in the upper right corner. The curve for a $2^k \times 2^k$ grid is composed of four $2^{k-1} \times 2^{k-1}$ grid curves one in each quadrant of the $2^k \times 2^k$ grid and the tail of one curve is connected to the head of the next as shown in the figure. The order in which the curves are connected is the same as the order of traversal of the 2×2 curve. Note that Morton ordering of cells is consistent with the cell ordering specified above. Other space filling curves orderings such as graycode [17] and Hilbert [18] curve can be used and quadtree ordering schemes consistent with these can also be utilized. We will continue to utilize the Z-curve ordering as it permits a simpler bit interleaving scheme which will be presented and exploited later.

Algorithms on compressed quadtree rely on the following operation due to Clarkson [11]:

Lemma 20.1

Let R be the product of d intervals $I_1 \times I_2 \times \dots \times I_d$, that is, R is a hyperrectangular region in d dimensional space. The smallest cell containing R can be found in $O(d)$ time, which is constant for any fixed d .

The procedure for computing the smallest cell uses floor, logarithm and bitwise exclusive-or operations. An extended RAM model is assumed in which these are considered constant time operations. The reader interested in proof of Lemma 20.1 is referred to [11,19]. The operation is useful in several ways. For example, the order in which two points appear in the quadtree as per our ordering scheme is independent of the location of other points. To determine the order for two points, say (x_1, x_2, \dots, x_d) and (y_1, y_2, \dots, y_d) , find the smallest cell that contains $[x_1, y_1] \times [x_2, y_2] \times \dots \times [x_d, y_d]$. The points can then be ordered according to its immediate subcells that contain the respective points. Similarly, the smallest cell containing a pair of other cells, or a point and a cell, can be determined in $O(d)$ time.

20.2.5 Construction of Compressed Quadtrees

20.2.5.1 A Divide-and-Conquer Construction Algorithm

Let T_1 and T_2 be two compressed quadtrees representing two distinct sets S_1 and S_2 of points. Let r_1 (respectively, r_2) be the root node of T_1 (respectively, T_2). Suppose that $L(r_1) = L(r_2)$, that is, both T_1 and T_2 are constructed starting from a cell large enough to contain $S_1 \cup S_2$. A compressed quadtree T for $S_1 \cup S_2$ can be constructed in $O(|S_1| + |S_2|)$ time by merging T_1 and T_2 .

To merge T_1 and T_2 , start at their roots and merge the two trees recursively. Suppose that at some stage during the execution of the algorithm, node u in T_1 and node v in T_2 are being considered. An invariant of the merging algorithm is that $L(u)$ and $L(v)$ cannot be disjoint. Furthermore, it can be asserted that $S(u) \cup S(v) \subseteq L(u) \cap L(v)$. In merging two nodes, only the small cell information is relevant because the rest of the large cell ($L(v) - S(v)$) is empty. For convenience, assume that a node may be empty. If a node has less than 2^d children, we may assume empty nodes in place of the absent children. Four distinct cases arise:

- *Case I:* If a node is empty, the result of merging is simply the tree rooted at the other node.
- *Case II:* If $S(u) = S(v)$, the corresponding children of u and v have the same large cells which are the immediate subcells of $S(u)$ (or equivalently, $S(v)$). In this case, merge the corresponding children one by one.
- *Case III:* If $S(v) \subset S(u)$, the points in v are also in the large cell of one of the children of u . Thus, this child of u is merged with v . Similarly, if $S(u) \subset S(v)$, u is merged with the child of v whose large cell contains $S(u)$.
- *Case IV:* If $S(u) \cap S(v) = \emptyset$, then the smallest cell containing both $S(u)$ and $S(v)$ contains $S(u)$ and $S(v)$ in different immediate subcells. In this case, create a new node in the merged tree with its small cell as the smallest cell that contains $S(u)$ and $S(v)$ and make u and v the two children of this node. Subtrees of u and v are disjoint and need not be merged.

Lemma 20.2

Two compressed quadtrees with a common root cell can be merged in time proportional to the sum of their sizes.

Proof. The merging algorithm presented above performs a preorder traversal of each compressed quadtree. The whole tree may not need to be traversed because in merging a node, it may be determined that the whole subtree under the node directly becomes a subtree of the resulting tree. In every step of the merging algorithm, we advance on one of the trees after performing at most $O(d)$ work. Thus, the run time is proportional to the sum of the sizes of the trees to be merged. ■

To construct a compressed quadtree for n points, scan the points and find the smallest and largest coordinate along each dimension. Find a region that contains all the points and use this as the root cell of every compressed quadtree constructed in the process. Recursively construct compressed quadtrees for $\lfloor \frac{n}{2} \rfloor$ points and the remaining $\lceil \frac{n}{2} \rceil$ points and merge them in $O(dn)$ time. The compressed quadtree for a single point is a single node v with the root cell as $L(v)$. The run time satisfies the recurrence

$$T(n) = T\left(\left\lfloor \frac{n}{2} \right\rfloor\right) + T\left(\left\lceil \frac{n}{2} \right\rceil\right) + O(dn)$$

resulting in $O(dn \log n)$ run time.

20.2.5.2 Bottom-up Construction

To perform a bottom-up construction, first compute the order of the points in $O(dn \log n)$ time using any optimal sorting algorithm and the ordering scheme described previously. The compressed quadtree is then incrementally constructed starting from the single node tree for the first point and inserting the remaining points as per the sorted list. During the insertion process, keep track of the most recently inserted leaf. Let p be the next point to be inserted. Starting from the most recently inserted leaf, traverse the path from the leaf to the root until the first node v such that $p \in L(v)$ is encountered. Two possibilities arise:

- *Case I:* If $p \notin S(v)$, then p is in the region $L(v) - S(v)$, which was empty previously. The smallest cell containing p and $S(v)$ is a subcell of $L(v)$ and contains p and $S(v)$ in different immediate subcells. Create a new node u between v and its parent and insert p as a child of u .
- *Case II:* If $p \in S(v)$, v is not a leaf node. The compressed quadtree presently does not contain a node that corresponds to the immediate subcell of $S(v)$ that contains p , that is, this immediate subcell does not contain any of the points previously inserted. Therefore, it is enough to insert p as a child of v corresponding to this subcell.

Once the points are sorted, the rest of the algorithm is identical to a post-order walk on the final compressed quadtree with $O(d)$ work per node. The number of nodes visited per insertion is not bounded by a constant but the number of nodes visited over all insertions is $O(n)$, giving $O(dn)$ run time. Combined with the initial sorting of the points, the tree can be constructed in $O(dn \log n)$ time.

20.2.6 Basic Operations

Fast algorithms for operations on quadtrees can be designed by simultaneously keeping track of spatial ordering and one dimensional ordering of cells in the compressed quadtree. The spatial ordering is given by the compressed quadtree itself. In addition, a balanced binary search tree (BBST) is maintained on the large cells of the nodes to enable fast cell searches. Both the trees consist of the same nodes and this can be achieved by allowing each node to have pointers corresponding to compressed quadtree structure and pointers corresponding to BBST structure.

20.2.6.1 Point and Cell Queries

Point and cell queries are similar since a point can be considered to be a zero length cell. A node v is considered to represent cell C if $S(v) \subseteq C \subseteq L(v)$. The node in the compressed quadtree representing the given cell is located using the BBST. Traverse the path

in the BBST from the root to the node that is being searched in the following manner: To decide which child to visit next on the path, compare the query cell with the large and small cells at the node. If the query cell precedes the small cell in cell ordering, continue the search with the left child. If it succeeds the large cell in cell ordering, continue with the right child. If it lies between the small cell and large cell in cell ordering, the node represents the query cell. As the height of a BBST is $O(\log n)$, the time taken for a point or cell query is $O(d \log n)$.

20.2.6.2 Insertions and Deletions

As points can be treated as cells of zero length, insertion and deletion algorithms will be discussed in the context of cells. These operations are meaningful only if a cell is inserted as a leaf node or deleted if it is a leaf node. Note that a cell cannot be deleted unless all its subcells are previously deleted from the compressed quadtree.

20.2.6.3 Cell Insertion

To insert a given cell C , first check whether it is represented in the compressed quadtree. If not, it should be inserted as a leaf node. Create a node v with $S(v) = C$ and first insert v in the BBST using a standard binary search tree insertion algorithm. To insert v in the compressed quadtree, first find the BBST successor of v , say u . Find the smallest cell D containing C and the $S(u)$. Search for cell D in the BBST and identify the corresponding node w . If w is not a leaf, insert v as a child of w in compressed quadtree. If w is a leaf, create a new node w' such that $S(w') = D$. Nodes w and v become the children of w' in the compressed quadtree. The new node w' should be inserted in the BBST. The overall algorithm requires a constant number of insertions and searches in the BBST, and takes $O(d \log n)$ time.

20.2.6.4 Cell Deletion

As in insertion, the cell should be deleted from the BBST and the compressed quadtree. To delete the cell from BBST, the standard deletion algorithm is used. During the execution of this algorithm, the node representing the cell is found. The node is deleted from the BBST only if it is present as a leaf node in the compressed quadtree. If the removal of this node from the compressed quadtree leaves its parent with only one child, the parent is deleted as well. Since each internal node has at least two children, the delete operation cannot propagate to higher levels in the compressed quadtree.

20.2.7 Practical Considerations

In most practical applications, the height of a region quadtree is rather small because the spatial resolution provided by a quadtree is exponential in its height. This can be used to design schemes that will greatly simplify and speedup quadtree algorithms.

Consider numbering the 2^{2k} cells of a $2^k \times 2^k$ two dimensional cell decomposition in the order specified by the Z-curve using integers $0 \dots 4^k - 1$ (Figure 20.6). Represent each cell in the cell space using a coordinate system with k bits for each coordinate. From the definition of the Z-curve, it follows that the number of a cell can be obtained by interleaving the bits representing the x and y coordinates of the cell, starting from the x coordinate. For example, $(3, 5) = (011, 101)$ translates to $011011 = 27$. The procedure can be extended to higher dimensions. If (x_1, x_2, \dots, x_d) represents the location of a d dimensional cell, the corresponding number can be obtained by taking bit representations of x_1, x_2, \dots, x_d , and interleaving them.

The same procedure can be described using uncompressed region quadtrees. Label the 2^d edges connecting a node to its children with bit strings of length d . This is equivalent to describing the immediate subcells of a cell using one bit for each coordinate followed by bit interleaving. A cell can then be described using concatenation of the bits along the path from the root to the cell. This mechanism can be used to simultaneously describe cells at various length scales. The bit strings are conveniently stored in groups of 32 or 64 bits using integer data types. This creates a problem in distinguishing certain cells. For instance, consider distinguishing cell “000” from cell “000000” in an octree. To ensure each bit string translates to a unique integer when interpreted as a binary number, it is prefixed by a 1. It also helps in easy determination of the length of a bit string by locating the position of the leftmost 1. This leads to a representation that requires $dk + 1$ bits for a d dimensional quadtree with a height of at most k . Such a representation is very beneficial because primitive operations on cells can be implemented using bit operations such as and, or, exclusive-or etc. For example, 128 bits (4 integers on a 32 bit computer and 2 integers on a 64 bit computer) are sufficient to describe an octree of height 42, which allows representation of length scales $2^{42} : 1 > 4 \times 10^{12} : 1$.

The bit string based cell representation greatly simplifies primitive cell operations. In the following, the name of a cell is also used to refer to its bit representation:

- Check if $C_1 \subseteq C_2$. If C_2 is a prefix of C_1 , then C_1 is contained in C_2 , otherwise not.
- Find the smallest cell enclosing C_1 and C_2 . This is obtained by finding the longest common prefix of C_1 and C_2 whose length is $1 \bmod d$.

- Find the immediate subcell of C_1 that contains C_2 . If $dl + 1$ is the number of bits representing C_1 , the required immediate subcell is given by the first $(d + 1)l + 1$ bits of C_2 .

Consider n points in a root cell and let k denote the largest resolution to be used. Cells are not subdivided further even if they contain multiple points. From the coordinates of a point, it is easy to compute the leaf cell containing it. Because of the encoding scheme used, if cell C should precede cell D in the cell ordering, the number corresponding to the binary interpretation of the bit string representation of C is smaller than the corresponding number for D . Thus, cells can be sorted by simply treating them as numbers and ordering them accordingly.

Finally, binary search trees and the attendant operations on them can be completely avoided by using hashing to directly access a cell. An n leaf compressed quadtree has at most $2n - 1$ nodes. Hence, an array of that size can be conveniently used for hashing. If all cells at the highest resolution are contained in the quadtree, that is, $n = d^k$, then an array of size $2n - 1$ can be used to directly index cells. Further details of such representation are left as an exercise to the reader.

20.3 Spatial Queries with Region Quadtrees

In this section, we consider a number of spatial queries involving point data, and algorithms for them using compressed region quadtrees.

20.3.1 Range Query

Range queries are commonly used in database applications. Database records with d keys can be represented as points in d -dimensional space. In a range query, ranges of values are specified for all or a subset of keys with the objective of retrieving all the records that satisfy the range criteria. Under the mapping of records to points in multidimensional space, the ranges define a (possibly open-ended) hyperrectangular region. The objective is to retrieve all the points that lie in this query region.

As region quadtrees organize points using a hierarchy of cells, the range query can be answered by finding a collection \mathcal{C} of cells that are both fully contained in the query region and completely encompass the points in it. This can be achieved by a top-down traversal of the compressed region quadtree starting from the root. To begin with, \mathcal{C} is empty. Consider a node v and its small cell $S(v)$. If $S(v)$ is outside the query region, the subtree underneath it can be safely discarded. If $S(v)$ is completely inside the query region, it is added to \mathcal{C} . All points in the subtree of $S(v)$ are within the query region and reported as part of the output. If $S(v)$ overlaps with the query region but is not contained in it, each child of v is examined in turn.

If the query region is small compared to the size of the root cell, it is likely that a path from the root is traversed where each cell on the path completely contains the query region. To avoid this problem, first compute the smallest cell encompassing the query region. This cell can be searched in $O(d \log n)$ time using the cell search algorithm described before, or perhaps in $O(d)$ time if the hashing/indexing technique is applicable. The top-down traversal can start from the identified cell. When the cell is subdivided, at least two of its children represent cells that overlap with the query region. Consider a child cell and the part of the query region that is contained in it. The same idea can be recursively applied by finding the smallest cell that encloses this part of the query region and directly finding this cell rather than walking down a path in the tree to reach there. This ensures that the number of cells examined during the algorithm is $O(|\mathcal{C}|)$. To see why, consider the cells examined as organized into a tree based on subcell-supercell relationships. The leaves of the tree are the collection of cells \mathcal{C} . Each cell in the tree is the smallest cell that encloses a subregion of the query region. Therefore, each internal node has at least two children. Consequently, the size of the tree, or the number of cells examined in answering the range query is $O(|\mathcal{C}|)$. For further study of range queries and related topics, see [17, 20, 21].

Next, we turn our attention to a number of spatial queries which we categorize as group queries. In group queries, a query to retrieve points that bear a certain relation to a query point is specified. The objective of the group query is to simultaneously answer n queries with each input point treated as a query point. For example, given n points, finding the nearest neighbor of each point is a group query. While the run time of performing the query on an individual point may be large, group queries can be answered more efficiently by intelligently combining the work required in answering queries for the individual points. Instead of presenting a different algorithm for each query, we show that the same generic framework can be used to solve a number of such queries. The central idea behind the group query algorithm is to realize run time savings by processing queries together for nearby points. Consider a cell C in the compressed quadtree and the (as yet uncomputed) set of points that result from answering the query for each point in C . The algorithm keeps track of a collection of cells of size as close to C as possible that is guaranteed to contain these points. The algorithm proceeds in a hierarchical manner by computing this information for cells of decreasing sizes (see [Figure 20.7](#)).

A node u is said to be *resolved* with respect to node v if, either all points in $S(u)$ are in the result of the query for all points in $S(v)$ or none of the points in $S(u)$ is in the result of the query for any point in $S(v)$. Define the *active set* of a node v to be the set of

Algorithm 1
Group-query (v)

```

 $P = \text{active set at } v\text{'s parent}$ 
 $A = \text{active set at } v = \emptyset$ 
 $\text{While } P \neq \emptyset \text{ do}$ 
     $u = \text{Select}(P)$ 
     $P = P - \{u\}$ 
     $\text{decision} = \text{Status}(v, u)$ 
     $\text{If decision} = \text{PROCESS}$ 
         $\text{Process}(v, u)$ 
     $\text{If decision} = \text{UNKNOWN}$ 
         $\text{If } S(u) \subseteq S(v)$ 
             $A = A \cup \{u\}$ 
         $\text{Else } P = P \cup \text{children}(u)$ 
     $\text{For each child } u \text{ of } v$ 
        Group-query ( $u$ )

```

FIGURE 20.7 Unified algorithm for the group queries.

nodes u that cannot be resolved with respect to v such that $S(u) \subseteq S(v) \subseteq L(u)$. The algorithm uses a depth first search traversal of the compressed quadtree. The active set of the root node contains itself. The active set of a node v is calculated by traversing portions of the subtrees rooted at the nodes in the active set of its parent. The functions *Select*, *Status* and *Process* used in the algorithm are designed based on the specific group query. When considering the status of a node u with respect to the node v , the function *Status(v,u)* returns one of the following three values:

- PROCESS – If $S(u)$ is in the result of the query for all points in $S(v)$
- DISCARD – If $S(u)$ is not in the result of the query for all points in $S(v)$
- UNKNOWN – If neither of the above is true

If the result is either PROCESS or DISCARD, the children of u are not explored. Otherwise, the size of $S(u)$ is compared with the size of $S(v)$. If $S(u) \subseteq S(v)$, then u is added to the set of active nodes at v for consideration by v 's children. If $S(u)$ is larger, then u 's children are considered with respect to v . It follows that the active set of a leaf node is empty, as the length of its small cell is zero. Therefore, entire subtrees rooted under the active set of the parent of a leaf node are explored and the operation is completed for the point inhabiting that leaf node. The function *Process(v,u)* reports all points in $S(u)$ as part of the result of query for each point in $S(v)$.

The order in which nodes are considered is important for proving the run time of some operations. The function *Select* is used to accommodate this.

20.3.2 Spherical Region Queries

Given a query point and a distance $r > 0$, the spherical region query is to find all points that lie within a distance of r from the query point. The group version of the spherical region query is to take n points and a distance $r > 0$ as input, and answer spherical region queries with respect to each of the input points.

A cell D may contain points in the spherical region corresponding to some points in cell C only if the smallest distance between D and C is less than r . If the largest distance between D and C is less than r , then all points in D are in the spherical region of every point in C . Thus, the function *Status(v,u)* is defined as follows: If the largest distance between $S(u)$ and $S(v)$ is less than r , return PROCESS. If the smallest distance between $S(u)$ and $S(v)$ is greater than r , return DISCARD. Otherwise, return UNKNOWN.

Processing u means including all the points in u in the query result for each point in v . For this query, no special selection strategy is needed.

20.3.3 k -Nearest Neighbors

For computing the k -nearest neighbors of each point, some modifications to the algorithm presented in Figure 20.7 are necessary. For each node w in P , the algorithm keeps track of the largest distance between $S(v)$ and $S(w)$. Let d_k be the k th smallest of these distances. If the number of nodes in P is less than k , then d_k is set to ∞ . The function $Status(v,u)$ returns DISCARD if the smallest distance between $S(v)$ and $S(u)$ is greater than d_k . The option PROCESS is never used. Instead, for a leaf node, all the points in the nodes in its active set are examined to select the k nearest neighbors. The function Select picks the largest cell in P , breaking ties arbitrarily.

Computing k -nearest neighbors is a well-studied problem [11,22]. The algorithm presented here is equivalent to Vaidya's algorithm [22,23], even though the algorithms appear to be very different on the surface. Though Vaidya does not consider compressed quadtrees, the computations performed by his algorithm can be related to traversal on compressed quadtrees and a proof of the run time of the presented algorithm can be established by a correspondence with Vaidya's algorithm. The algorithm runs in $O(kn)$ time. The proof is quite elaborate, and omitted for lack of space. For details, see [22,23]. The special case of $n = 1$ is called the all nearest neighbor query, which can be computed in $O(n)$ time.

20.4 Image Processing Applications

Quadtrees are ubiquitously used in image processing applications. Consider a two dimensional square array of pixels representing a binary image with black foreground and white background (Figure 20.8). As with region quadtrees used to represent point data, a hierarchical cell decomposition is used to represent the image. The pixels are the smallest cells used in the decomposition and the entire image is the root cell. The root cell is decomposed into its four immediate subcells and represented by the four children of the root node. If a subcell is completely composed of black pixels or white pixels, it becomes a leaf in the quadtree. Otherwise, it is recursively decomposed. If the resolution of the image is $2^k \times 2^k$, the height of the resulting region quadtree is at most k . A two dimensional image and its corresponding region quadtree are shown in Figure 20.8. In drawing the quadtree, the same ordering of the immediate subcells of a cell into SW, NW, SE and NE quadrants is followed. Each node in the tree is colored black, white, or gray, depending on if the cell consists of all black pixels, all white pixels, or a mixture of both black and white pixels, respectively. Thus, internal nodes are colored gray and leaf nodes are colored either black or white.

Each internal node in the image quadtree has four children. For an image with n leaf nodes, the number of internal nodes is $\frac{(n-1)}{3}$. For large images, the space required for storing the internal nodes and the associated pointers may be expensive and several space-efficient storage schemes have been investigated. These include storing the quadtree as a collection of leaf cells using the Morton numbering of cells [24], or as a collection of black leaf cells only [25,26], and storing the quadtree as its preorder traversal [27]. Iyengar *et al.* introduced a number of space-efficient representations of image quadtrees including forests of quadtrees [28,29], translation invariant data structures [30–32] and virtual quadtrees [33].

The use of quadtrees can be easily extended to grayscale images and color images. Significant space savings can be realized by choosing an appropriate scheme. For example, 2^r gray levels can be encoded using r bits. The image can be represented using r binary valued quadtrees. Because adjacent pixels are likely to have gray levels that are closer, a gray encoding of the 2^r levels is

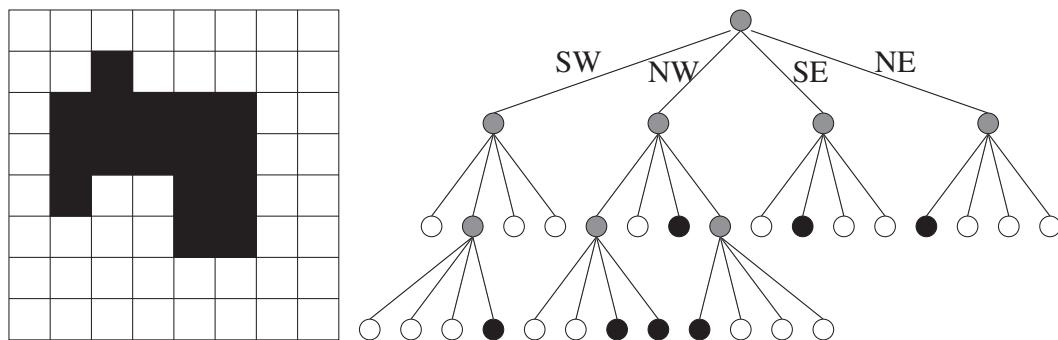

FIGURE 20.8 A two dimensional array of pixels, and the corresponding region quadtree.

advantageous over a binary encoding [27]. The gray encoding has the property that adjacent levels differ by one bit in the gray code representation. This should lead to larger blocks having the same value for a given bit position, leading to shallow trees.

20.4.1 Construction of Image Quadtrees

Region quadtrees for image data can be constructed using an algorithm similar to the bottom-up construction algorithm for point region quadtrees described in Section 20.2.5. In fact, constructing quadtrees for image data is easier because the smallest cells in the hierarchical decomposition are given by the pixels and all the pixels can be read by the algorithm as the image size is proportional to the number of pixels. Thus, quadtree for region data can be built in time linear in the size of the image, which is optimal. The pixels of the image are scanned in Morton order which eliminates the need for the sorting step in the bottom-up construction algorithm. It is wasteful to build the complete quadtree with all pixels as leaf nodes and then compact the tree by replacing maximal subtrees having all black or all white pixels with single leaf nodes, though such a method would still run in linear time and space. By reading the pixels in Morton order, a maximal black or white cell can be readily identified and the tree can be constructed using only such maximal cells as leaf nodes [8]. This will limit the space used by the algorithm to the final size of the quadtree.

20.4.2 Union and Intersection of Images

The union of two images is the overlay of one image over another. In terms of the array of pixels, a pixel in the union is black if the pixel is black in at least one of the images. In the region quadtree representation of images, the quadtree corresponding to the union of two images should be computed from the quadtrees of the constituent images. Let I_1 and I_2 denote the two images and T_1 and T_2 denote the corresponding region quadtrees. Let T denote the region quadtree of the union of I_1 and I_2 . It is computed by a preorder traversal of T_1 and T_2 and examining the corresponding nodes/cells. Let v_1 in T_1 and v_2 in T_2 be nodes corresponding to the same region. There are three possible cases:

- Case I: If v_1 or v_2 is black, the corresponding node is created in T and is colored black. If only one of them is black and the other is gray, the gray node will contain a subtree underneath. This subtree need not be traversed.
- Case II: If v_1 (respectively, v_2) is white, v_2 (respectively, v_1) and the subtree underneath it (if any) is copied to T .
- Case III: If both v_1 and v_2 are gray, then the corresponding children of v_1 and v_2 are considered.

The tree resulting from the above merging algorithm may consist of unnecessary subdivisions of a cell consisting of completely black pixels. For example, if a region is marked gray in both T_1 and T_2 but each of the four quadrants of the region is black in at least one of T_1 and T_2 , then the node corresponding to the region in T will have four children colored black. This is unnecessary as the node itself can be colored black and should be considered a leaf node. Such adjustments need not be local and may percolate up the tree. For instance, consider a checker board image of $2^k \times 2^k$ pixels with half black and half white pixels such that the north, south, east and west neighbors of a black pixel are white pixels and vice versa. Consider another checker board image with black and white interchanged. The quadtree for each of these images is a full 4-ary tree of level k . But overlaying one image over another produces one black square of size $2^k \times 2^k$. The corresponding quadtree should be a single black node. However, merging initially creates a full 4-ary tree of depth k . To compact the tree resulting from merging to create the correct region quadtree, a bottom-up traversal is performed. If all children of a node are black, then the children are removed and the node is colored black.

The intersection of two images can be computed similarly. A pixel in the intersection of two images is black only if the corresponding pixels in both the images are black. For instance, the intersection of the two complementary checkerboard images described above is a single white cell of size $2^k \times 2^k$. The algorithm for intersection can be obtained by interchanging the roles of black and white in the union algorithm. Similarly, a bottom-up traversal is used to detect nodes all of whose children are white, remove the children, and color the node white. Union and intersection algorithms can be easily generalized to multiple images.

20.4.3 Rotation and Scaling

Quadtree representation of images facilitates certain types of rotation and scaling operations. Rotations on images are often performed in multiples of 90 degrees. Such a rotation has the effect of changing the quadrants of a region. For example, a 90 degree clockwise rotation changes the SW, NW, SE, NE quadrants to NW, NE, SW, SE quadrants, respectively. This change should be recursively carried out for each region. Hence, a rotation that is a multiple of 90 degrees can be effected by simply reordering the child pointers of each node. Similarly, scaling by a power of two is trivial using quadtrees since it is simply a loss of resolution. For other linear transformations, see the work of Hunter [34,35].

20.4.4 Connected Component Labeling

Two black pixels of a binary image are considered adjacent if they share a horizontal or vertical boundary. A pair of black pixels is said to be connected if there is a sequence of adjacent pixels leading from one to the other. A connected component is a maximal set of black pixels where every pair of pixels is connected. The connected component labeling problem is to find the connected components of a given image and give each connected component a unique label. Identifying the connected components of an image is useful in object counting and image understanding. Samet developed algorithms for connected component labeling using quadtrees [36].

Let B and W denote the number of black nodes and white nodes, respectively, in the quadtree. Samet's connected component labeling algorithm works in three stages:

1. Establish the adjacency relationships between pairs of black pixels.
2. Identify a unique label for each connected component. This can be thought of as computing the transitive closure of the adjacency relationships.
3. Label each black cell with the corresponding connected component.

The first stage is carried out using a postorder traversal of the quadtree during which adjacent black pixels are discovered and identified by giving them the same label. To begin with, all the black nodes are unlabeled. When a black region is considered, black pixels adjacent to it in two of the four directions, say north and east, are searched. The post order traversal of the tree traverses the regions in Morton order. Thus when a region is encountered, its south and west adjacent black regions (if any) would have already been processed. At that time, the region would have been identified as a neighbor. Thus, it is not necessary to detect adjacency relationships between a region and its south or west adjacent neighbors.

Suppose the postorder traversal is currently at a black node or black region R . Adjacent black regions in a particular direction, say north, are identified as follows. First, identify the adjacent region of the same size as R that lies to the north of R . Traverse the quadtree upwards to the root to identify the first node on the path that contains both the regions, or equivalently, find the lowest common ancestor of both the regions in the quadtree. If such a node does not exist, R has no north neighbor and it is at the boundary of the image. Otherwise, a child of this lowest common ancestor will be a region adjacent to the north boundary of R and of the same size as or larger than R . If this region is black, it is part of the same connected component as R . If neither the region nor R is currently labeled, create a new label and use it for both. If only one of them is labeled, use the same label for the other. If they are both already labeled with the same label, do nothing. If they are both already labeled with different labels, the label pair is recorded as corresponding to an adjacency relationship. If the region is gray, it is recursively subdivided and adjacent neighbors examined to find all black regions that are adjacent to R . For each black neighbor, the labeling procedure described above is carried out.

The run time of this stage of the algorithm depends on the time required to find the north and east neighbors. This process can be improved using the smallest-cell primitive described earlier. However, Samet proved that the average of the maximum number of nodes visited by the above algorithm for a given black region and a given direction is smaller than or equal to 5, under the assumption that a black region is equally likely to occur at any position and level in the quadtree [36]. Thus, the algorithm should take time proportional to the size of the quadtree, that is, $O(W + B)$ time.

Stage two of the algorithm is best performed using the union-find data structure [37]. Consider all the labels that are used in stage one and treat them as singleton sets. For every pair of labels recorded in stage one, perform a find operation to find the two sets that contain the labels currently, and do a union operation on the sets. At the end of stage two, all labels used for the same connected component will be grouped together in one set. This can be used to provide a unique label for each set (called the set label), and subsequently identify the set label for each label. The number of labels used is bounded by B . The amortized run time per operation using the union-find data structure is given by the inverse Ackermann's function [37], a constant (≤ 4) for all practical purposes. Therefore, the run time of stage two can be considered to be $O(B)$. Stage three of the algorithm can be carried out by another postorder traversal of the quadtree to replace the label of each black node with the corresponding set label in $O(B + W)$ time. Thus, the entire algorithm runs in $O(B + W)$ time.

20.5 Scientific Computing Applications

Region quadtrees are widely used in scientific computing applications. Most of the problems are three dimensional, prompting the development of octree based methods. In fact, some of the practical techniques and shortcuts presented earlier for storing region quadtrees and bit string representation of cells owe their origin to applications in scientific computing.

Octree are used in many ways in scientific computing applications. In many scientific computing applications, the behavior of a physical system is captured through either (1) a discretization of the space using a finite grid, followed by determining the quantities of interest at each of the grid cells, or (2) computing the interactions between a system of (real or virtual) particles

which can be related to the behavior of the system. The former are known as grid-based methods and typically correspond to the solution of differential equations. The latter are known as particle-based methods and often correspond to the solution of integral equations. Both methods are typically iterative and the spatial information, such as the hierarchy of grid cells or the spatial distribution of the particles, often changes from iteration to iteration.

Examples of grid-based methods include finite element methods, finite difference methods, multigrid methods and adaptive mesh refinement methods. Many applications use a cell decomposition of space as the grid or grid hierarchy and the relevance of octrees for such applications is immediate. Algorithms for construction of octrees and methods for cell insertions and deletions are all directly applicable to such problems. It is also quite common to use other decompositions, especially for the finite-element method. For example, a decomposition of a surface into triangular elements is often used. In such cases, each basic element can be associated with a point (for example, the centroid of a triangle), and an octree can be built using the set of points. Information on the neighboring elements required by the application is then related to neighborhood information on the set of points.

Particle based methods include such simulation techniques as molecular dynamics, smoothed particle hydrodynamics, and N-body simulations. These methods require many of the spatial queries discussed in this chapter. For example, van der Waal forces between atoms in molecular dynamics fall off so rapidly with increasing distance (inversely proportional to the sixth power of the distance between atoms) that a cutoff radius is employed. In computing the forces acting on an individual atom, van der Waal forces are taken into account only for atoms that lie within the cutoff radius. The list of such atoms is typically referred to as the neighbor list. Computing neighbor lists for all atoms is just a group spherical region query, already discussed before. Similarly, k -nearest neighbors are useful in applications such as smoothed particle hydrodynamics. In this section, we further explore the use of octrees in scientific computing by presenting an optimal algorithm for the N-body problem.

20.5.1 The N-Body Problem

The N-body problem is defined as follows: Given n bodies and their positions, where each pair of bodies interact with a force inversely proportional to the square of the distance between them, compute the force on each body due to all other bodies. A direct algorithm for computing all pairwise interactions requires $O(n^2)$ time. Greengard's fast multipole method [15], which uses an octree data structure, reduces this complexity by approximating the interaction between clusters of bodies instead of computing individual interactions. For each cell in the octree, the algorithm computes a multipole expansion and a local expansion. The multipole expansion at a cell C , denoted $\phi(C)$, is the effect of the bodies within C on distant bodies. The local expansion at C , denoted $\psi(C)$, is the effect of all distant bodies on bodies within C .

The N-body problem can be solved in $O(n)$ time using a compressed octree [12]. For two cells C and D which are not necessarily of the same size, define a predicate *well-separated*(C, D) to be true if D 's multipole expansion converges at any point in C , and false otherwise. If two cells are not well-separated, they are *proximate*. Similarly, two nodes v_1 and v_2 in the compressed octree are said to be *well-separated* if and only if $S(v_1)$ and $S(v_2)$ are well-separated. Otherwise, we say that v_1 and v_2 are proximate.

For each node v in the compressed octree, the multipole expansion $\phi(v)$ and the local expansion $\psi(v)$ need to be computed. Both $\phi(v)$ and $\psi(v)$ are with respect to the cell $S(v)$. The multipole expansions can be computed by a simple bottom-up traversal in $O(n)$ time. For a leaf node, its multipole expansion is computed directly. At an internal node v , $\phi(v)$ is computed by aggregating the multipole expansions of the children of v .

The algorithm to compute the local expansions is given in Figure 20.9. The astute reader will notice that this is the same group query algorithm described in Section 20.3, reproduced here again with slightly different notation for convenience. The computations are done using a top-down traversal of the tree. To compute local expansion at node v , consider the set of nodes that are proximate to its parent, which is the *proximity set*, $P(\text{parent}(v))$. The proximity set of the root node contains only itself. Recursively decompose these nodes until each node is either (1) well-separated from v or (2) proximate to v and the length of the small cell of the node is no greater than the length of $S(v)$. The nodes satisfying the first condition form the *interaction set* of v , $I(v)$ and the nodes satisfying the second condition are in the proximity set of v , $P(v)$. In the algorithm, the set $E(v)$ contains the nodes that are yet to be processed. Local expansions are computed by combining parent's local expansion and the multipole expansions of the nodes in $I(v)$. For the leaf nodes, potential calculation is completed by using the direct method.

The following terminology is used in analyzing the run time of the algorithm. The set of cells that are proximate to C and having same length as C is called the *proximity set of C* and is defined by $P^=(C) = \{D \mid \text{length}(C) = \text{length}(D), \neg\text{well-separated}(C, D)\}$. The superscript “=” is used to indicate that cells of the same length are being considered. For node v , define the *proximity set* $P(v)$ as the set of all nodes proximate to v and having the small cell no greater than and large cell no smaller than $S(v)$. More precisely, $P(v) = \{w \mid \neg\text{well-separated}(S(v), S(w)), \text{length}(S(w)) \leq \text{length}(S(v)) \leq \text{length}(L(w))\}$. The *interaction set* $I(v)$ of v is defined as $I(v) = \{w \mid \text{well-separated}(S(v), S(w)), [w \in P(\text{parent}(v)) \vee \{\exists u \in P(\text{parent}(v)), w \text{ is a descendant of } u, \neg\text{sep}(v, \text{parent}(w)), \text{length}(S(v)) < \text{length}(S(\text{parent}(w)))\}]\}$. We use $\text{parent}(w)$ to denote the parent of the node w .

The algorithm achieves $O(n)$ run time for any predicate *well-separated* that satisfies the following three conditions:

Algorithm 2**Compute-Local-Exp (v)**

I. Find the proximity set $P(v)$ and interaction set $I(v)$ for v

```

 $E(v) = P(\text{parent}(v))$ 
 $I(v) = \emptyset; P(v) = \emptyset$ 
While  $E(v) \neq \emptyset$  do
    Pick some  $u \in E(v)$ 
     $E(v) = E(v) - \{u\}$ 
    If well-separated( $S(v), S(u)$ )
         $I(v) = I(v) \cup \{u\}$ 
    Else if  $S(u) \subseteq S(v)$ 
         $P(v) = P(v) \cup \{u\}$ 
    Else  $E(v) = E(v) \cup \text{children}(u)$ 

```

II. Calculate the local expansion at v

```

Assign shifted  $\psi(\text{parent}(v))$  to  $\psi(v)$ 
For each node  $u \in I(v)$ 
    Add shifted  $\phi(u)$  to  $\psi(v)$ 

```

III. Calculate the local expansions at the children of v with recursive calls

For each child u of v

Compute-Local-Exp (u)

FIGURE 20.9 Algorithm for calculating local expansions of all nodes in the tree rooted at v .

1. The relation *well-separated* is symmetric for equal length cells, that is, $\text{length}(C) = \text{length}(D) \Rightarrow \text{well-separated}(C, D) = \text{well-separated}(D, C)$.
2. For any cell C , $|P^=(C)|$ is bounded by a constant.
3. If two cells C and D are not well-separated, any two cells C' and D' such that $C \subseteq C'$ and $D \subseteq D'$ are not well-separated as well.

These three conditions are respected by the various well-separatedness criteria used in N-body algorithms and in particular, Greengard's algorithm. In N-body methods, the well-separatedness decision is solely based on the geometry of the cells and their relative distance and is oblivious to the number of bodies or their distribution within the cells. Given two cells C and D of the same length, if D can be approximated with respect to C , then C can be approximated with respect to D as well, as stipulated by Condition C1. The size of the proximity sets of cells of the same length should be $O(1)$ as prescribed by Condition C2 in order that an $O(n)$ algorithm is possible. Otherwise, an input that requires processing the proximity sets of $\Omega(n)$ such cells can be constructed, making an $O(n)$ algorithm impossible. Condition C3 merely states that two cells C' and D' are not well-separated unless every subcell of C' is well-separated from every subcell of D' .

Lemma 20.3

For any node v in the compressed octree, $|P(v)| = O(1)$.

Proof. Consider any node v . Each $u \in P(v)$ can be associated with a unique cell $C \in P^=(S(v))$ such that $S(u) \subseteq C$. This is because any subcell of C which is not a subcell of $S(u)$ is not represented in the compressed octree. It follows that $|P(v)| \leq |P^=(S(v))| = O(1)$ (by Condition C2). ■

Lemma 20.4

The sum of interaction set sizes over all nodes in the compressed octree is linear in the number of nodes in the compressed octree, that is, $\sum_v |I(v)| = O(n)$.

Proof. Let v be a node in the compressed octree. Consider any $w \in I(v)$, either $w \in P(\text{parent}(v))$ or w is in the subtree rooted by a node $u \in P(\text{parent}(v))$. Thus,

$$\begin{aligned} \sum_v |I(v)| &= \sum_v |\{w \mid w \in I(v), w \in P(\text{parent}(v))\}| \\ &\quad + \sum_v |\{w \mid w \in I(v), w \notin P(\text{parent}(v))\}|. \end{aligned}$$

Consider these two summations separately. The bound for the first summation is easy; From Lemma 20.3, $|P(\text{parent}(v))| = O(1)$. So,

$$\sum_v |\{w \mid w \in I(v), w \in P(\text{parent}(v))\}| = \sum_v O(1) = O(n).$$

The second summation should be explored more carefully.

$$\sum_v |\{w \mid w \in I(v), w \notin P(\text{parent}(v))\}| = \sum_w |\{v \mid w \in I(v), w \notin P(\text{parent}(v))\}|$$

In what follows, we bound the size of the set $M(w) = \{v \mid w \in I(v), w \notin P(\text{parent}(v))\}$ for any node.

Since $w \notin P(\text{parent}(v))$, there exists a node $u \in P(\text{parent}(v))$ such that w is in the subtree rooted by u . Consider $\text{parent}(w)$: The node $\text{parent}(w)$ is either u or a node in the subtree rooted at u . In either case, $\text{length}(S(\text{parent}(w))) \leq \text{length}(S(\text{parent}(v)))$. Thus, for each $v \in M(w)$, there exists a cell C such that $S(v) \subseteq C \subseteq S(\text{parent}(v))$ and $\text{length}(S(\text{parent}(w))) = \text{length}(C)$. Further, since v and $\text{parent}(w)$ are not well-separated, C and $S(\text{parent}(w))$ are not well-separated as well by Condition C3. That is to say $S(\text{parent}(w)) \in P^=(C)$ and $C \in P^=(S(\text{parent}(w)))$ by Condition C1. By Condition C2, we know that $|P^=(S(\text{parent}(w)))| = O(1)$. Moreover, for each cell $C \in P^=(S(\text{parent}(w)))$, there are at most 2^d choices of v because $\text{length}(C) \leq \text{length}(S(\text{parent}(v)))$. As a result, $|M(w)| \leq 2^d \times O(1) = O(1)$ for any node w . Thus, $\sum_v |I(v)| = \sum_w |\{v \mid w \in I(v), w \notin P(\text{parent}(v))\}| = \sum_w O(1) = O(n)$. ■

Theorem 20.1

Given a compressed octree for n bodies, the N-body problem can be solved in $O(n)$ time.

Proof. Computing the multipole expansion at a node takes constant time and the number of nodes in the compressed octree is $O(n)$. Thus, total time required for the multipole expansion calculation is $O(n)$. The nodes explored during the local expansion calculation at a node v are either in $P(v)$ or $I(v)$. In both cases, it takes constant time to process a node. By Lemmas 20.3 and 20.4, the total size of both sets for all nodes in the compressed octree is bounded by $O(n)$. Thus, local expansion calculation takes $O(n)$ time. As a conclusion, the running time of the fast multipole algorithm on the compressed octree takes $O(n)$ time irrespective of the distribution of the bodies. ■

It is interesting to note that the same generic algorithmic framework is used for spherical region queries, all nearest neighbors, k -nearest neighbors and solving the N-body problem. While the proofs are different, the algorithm also provides optimal solution for k -nearest neighbors and the N-body problem.

While this chapter is focused on applications of quadtrees and octrees in image processing and scientific computing applications, they are used for many other types of spatial data and in the context of numerous other application domains. A detailed study of the design and analysis of quadtree based data structures and their applications can be found in [4,5].

21.1 Introduction

In most applications involving computation with 3D geometric models, manipulating objects and generating images of objects are crucial operations. Performing these operations requires determining for every frame of an animation the spatial relations between objects: how they might intersect each other, and how they may occlude each other. However, the objects, rather than being monolithic, are most often comprised of many pieces, such as by many polygons forming the faces of polyhedra. The number of pieces may be anywhere from the 100's to the 1,000,000's. To compute spatial relations between n polygons by brute force entails comparing every pair of polygons, and so would require $O(n^2)$. For large scenes comprised of 10^5 polygons, this would mean 10^{10} operations, which is much more than necessary.

The number of operations can be substantially reduced to anywhere from $O(n \log_2 n)$ when the objects interpenetrate (and so in our example reduced to 10^6), to as little as constant time, $O(1)$, when they are somewhat separated from each other. This can be accomplished by using Binary Space Partitioning Trees, also called BSP Trees. They provide a computational representation of space that simultaneously provides a search structure and a representation of geometry. The reduction in number of operations occurs because BSP Trees provide a kind of “spatial sorting.” In fact, they are a generalization to dimensions > 1 of binary search trees, which have been widely used for representing sorted lists. [Figure 21.1](#) below gives an introductory example showing how a binary tree of lines, instead of points, can be used to “sort” four geometric objects, as opposed to sorting symbolic objects such as names.

Constructing a BSP Tree representation of one or more polyhedral objects involves computing the spatial relations between polygonal faces once and encoding these relations in a binary tree ([Figure 21.2](#)). This tree can then be transformed and merged with other trees to very quickly compute the spatial relations (for visibility and intersections) between the polygons of two moving objects.

As long as the relations encoded by a tree remain valid, which for a rigid body is forever, one can reap the benefits of having generated this tree structure every time the tree is used in subsequent operations. The return on investment manifests itself as substantially faster algorithms for computing intersections and visibility orderings. And for animation and interactive applications, these savings can accrue over hundreds of thousands of frames. BSP Trees achieve an elegant solution to a number of important problems in geometric computation by exploiting two very simple properties occurring whenever a single plane separates (lies between) two or more objects: (1) any object on one side of the plane cannot intersect any object on the other side, (2) given a viewing position, objects on the same side as the viewer can have their images drawn on top of the images of objects on the opposite side (Painter’s Algorithm). See [Figure 21.3](#).

These properties can be made dimension independent if we use the term “hyperplane” to refer to planes in 3D, lines in 2D, and in general for d -space, to a $(d - 1)$ -dimensional subspace defined by a single linear equation. The only operation we will need for

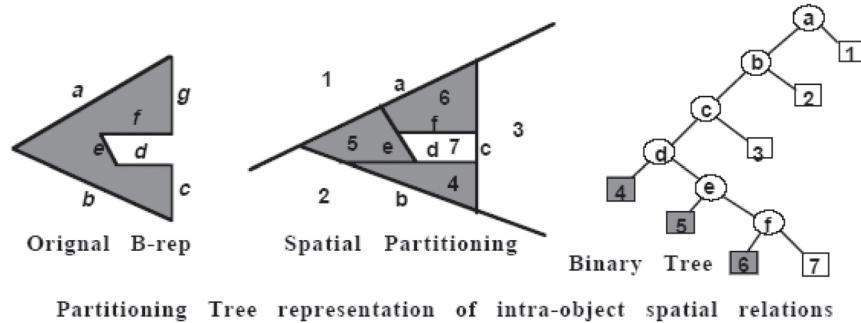

FIGURE 21.2 Partitioning Tree representation of intra-object spatial relations.

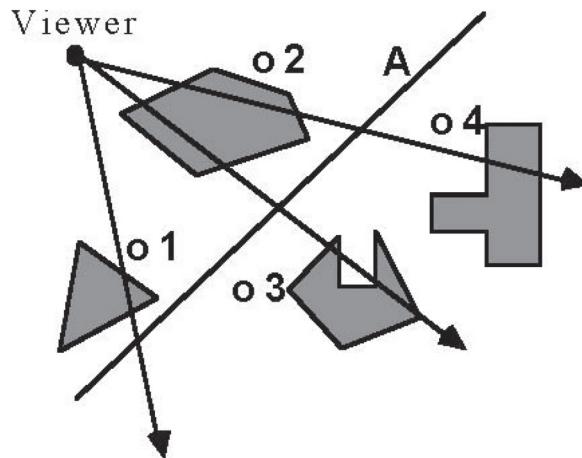

FIGURE 21.3 Plane power: sorting objects w.r.t a hyperplane.

constructing BSP Trees is the partitioning of a convex region by a single hyperplane into two child regions, both of which are also convex as a result ([Figure 21.4](#)).

BSP Trees exploit the properties of separating planes by using one very simple but powerful technique to represent any object or collection of objects: recursive subdivision by hyperplanes. A BSP Tree is the recording of this process of recursive subdivision in the form of a binary tree of hyperplanes. Since there is no restriction on what hyperplanes are used, polytopes (polyhedra, polygons, etc.) can be represented exactly. A BSP Tree is a program for performing intersections between the hyperplane's halfspaces and any other geometric entity. Since subdivision generates increasingly smaller regions of space, the order of the hyperplanes is chosen so that following a path deeper into the tree corresponds to adding more detail, yielding a multi-resolution representation. This leads to efficient intersection computations. To determine visibility, all that is required is choosing at each tree node which of the two branches to draw first based solely on which branch contains the viewer. No other single representation of geometry inherently answers questions of intersection and visibility for a scene of 3D moving objects. And this is accomplished in a computationally efficient and parallelizable manner.

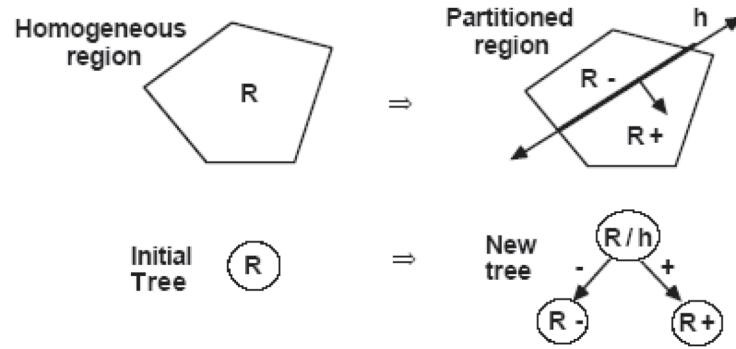

FIGURE 21.4 Elementary operation used to construct BSP Trees.

21.2 BSP Trees as a Multi-Dimensional Search Structure

Spatial search structures are based on the same ideas that were developed in Computer Science during the 60's and 70's to solve the problem of quickly processing large sets of symbolic data, as opposed to geometric data, such as lists of people's names. It was discovered that by first sorting a list of names alphabetically, and storing the sorted list in an array, one can find out whether some new name is already in the list in $\log_2 n$ operations using a binary search algorithm, instead of $n/2$ expected operations required by a sequential search. This is a good example of extracting structure (alphabetical order) existing in the list of names and exploiting that structure in subsequent operations (looking up a name) to reduce computation. However, if one wishes to permit additions and deletions of names while maintaining a sorted list, then a dynamic data structure is needed, that is, one using pointers. One of the most common examples of such a data structure is the binary search tree.

A binary search tree (See also [Chapter 3](#)) is illustrated in [Figure 21.5](#), where it is being used to represent a set of integers $S = \{0, 1, 4, 5, 6, 8\}$ lying on the real line. We have included both the binary tree and the hierarchy of intervals represented by this tree. To find out whether a number/point is already in the tree, one inserts the point into the tree and follows the path corresponding to the sequence of nested intervals that contain the point. For a balanced tree, this process will take no more than $O(\log n)$ steps; for in fact, we have performed a binary search, but one using a tree instead of an array. Indeed, the tree itself encodes a portion of the search algorithm since it prescribes the order in which the search proceeds.

This now brings us back to BSP Trees, for as we said earlier, they are a generalization of binary search trees to dimensions > 1 (in 1D, they are essentially identical). In fact, constructing a BSP Tree can be thought of as a geometric version of Quick Sort. Modifications (insertions and deletions) are achieved by merging trees, analogous to merging sorted lists in Merge Sort. However, since points do not divide space for any dimension > 1 , we must use hyperplanes instead of points by which to subdivide. Hyperplanes always partition a region into two halfspaces regardless of the dimension. In 1D, they look like points since they are also 0D sets; the one difference being the addition of a normal denoting the "greater than" side. In [Figure 21.6](#), we show a restricted variety of BSP Trees that most clearly illustrates the generalization of binary search trees to higher dimensions. (You may want to call this a k-d tree, but the standard semantics of k-d trees does not include representing continuous sets of points, but rather

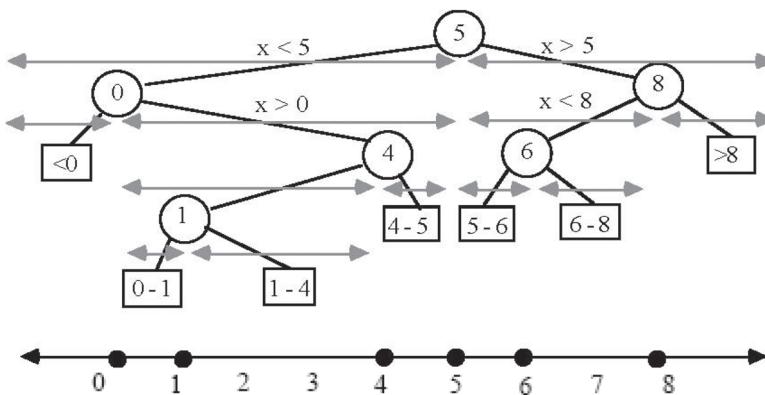

FIGURE 21.5 A binary search tree.

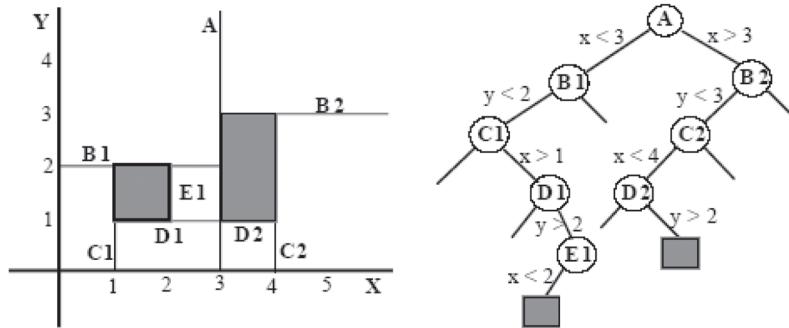

FIGURE 21.6 Extension of binary search trees to 2D as a BSP Tree.

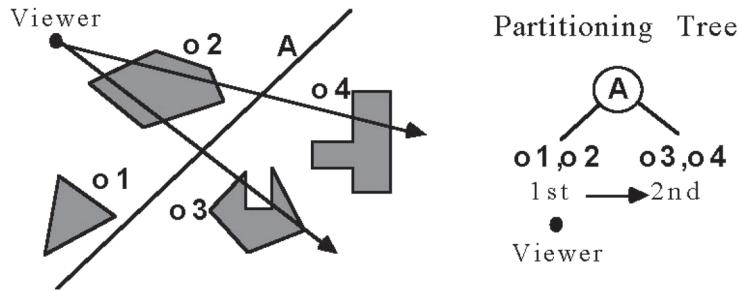

FIGURE 21.7 Left side has priority over right side.

finite sets of points.) BSP Trees are also a geometric variety of Decision Trees, which are commonly used for classification (e.g., biological taxonomies), and are widely used in machine learning. Decision trees have also been used for proving lower bounds, the most famous showing that sorting is $\Omega(n \log n)$. They are also the model of the popular “20 questions” game (I’m thinking of something and you have 20 yes/no question to guess what it is). For BSP Trees, the questions become “what side of a particular hyperplane does some piece of geometry lie.”

21.3 Visibility Orderings

Visibility orderings are used in image synthesis for visible surface determination (hidden surface removal), shadow computations, ray tracing, beam tracing, and radiosity. For a given center of projection, such as the position of a viewer or of a light source, they provide an ordering of geometric entities, such as objects or faces of objects, consistent with the order in which any ray originating at the center might intersect the entities. Loosely speaking, a visibility ordering assigns a priority to each object or face so that closer objects have priority over objects further away. Any ray emanating from the center or projection that intersects two objects or faces, will always intersect the surface with higher priority first. The simplest use of visibility orderings is with the “Painter’s Algorithm” for solving the hidden surface problem. Faces are drawn into a frame-buffer in far-to-near order (low-to-high priority), so that the image of nearer objects/polygons over-writes those of more distant ones.

A visibility ordering can be generated using a single hyperplane; however, each geometric entity or “object” (polyhedron, polygon, line, point) must lie completely on one side of the hyperplane, that is, no objects are allowed to cross the hyperplane. This requirement can always be induced by partitioning objects by the desired hyperplane into two “halves”. The objects on the side containing the viewer are said to have visibility priority over objects on the opposite side; that is, any ray emanating from the viewer that intersects two objects on opposite sides of the hyperplane will always intersect the near side object before it intersects the far side object. See Figures 21.7 and 21.8.

21.3.1 Total Ordering of a Collection of Objects

A single hyperplane cannot order objects lying on the same side, and so cannot provide a total visibility ordering. Consequently, in order to exploit this idea, we must extend it somehow so that a visibility ordering for the entire set of objects can be generated. One way to do this would be to create a unique separating hyperplane for every pair of objects. However, for n objects this would require n^2 hyperplanes, which is too many.

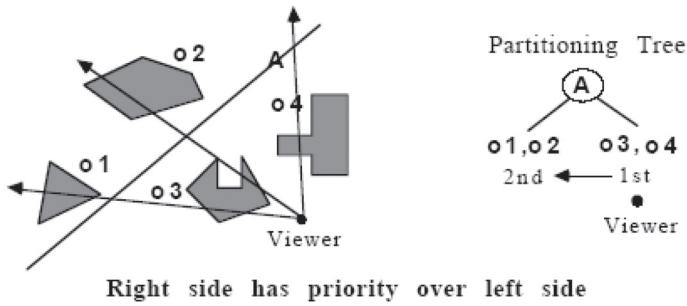

FIGURE 21.8 Right side has priority over left side.

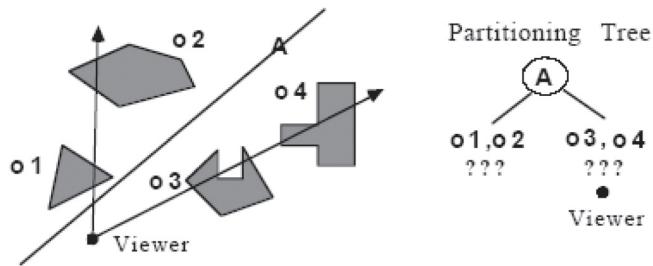

FIGURE 21.9 Separating objects with a hyperplane.

The required number of separating hyperplanes can be reduced to as little as n by using the geometric version of recursive subdivision (divide and conquer). If the subdivision is performed using hyperplanes whose position and orientation is unrestricted, then the result is a BSP Tree. The objects are first separated into two groups by some appropriately chosen hyperplane (Figure 21.9). Then each of the two groups is independently partitioned into two sub-groups (for a total now of 4 sub-groups). The recursive subdivision continues in a similar fashion until each object, or piece of an object, is in a separate cell of the partitioning. This process of partitioning space by hyperplanes is naturally represented as a binary tree (Figure 21.10).

21.3.2 Visibility Ordering as Tree Traversal

How can this tree be used to generate a visibility ordering on the collection of objects? For any given viewing position, we first determine on which side of the root hyperplane the viewer lies. From this we know that all objects in the near-side subtree have higher priority than all objects in the far-side subtree; and we have made this determination with only a constant amount of computation (in fact, only a dot product). We now need to order the near-side objects, followed by an ordering of the far-side objects. Since we have a recursively defined structure, any subtree has the same form computationally as the whole tree. Therefore, we simply apply this technique for ordering subtrees recursively, going left or right first at each node, depending upon which side of the node's hyperplane the viewer lies. This results in a traversal of the entire tree, in near-to-far order, using only $O(n)$ operations, which is optimal (this analysis is correct only if no objects have been split; otherwise it is $> n$).

21.3.3 Intra-Object Visibility

The schema we have just described is only for inter-object visibility, that is, between individual objects. And only when the objects are both convex and separable by a hyperplane is the schema a complete method for determining visibility. To address the general unrestricted case, we need to solve intra-object visibility, that is, correctly ordering the faces of a single object. BSP Trees can solve this problem as well. To accomplish this, we need to change our focus from convex cells containing objects to the idea of hyperplanes containing faces. Let us return to the analysis of visibility with respect to a hyperplane. If instead of ordering objects, we wish to order faces, we can exploit the fact that not only can faces lie on each side of a hyperplane as objects do, but they can also lie on the hyperplane itself. This gives us a 3-way ordering of: near → on → far (Figure 21.11).

If we choose hyperplanes by which to partition space that always contain a face of an object, then we can build a BSP Tree by applying this schema recursively as before, until every face lies in some partitioning hyperplane contained in the tree. To generate a visibility ordering of the faces in this intra-object tree, we use the method above with one extension: faces lying on hyperplanes are included in the ordering, that is, at each node, we generate the visibility ordering of near-subtree → on-faces →

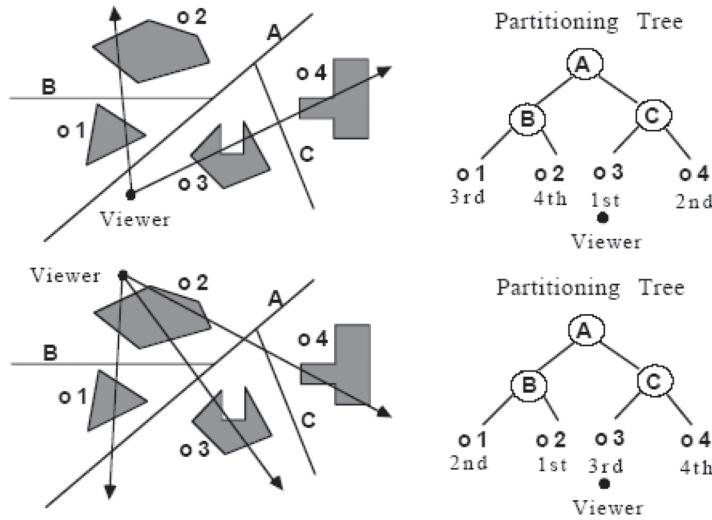

FIGURE 21.10 Binary tree representation of space partitioning.

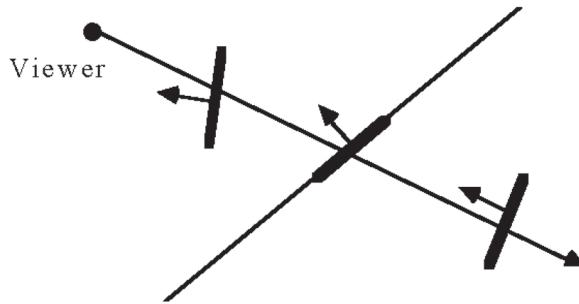

FIGURE 21.11 Ordering of polygons: near → on → far.

far-subtree. Using visibility orderings provides an alternative to z-buffer based algorithms. They obviate the need for computing and comparing z-values, which is very susceptible to numerical error because of the perspective projection. In addition, they eliminate the need for z-buffer memory itself, which can be substantial (80 Mbytes) if used at a sub-pixel resolution of 4×4 to provide anti-aliasing. More importantly, visibility orderings permit unlimited use of transparency (non-refractive) with no additional computational effort, since the visibility ordering gives the correct order for compositing faces using alpha blending. And in addition, if a near-to-far ordering is used, then rendering completely occluded objects/faces can be eliminated, such as when a wall occludes the rest of a building, using a beam-tracing based algorithm.

21.4 BSP Tree as a Hierarchy of Regions

Another way to look at BSP Trees is to focus on the hierarchy of regions created by the recursive partitioning, instead of focusing on the hyperplanes themselves. This view helps us to see more easily how intersections are efficiently computed. The key idea is to think of a BSP Tree region as serving as a bounding volume: each node v corresponds to a convex volume that completely contains all the geometry represented by the subtree rooted at v . Therefore, if some other geometric entity, such as a point, ray, object, etc., is found to not intersect the bounding volume, then no intersection computations need be performed with any geometry within that volume.

Consider as an example a situation in which we are given some test point and we want to find which object if any this point lies in. Initially, we know only that the point lies somewhere in space (Figure 21.12).

By comparing the location of the point with respect to the first partitioning hyperplane, we can find in which of the two regions (a.k.a. bounding volumes) the point lies. This eliminates half of the objects (Figure 21.13).

By continuing this process recursively, we are in effect using the regions as a hierarchy of bounding volumes, each bounding volume being a rough approximation of the geometry it bounds, to quickly narrow our search (Figure 21.14).

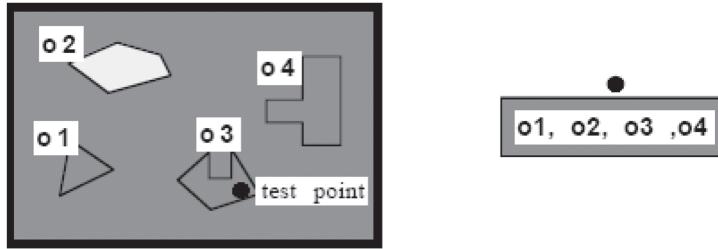

FIGURE 21.12 Point can lie anywhere.

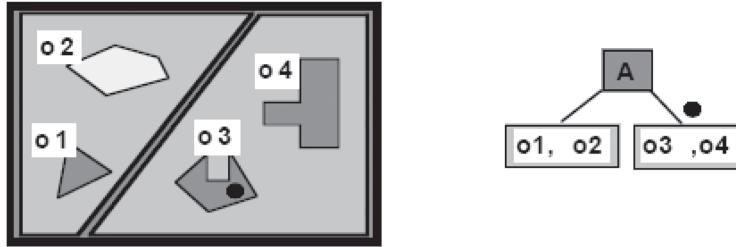

FIGURE 21.13 Point must lie to the right of the hyperplane.

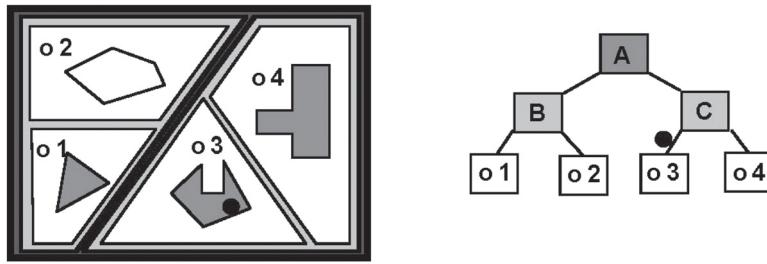

FIGURE 21.14 Point's location is narrowed down to one object.

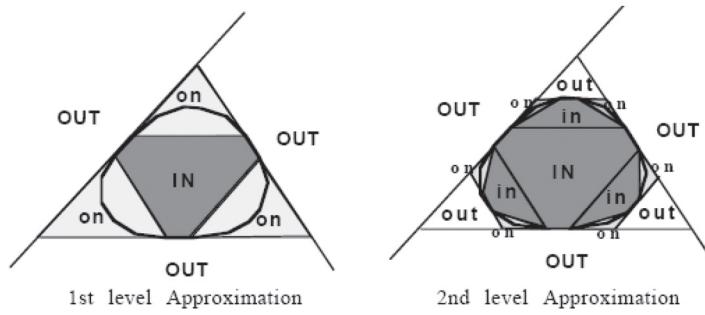

FIGURE 21.15 Multiresolution representation provided by BSP tree.

For a BSP Tree of a single object, this region-based (volumetric) view reveals how BSP Trees can provide a multi-resolution representation. As one descends a path of the tree, the regions decrease in size monotonically. For curved objects, the regions converge in the limit to the curve/surface. Truncating the tree produces an approximation, ala the Taylor series of approximations for functions (Figure 21.15).

21.4.1 Tree Merging

The spatial relations between two objects, each represented by a separate tree, can be determined efficiently by merging two trees. This is a fundamental operation that can be used to solve a number of geometric problems. These include set operations for CSG modeling as well as collision detection for dynamics. For rendering, merging all object-trees into a single model-tree determines

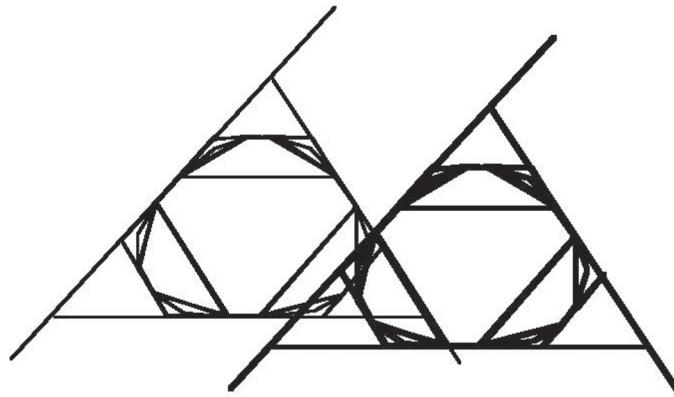

FIGURE 21.16 Merging BSP Trees.

inter-object visibility orderings; and the model-tree can be intersected with the view-volume to efficiently cull away off-screen portions of the scene and provide solid cutaways with the near clipping plane. In the case where objects are both transparent and interpenetrate, tree merging acts as a view independent geometric sorting of the object faces; each tree is used in a manner analogous to the way Merge Sort merges previously sorted lists to quickly create a new sorted list (in our case, a new tree). The model-tree can be rendered using ray tracing, radiosity, or polygon drawing using a far-to-near ordering with alpha blending for transparency. An even better alternative is multi-resolution beam-tracing, since entire occluded subtrees can be eliminated without visiting the contents of the subtree, and distance subtrees can be pruned to the desired resolution. Beam tracing can also be used to efficiently compute shadows.

All of this requires as a basic operation an algorithm for merging two trees. Tree merging is a recursive process, which proceeds down the trees in a multi-resolution fashion, going from low-res to high-res. It is easiest to understand in terms of merging a hierarchy of bounding volumes. As the process proceeds, pairs of tree regions, a.k.a. convex bounding volumes, one from each tree, are compared to determine whether they intersect or not. If they do not, the contents of the corresponding subtrees are never compared. This has the effect of “zooming in” on those regions of space where the surfaces of the two objects intersect ([Figure 21.16](#)).

The algorithm for tree merging is quite simple once you have a routine for partitioning a tree by a hyperplane into two trees. The process can be thought of in terms of inserting one tree into the other in a recursive manner. Given trees T1 and T2, at each node of T1 the hyperplane at that node is used to partition T2 into two “halves”. Then each half is merged with the subtree of T1 lying on the same side of the hyperplane. (In actuality, the algorithm is symmetric w.r.t. the role of T1 and T2 so that at each recursive call, T1 can split T2 or T2 can split T1.)

```

```

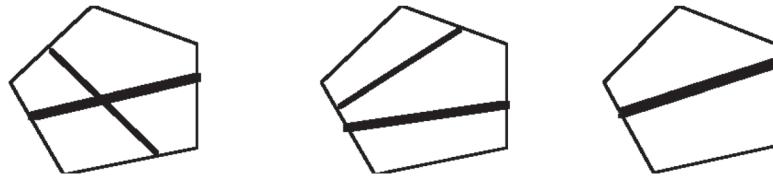

FIGURE 21.17 Three cases (intersecting, non-intersecting, coincident) when comparing sub-hyperplanes during tree merging.

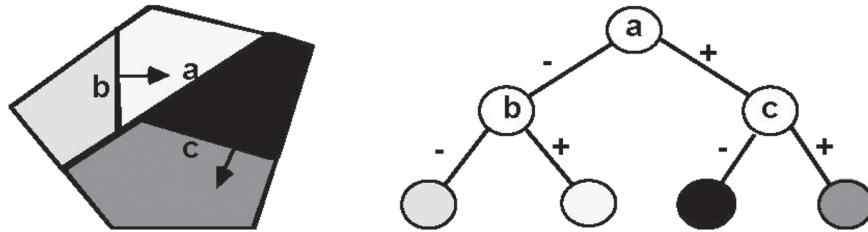

FIGURE 21.18 Before pruning.

FIGURE 21.19 After pruning.

While tree merging is easiest to understand in terms of comparing bounding volumes, the actual mechanism uses *sub-hyperplanes*, which is more efficient. A sub-hyperplane is created whenever a region is partitioned by a hyperplane, and it is just the subset of the hyperplane lying within that region. In fact, all of the illustrations of trees we have used are drawings of sub-hyperplanes. In 3D, these are convex polygons, and they separate the two child regions of an internal node. Tree merging uses sub-hyperplanes to simultaneously determine the spatial relations of four regions, two from each tree, by comparing the two sub-hyperplanes at the root of each tree. For 3D, this is computed using two applications of convex-polygon clipping to a plane, and there are three possible outcomes: intersecting, non-intersecting and coincident (Figure 21.17). This is the only overtly geometric computation in tree merging; everything else is data structure manipulation.

21.4.2 Good BSP Trees

For any given set, there exist an arbitrary number of different BSP Trees that can represent that set. This is analogous to there being many different programs for computing the same function, since a BSP Tree may in fact be interpreted as a computation graph specifying a particular search of space. Similarly, not all programs/algorithms are equally efficient, and not all searches/trees are equally efficient. Thus the question arises as to what constitutes a good BSP Tree. The answer is a tree that represents the set as a sequence of approximations. This provides a multi-resolution representation. By pruning the tree at various depths, different approximations of the set can be created. Each pruned subtree is replaced with a cell containing a low degree polynomial approximation of the set represented by the subtree (Figures 21.18 and 21.19).

In Figure 21.20, we show two quite different ways to represent a convex polygon, only the second of which employs the sequence of approximations idea. The tree on the left subdivides space using lines radiating from the polygonal center, splitting the number of faces in half at each step of the recursive subdivision. The hyperplanes containing the polygonal edges are chosen only when the number of faces equals one, and so are last along any path. If the number of polygonal edges is n , then the tree is of size $O(n)$ and of depth $O(\log n)$. In contrast, the tree on the right uses the idea of a sequence of approximations. The first three partitioning hyperplanes form a first approximation to the exterior while the next three form a first approximation to the interior. This divides the set of edges into three sets. For each of these, we choose the hyperplane of the middle face by which to partition, and by doing

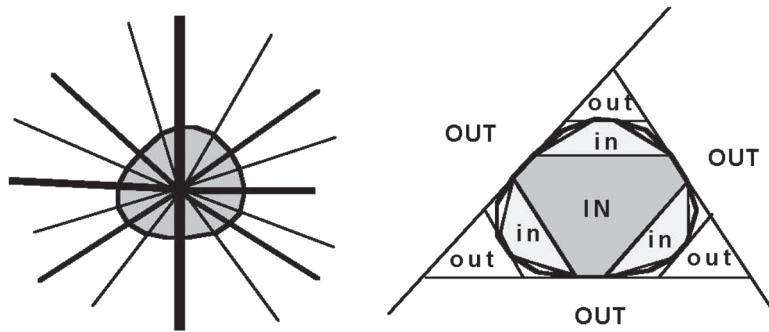

FIGURE 21.20 Illustration of bad vs. good trees.

so refine our representation of the exterior. Two additional hyperplanes refine the interior and divide the remaining set of edges into two nearly equal sized sets. This process precedes recursively until all edges are in partitioning hyperplanes. Now, this tree is also of size $O(n)$ and depth $O(\log n)$, and thus the worst case, say for point classification, is the same for both trees. Yet they appear to be quite different.

This apparent qualitative difference can be made quantitative by, for example, considering the expected case for point classification. With the first tree, all cells are at depth $\log n$, so the expected case is the same as the worst case regardless of the sample space from which a point is chosen. However, with the second tree, the top three out-cells would typically constitute most of the sample space, and so a point would often be classified as OUT by, on average, two point-hyperplane tests. Thus the expected case would converge to $O(1)$ as the ratio of polygon-area/sample-area approaches 0. For line classification, the two trees differ not only in the expected case but also in the worst case: $O(n)$ vs. $O(\log n)$. For merging two trees the difference is $O(n^2)$ vs. $O(n \log n)$. This reduces even further to $O(\log n)$ when the objects are only contacting each other, rather overlapping, as is the case for collision detection. However, there are worst case “basket weaving” examples that do require $O(n^2)$ operations. These are geometric versions of the Cartesian product, as for example when a checkerboard is constructed from n horizontal strips and n vertical strips to produce $n \times n$ squares. These examples, however, violate the Principle of Locality: that geometric features are local not global features. For almost all geometric models of physical objects, the geometric features are local features. Spatial partitioning schemes can accelerate computations only when the features are in fact local, otherwise there is no significant subset of space that can be eliminated from consideration. The key to a quantitative evaluation, and also generation, of BSP Trees is to use expected case models, instead of worst-case analysis. Good trees are ones that have low expected cost for the operations and distributions of input of interest. This means, roughly, that high probability regions can be reached with low cost, that is, they have short paths from the root to the corresponding node, and similarly low probability regions should have longer paths. This is exactly the same idea used in Huffman codes. For geometric computation, the probability of some geometric entity, such as a point, line segment, plane, etc., lying in some arbitrary region is typically correlated positively to the size of the region: the larger the region the greater the probability that a randomly chosen geometric entity will intersect that region. To compute the expected cost of a particular operation for a given tree, we need to know at each branch in the tree the probability of taking the left branch, p , and the probability of taking the right branch p^+ . If we assign a unit cost to the partitioning operation, then we can compute the expected cost exactly, given the branch probabilities, using the following recurrence relation:

$$\begin{aligned} E_{\text{cost}}[T] = & \\ & \text{IF } T \text{ is a cell} \\ & \text{THEN } 0 \\ & \text{ELSE } 1 + p^- * E_{\text{cost}}[T^-] + p^+ * E_{\text{cost}}[T^+] \end{aligned}$$

This formula does not directly express any dependency upon a particular operation; those characteristics are encoded in the two probabilities p^- and p^+ . Once a model for these is specified, the expected cost for a particular operation can be computed for any tree.

As an example, consider point classification in which a random point is chosen from a uniform distribution over some initial region R . For a tree region of r with child regions r^+ and r^- , we need the conditional probability of the point lying in r^+ and r^- , given that it lies in r . For a uniform distribution, this is determined by the sizes of the two child-regions relative to their parent:

$$p^+ = \text{vol}(r^+)/\text{vol}(r)$$

$$p^- = \text{vol}(r^-)/\text{vol}(r)$$

Similar models have been developed for line, ray and plane classification. Below we describe how to use these to build good trees.

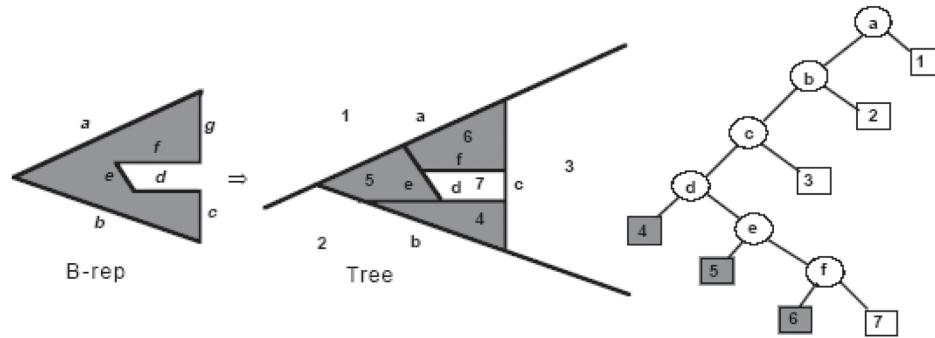

FIGURE 21.21 B-rep and Tree representation of a polygon.

21.4.3 Converting B-Reps to Trees

Since humans do not see physical objects in terms of binary trees, it is important to know how such a tree be constructed from something that is more intuitive. The most common method is to convert a boundary representation, which corresponds more closely to how humans see the world, into a tree. In order for a BSP Tree to represent a solid object, each cell of the tree must be classified as being either entirely inside or outside of the object; thus, each leaf node corresponds to either an in-cell or an out-cell. The boundary of the set then lies between in-cells and out-cells; and since the cells are bounded by the partitioning hyperplanes, it is necessary for the entire boundary to lie in the partitioning hyperplanes (Figure 21.21).

Therefore, we can convert from a b-rep to a tree simply by using all of the face hyperplanes as partitioning hyperplanes. The face hyperplanes can be chosen in any order and the resulting tree will always generate a convex decomposition of the interior and the exterior. If the hyperplane normals of the b-rep faces are consistently oriented to point to the exterior, then all left leaves will be in-cells and all right leaves will be out-cells. The following algorithm summarizes the process.

```
Brep_to_Bspt: Brep b -> Bspt T
IF b == NULL
THEN
  T = if a left-leaf then an in-cell else an out-cell
ELSE
  h = Choose_Hyperplane(b)
  {b+, b-, b0} = Partition_Brep(b,h)
  T.faces = b0
  T.pos_subtree = Brep_to_Bspt(b+)
  T.neg_subtree = Brep_to_Bspt(b-)
END
```

However, this does not tell us in what order to choose the hyperplanes so as to produce the best trees. Since the only known method for finding the optimal tree is by exhaustive enumeration, and there are at least $n!$ trees given n unique face hyperplanes, we must employ heuristics. In 3D, we use both the face planes as candidate partitioning hyperplanes, as well as planes that go through face vertices and have predetermined directions, such as aligned with the coordinates axes. Given any candidate hyperplane, we can try to predict how effective it will be using expected case models; that is, we can estimate the expected cost of a subtree should we choose this candidate to be at its root. We will then choose the least cost candidate. Given a region r containing boundary b which we are going to partition by a candidate h , we can compute exactly p^+ and p^- for a given operation, as well as the size of b^+ and b^- . However, we can only estimate $E_{cost}[T^+]$ and $E_{cost}[T^-]$. The estimators for these values can depend only upon a few simple properties such as number of faces in each halfspace, how many faces would be split by this hyperplane, and how many faces lie on the hyperplane (or area of such faces). Currently, we use $|b^+|^n$ for $E_{cost}[T^+]$, where n typically varies between .8 and .95, and similarly for $E_{cost}[T^-]$. We also include a small penalty for splitting a face by increasing its contribution to b^+ and b^- from 1.0 to somewhere between 1.25 and 1.75, depending upon the object. We also favor candidates containing larger surface area, both in our heuristic evaluation and by first sorting the faces by surface area and considering only the planes of the top k faces as candidates. One interesting consequence of using expected case models is that choosing the candidate that attempts to balance the tree is usually not the best; instead the model prefers candidates that place small amounts of geometry in large regions, since this will result in high probability and low cost subtrees, and similarly large amounts of geometry in small regions. Balanced is optimal only when the geometry is uniformly distributed, which is rarely the case (Figure 21.22). More importantly,

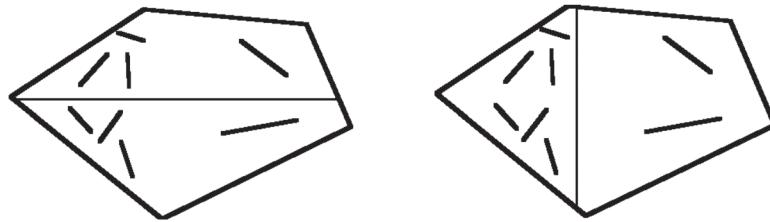

FIGURE 21.22 Balanced is not optimal for non-uniform distributions.

minimizing expected costs produces trees that represent the object as a sequence of approximations, and so in a multi-resolution fashion.

21.4.4 Boundary Representations vs. BSP Trees

Boundary Representations and BSP Trees may be viewed as complementary representations expressing different aspects of geometry, the former being topological, the latter expressing hierarchical set membership. B-reps are well suited for interactive specification of geometry, expressing topological deformations, and scan-conversion. BSP Trees are well suited for intersection and visibility calculations. Their relationship is probably more akin to the capacitor vs. inductor, than the tube vs. transistor.

The most often asked question is what is the size of a BSP Tree representation of a polyhedron vs. the size of its boundary representation. This, of course, ignores the fact that expected cost, measured over the suite of operations for which the representation will be used, is the appropriate metric. Also, boundary representations must be supplemented by other devices, such as octrees, bounding volumes hierarchies, and z-buffers, in order to achieve an efficient system; and so the cost of creating and maintaining these structures should be brought into the equation. However, given the intrinsic methodological difficulties in performing a compelling empirical comparison, we will close with a few examples giving the original number of b-rep faces and the resulting tree using our currently implemented tree construction machinery. The first ratio is number-of-tree-faces/number-of-brep-faces. The second ratio is number-of-tree-nodes/number-of-brep-faces, where number-of-tree-nodes is the number of internal nodes. The last column is the expected cost in terms of point, line and plane classification, respectively, in percentage of the total number of internal nodes, and where the sample space was a bounding box 1.1 times the minimum axis-aligned bounding box. These numbers are pessimistic since typical sample spaces would be much larger than an object's bounding box. Also, the heuristics are controlled by 4 parameters, and these numbers were generated, with some exceptions, without a search of the parameter space but rather using default parameters. There are also quite a number of ways to improve the conversion process, so it should be possible to do even better.

22.1 Introduction

Spatial database management systems must be able to store and process large amounts of disk-resident spatial data. Multidimensional data support is needed in many fields including geographic information systems (GIS), computer aided design (CAD), and medical, multimedia, and scientific databases. Spatial data operations that need to be supported include spatial joins and various types of queries such as intersection, containment, topological and proximity queries. The challenge, and primary performance objective, for applications dealing with disk-resident data is to minimize the number of disk retrievals, or I/Os, needed to answer a query. Main memory data structures are designed to reduce computation time rather than I/O, and hence are not directly applicable to a disk based environment.

Just as the B-tree [1] ([Chapter 16](#)) and its variants were proposed to optimize I/O while processing single dimensional disk resident data, the original R-tree [2] and later variants have been proposed to index disk resident multidimensional data efficiently.

R-trees are very versatile, in the sense that they can be used with little or no modification to tackle many different problems related to spatial data. Asymptotically better data structures exist for specific instances of these problems, but the solution of choice is different for different types of inputs or queries. Thus, one of the main advantages of R-trees is that the same data structure can be used to handle different problems on arbitrary types of multidimensional data.

In this chapter we describe the original R-tree proposal and some of its variants. We analyze the efficiency of various operations and examine various performance models. We also describe R-tree based algorithms for additional operations, such as proximity queries and spatial joins. There are many more applications, variants and issues related to R-trees than we can possibly cover in one chapter. Some of the ones we do not cover include parallel and distributed R-trees [3–6], variants for high dimensional [7–9] and for spatio-temporal data [10–16], and concurrency [17,18]. See [Chapter 48](#) for more on concurrent data structures. Other data structures with similar functionality, such as range, quad and k - d trees, are covered in other chapters of Part IV of this handbook. Some of these (see [Chapter 28](#)) are specifically designed for disk-resident data.

22.2 Basic Concepts

R-trees were first introduced in Reference 2. An R-tree is a hierarchical data structure derived from the B^+ -tree and originally designed to perform intersection queries efficiently. The tree stores a collection of d -dimensional points or rectangles which can change in time via insertions and deletions. Other object types, such as polygons or polyhedra, can be handled by storing their minimum bounding rectangles (MBRs) and performing additional tests to eliminate false hits. A false hit happens when the query object intersects the MBR of a data object but does not intersect the object itself. In the sequel we talk about rectangles only,

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

with the understanding that a point is simply a degenerate rectangle. We use the terms MBR and bounding box, interchangeably. In our context, the d -dimensional rectangles are “upright,” that is, each rectangle is the Cartesian product of d one-dimensional intervals: $[l_1, h_1] \times \dots \times [l_d, h_d]$. Thus, $2d$ values are used to specify a rectangle.

Each node of the tree stores a maximum of B entries. With the exception of the root, each node also stores a minimum of $b \leq B/2$ entries. This constraint guarantees a space utilization of at least b/B . Each entry E consists of a rectangle r and a pointer p_r . As with B^+ -trees all input values are stored at the leaves. Thus, at the leaf level, r is the bounding box of an actual object pointed to by p_r . At internal nodes, r is the bounding box of all rectangles stored in the subtree pointed to by p_r .

A downward path in the tree corresponds to a sequence of nested rectangles. All leaf nodes occur at the same level (i.e., have the same depth), even after arbitrary sequences of updates. This guarantees that the height of the tree is $O(\log_b n)$, where n is the number of input rectangles. Notice that MBRs at the same level may overlap, even if the input rectangles are disjoint.

Figure 22.1 illustrates an R-tree with 3 levels (the root is at level 0) and a maximum of $B = 4$ rectangles per node. The 64 small dark data rectangles are grouped into 16 leaf level nodes, numbered 1–16. The bounding box of the set of rectangles stored at the same node is one of the rectangles stored at the parent of the node. In our example, the MBRs of leaf level nodes 1 through 4 are placed in node 17, in level 1. The root node contains the MBRs of the four level 1 nodes: 17, 18, 19, and 20.

22.2.1 Intersection Queries

To perform an intersection query Q , all rectangles that intersect the query region must be retrieved and examined (regardless of whether they are stored in an internal node or a leaf node). This retrieval is accomplished by using a simple recursive procedure that starts at the root node and which may follow *multiple* paths down the tree. In the worst case, all nodes may need to be retrieved, even though some of the input data need not be reported. A node is processed by first identifying all the rectangles stored at that node which intersect Q . If the node is an internal node, the subtrees corresponding to the identified rectangles are

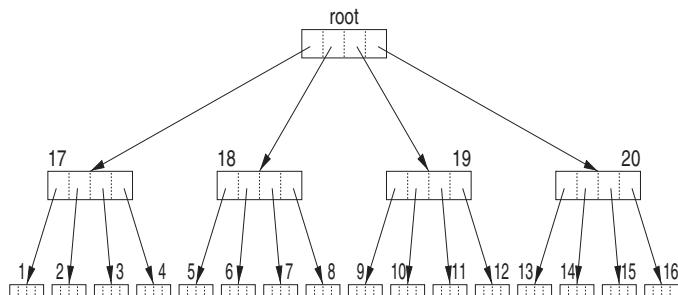

FIGURE 22.1 A sample R-tree using $B = 4$. Input rectangles are shown solid.

searched recursively. Otherwise, the node is a leaf node and the retrieved rectangles (or the data objects themselves) are simply reported.

For illustration, consider the query Q in the example of [Figure 22.1](#). After examining the root node, we determine that nodes 19 and 20 of level 1 must be searched. The search then proceeds with each of these nodes. Since the query region does not intersect any of the MBRs stored in node 19, this sub-query is terminated. While processing the other sub-query, it is determined that Q intersects the MBR corresponding to node 13 and this node is retrieved. Upon checking the rectangles in node 13, the one data rectangle intersected by Q is returned.

Other type of queries, such as arbitrarily shaped queries (e.g., point or polygonal queries) or retrieving all rectangles contained or containing Q , can be handled using a straightforward modification of the above procedure.

22.2.2 Updating the Tree

Many applications require support for update operations, such as insertion and deletion of rectangles. A tree that can change over time via such operations is said to be *dynamic*.

New rectangles can be inserted using a procedure similar to that used to insert a new key in a B^+ -tree. In other words, the new rectangle r is first added to a leaf node v and, if the node overflows, a split is performed that requires updating one rectangle and inserting another one in the parent of v . This procedure continues until either a node with fewer than B entries is found or the root is split, in which case a new node is created and the height of the tree grows by one. Independent of whether a split is performed or not, the bounding rectangles of all ancestors of r may need to be updated.

One important difference between R-trees and B^+ -trees is that, in our case, there is no incorrect leaf node to which the new rectangle can be added. Choosing a leaf node impacts performance, not correctness, and performance depends on our ability to cluster rectangles so as to minimize the expected number of rectangles intersected by a query of a given size. In practice this means that clustering should attempt to minimize the areas and perimeters of the resulting MBRs. Models for predicting the expected number of nodes that need to be visited while performing an intersection query are discussed in [Section 22.5](#).

The problem of partitioning a set of rectangles into buckets with capacity $B > 2$ such that the expected number of rectangles intersected by a random query is minimized is NP-hard [\[19\]](#). Hence, it is unlikely we will ever know how to build optimal R-trees efficiently. As a result, many heuristic algorithms for building the tree have been proposed. It is worth noting that, in practice, some of the proposed heuristics result in well tuned R-trees and near optimal I/O for 2-dimensional data. We start with Guttman's original heuristics, which are of two types: leaf selection and node splitting.

To identify a leaf for insertion, Guttman proposes proceeding down the tree, always choosing the rectangle in the current node of the path whose area would increase by the smallest amount were we to insert the new rectangle in the subtree that corresponds to that rectangle. The reasoning behind this approach is that rectangles with small areas are less likely to be chosen for further exploration during a search procedure.

When a node overflows, a split is performed. Ideally, when this happens, one would like to partition a set S of $B + 1$ rectangles into two sets S_1 and S_2 such that the sum of their areas is minimized and each set contains at least b entries. Guttman proposes three different strategies, only the first of which is guaranteed to yield an optimal partition. The first strategy is a brute force algorithm that chooses the best split by checking all candidate partitions of the overflowed set S . This strategy is not practical, as the number of candidates is exponential in the node capacity, which can easily exceed 50 or so rectangles. The second strategy, quadratic split, starts by selecting the two rectangles $r_1, r_2 \in S$ which maximize the quantity $\text{area}(r') - \text{area}(r_1) - \text{area}(r_2)$, where r' is the MBR of $r_1 \cup r_2$. These two rectangles act as seeds which are assigned to different sides of the partition, that is, one is assigned to S_1 and the other to S_2 . The remaining entries of S are then assigned to the set (S_1 or S_2) whose MBR area increases the least when including the new rectangle in that set. The entries are not considered in arbitrary order. Rather, the next entry to be allocated is the one with the strongest preference for a group, that is, the entry r that maximizes $|A_1 - A_2|$, where $A_i = \text{area}(\text{MBR}(S_i \cup \{r\})) - \text{area}(\text{MBR}(S_i))$. This heuristic runs in quadratic time and attempts to assign a priority to the unallocated entries according to the performance penalty that the wrong assignment could cause. If at any time during the allocation procedure the size of the smaller set plus the number of unallocated entries is equal to b , then all remaining entries are allocated to that set.

The third and final strategy, linear split, also assigns entries to the group whose MBR area increases the least, but differs from quadratic split in the method used to pick the seeds and in the order in which the remaining entries are allocated. The seeds are the two rectangles r_1 and r_2 whose separation is largest along (at least) one of the dimensions. We elaborate on this. Let $l_j(r)$ and $h_j(r)$ denote the low and high endpoints, respectively, of the j -th interval of r . The width of r along dimension j is simply $w_j = \max_r\{h_j(r)\} - \min_r\{l_j(r)\}$. The normalized separation of r along dimension j is $s_j = (\max_r\{l_j(r)\} - \min_r\{h_j(r)\})/w_j$. The seeds r_1 and r_2 are the two rectangles that yield the largest normalized separation considering all dimensions j . Once the seeds are chosen, the remaining entries are allocated to one set or the other in random order. This last heuristic runs in linear time.

A different linear split algorithm is described in [Reference 20](#). Other efforts [\[21,22\]](#) include polynomial time algorithms to partition a set of rectangles so as to minimize the sum of areas of the two resulting bounding rectangles.

In order to delete a rectangle r we first find the node v containing r and remove the entry, adjusting the bounding rectangles in all ancestors, as necessary. If the node occupancy goes below b the tree needs to be readjusted so as to keep the height in $O(\log_b n)$. There are different ways in which one can readjust the tree. One possibility is to redistribute the remaining entries of v among the siblings of v , in a manner similar to how underflowed nodes are treated in some B-tree algorithms. Instead, Guttman suggests reinserting the remaining entries of v , as this helps the global structure of the tree by considering non-sibling nodes during reinsertion. Of course, this procedure needs to be applied recursively, as internal nodes may underflow as well. Finally, if after deletion the root has exactly one child, the tree height shrinks by one and the only child becomes the new root.

22.3 Improving Performance

Since R-trees were first proposed in Reference 2, many variants and methods to improve the structure and performance of the tree have been proposed. We discuss a few of the more common ones: R^* -trees [23], Hilbert R-trees [24] and several bulk loading algorithms [25–27]. Other proposals for improving performance include [28–31].

22.3.1 R^* Tree

Given that the known R-tree insertion algorithms are based on heuristic optimization, it is reasonable to assess their merit experimentally. Beckmann et al. [23] conducted an extensive experimental study to explore the impact of alternative approaches for leaf selection and node splitting. Based on their experiments, they proposed the R^* tree which has become the most commonly implemented R-tree variant.

The R^* tree differs from the original Guttman R-tree in three ways.

First, the leaf where a new object is inserted is chosen differently. The path selection algorithm makes use of the concept of *overlap* of entry E_i in node v_j , defined as $\text{overlap}(E_i) = \sum_{j=1, j \neq i}^m \text{area}(r_i \cap r_j)$, where m is the number of entries in node v_j and r_i is the rectangle associated with E_i . When descending from the root, if the next node to be selected is a leaf, the algorithm chooses the node that requires the least increase in overlap, and resolves ties as least area enlargement. If the next node is not a leaf, the entry with the least area enlargement is chosen.

The second difference is the use of *forced reinserts*. The authors discovered that the initial order of inserts significantly impacts tree quality. They also observed that query performance of an existing R-tree can be improved by removing half of the entries and then re-inserting them. Of course, the authors do not recommend performing a restructuring of this magnitude frequently. Rather, they used this insight to modify the policy for dealing with overflowed nodes. If an insertion causes an overflow, calculate the distance from the center of each of the $B + 1$ entries to the center of the MBR enclosing all $B + 1$ entries. Then sort the entries in decreasing order of this distance. Remove the p furthest entries, where p is set to 30% of B , and re-insert the p removed entries into the tree. Some subset of the p re-inserts may be inserted into nodes other than the initial node that overflowed. For each of the p re-inserts, if they do not cause an overflow, do nothing; otherwise, split the node using the algorithm below.

The third difference is in the node splitting algorithm. When a split is needed, the node entries are first sorted twice along each of the d dimensions. The two sorts are based on the low and on the high MBR endpoint values, respectively. Remember that nodes must have a minimum of b and a maximum of B entries. Thus, using one of the sorted lists, the $B + 1$ entries can be partitioned into two groups, S_1 and S_2 , by splitting anyplace after the i -th entry, $b \leq i \leq B - b + 1$, of the sorted list. S_1 and S_2 consist of the entries before and after the split position, respectively. In order to choose the best split, the following three objective functions were considered (for 2-d data) and tested using different combinations:

1. Area-value = $\text{area}(\text{MBR}(S_1)) + \text{area}(\text{MBR}(S_2))$
2. Perimeter-value = $\text{perimeter}(\text{MBR}(S_1)) + \text{perimeter}(\text{MBR}(S_2))$
3. Overlap-value = $\text{area}(\text{MBR}(S_1) \cap \text{MBR}(S_2))$

Notice that for a fixed area, the MBR with smallest perimeter is the square.

Based on experiments, the following split policy is adopted. The R^* tree computes the perimeter-values for each possible grouping (S_1, S_2) over both sorted lists of all dimensions and chooses the dimension that yields the minimum perimeter-value. Once the dimension has been chosen, the algorithm then chooses the grouping for that dimension that minimizes the overlap-value.

These three changes were shown to substantially improve the I/O performance for all data sets studied.

22.3.2 Hilbert Tree

The Hilbert R-tree [24] further improves performance by imposing a linear order on the input rectangles that results in MBRs of small area and perimeter. The tree is actually an R-tree augmented with order information. Intersection queries are performed as

before, using the standard R-tree algorithm; but as a consequence of the ordering constraints, insertion and deletion can proceed as in B^+ -trees and there is no longer a need to consider various leaf selection heuristics. Additionally, the linear order allows for effective use of deferred splitting, a technique which improves node utilization and performance as trees require fewer nodes for a given input set.

To define an ordering of the input values, Kamel and Faloutsos [24] propose the use of a space-filling curve, such as the Hilbert curve. The power of these curve lies in its ability to linearly order multidimensional points such that nearby points in this order are also close in multidimensional space. Hilbert curves are not the only reasonable choice. Other curves, such as the Peano or Z-order curve, may also be used. See [32] for a discussion on space-filling curves.

A d -dimensional Hilbert curve of order k is a curve H_k^d that visits every vertex of a finite d dimensional grid of size $2^k \times \dots \times 2^k = 2^{kd}$. Its construction can best be viewed as a sequence of stages. At each stage, an instance of the curve of the previous stage is rotated and placed in each of 2^d equal-sized sub-quadrants. Endpoints of the 2^d sub-curves are then connected to produce the curve at the next stage. The first three stages of the Hilbert curve for two and three dimensions are illustrated in Figures 22.2 and 22.3, respectively.

Each grid vertex is assigned a Hilbert value, which is an integer that corresponds to its position along the curve. For instance, in H_2^2 , $(0, 0)$ and $(1, 2)$ have Hilbert values 0 and 7, respectively. This assignment is easily extended to rectangles, in which case the Hilbert value of the grid point closest to the rectangle center is assigned. Algorithms for computing the position of a point along a space filling curve are given in References 33–35.

The structure of the R-tree is modified as follows. Leaf nodes remain the same. Each entry of an internal node now has the form (r, p, v) , where r and p have the same interpretation as before, and v is the largest Hilbert value of all data items stored in the subtree with root p . This assignment results in update algorithms that are similar to those used for B^+ -trees. In particular, it is straightforward to implement an effective policy for *deferred splitting* which reduces the number of splits needed while performing insertions. The authors propose the following policy, which they call s -to- $(s + 1)$ splitting. When a node overflows, an attempt is first made to shift entries laterally to $s - 1$ sibling nodes at the same level. An actual split occurs only if the additional entry cannot be accommodated by shifting, because the $s - 1$ siblings are already full. When this happens a new node is created and the $sB + 1$ entries are distributed among the $s + 1$ nodes. Because entries at the leaves are sorted by Hilbert value, bounding boxes of leaves tend to have small area and perimeter, and node utilization is high. Notice that there is a clear trade-off between node

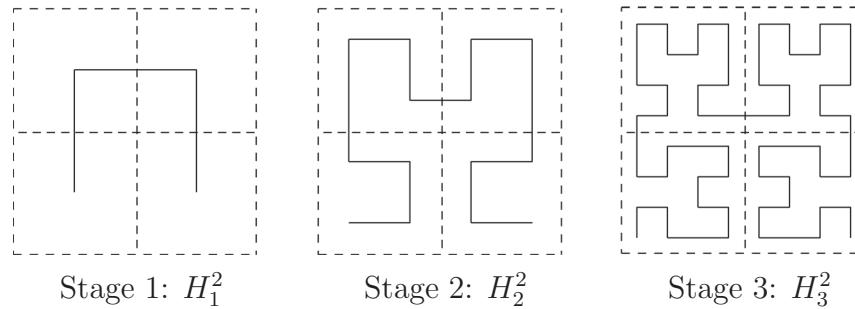

FIGURE 22.2 The first three stages of a 2-dimensional Hilbert curve.

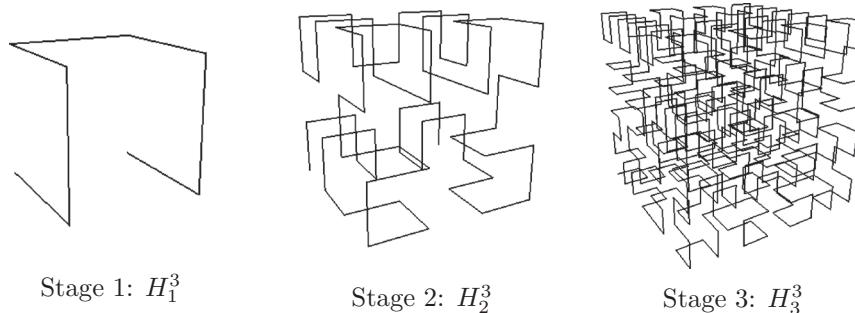

FIGURE 22.3 The first three stages of a 3-dimensional Hilbert curve.

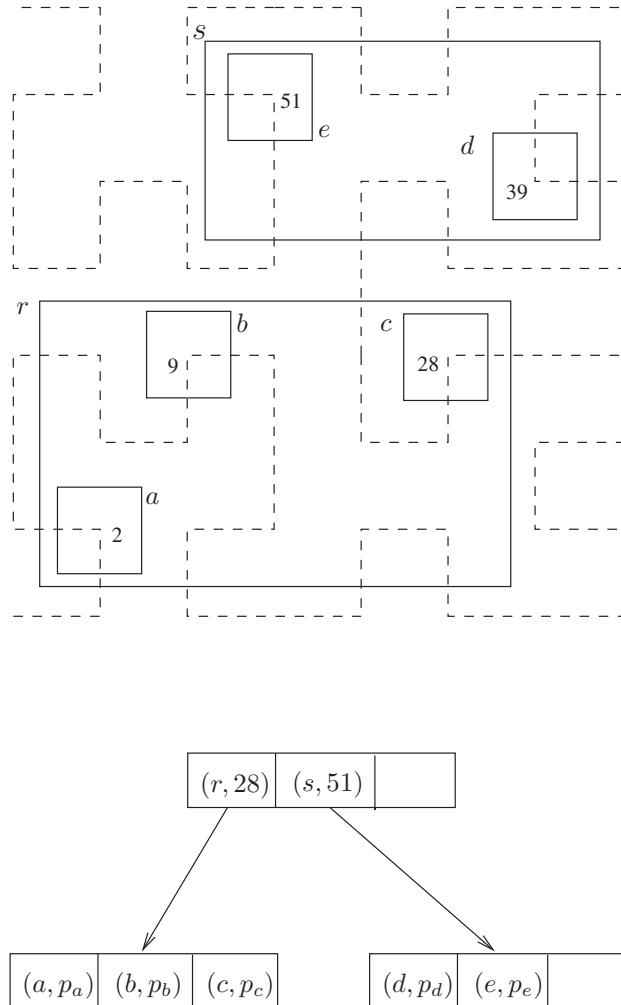

FIGURE 22.4 A Hilbert R-tree with $B = 3$.

utilization and insertion complexity (which increases as s increases). The case $s = 1$ corresponds to the regular split policy used in the original R-tree, that is, split whenever a node overflows.

A sample tree with 5 data rectangles is shown in Figure 22.4. There are two leaf nodes and one internal node (the root). The pointer entries of the internal node are represented by arrows. Each input rectangle has been annotated with its Hilbert value. In reality, the corners of the rectangles would fall on grid vertices. They have been made smaller in order to make the figure more readable. Inserting a new rectangle whose center has Hilbert value 17 would cause an overflow in r . With deferred splitting, a split is not necessary. Instead, the new rectangle would be accommodated in r after shifting rectangle c (with Hilbert value 28) to its sibling s .

The authors report improvements of up to 28% in performance over R*-trees and recommend using 2-to-3 splitting which results in an average node utilization of 82.2%.

In practice, one does not store or compute all bit values on the hypothetical grid. Let β be the number of bits required to describe one coordinate. Storing the Hilbert value of a d -dimensional point requires $d\beta$ bits of storage, which may be larger than the size of native machine integers. It is possible to compare the Hilbert values of two points without storing the values explicitly. Conceptually, the process computes bit positions, one at a time, until discrimination is possible. Consider the case of 2-d and notice that the first bit of the x - and y -coordinates of a point determine which quadrant contains it. Successive bits determine which successively smaller sub-quadrants contain the point. When two center points (x_1, y_1) and (x_2, y_2) need to be compared, the bits of each coordinate are examined until it can be determined that one of the points lies in a different sub-quadrant than the other (one can use the sense and rotation tables described in Reference 25 to accomplish this task). The information gathered is used to decide which point is closer to the origin (along the Hilbert Curve).

22.3.3 Bulk Loading

There are applications where the data is static, or does not change very frequently. Even if the data is dynamic, it may happen that an index needs to be constructed for a large data set which is available a priori. In these circumstances, building an R-tree by inserting one object at a time has several disadvantages: (a) high load time, (b) sub-optimal space utilization, and, most important, (c) poor R-tree structure requiring the retrieval of a large number of nodes in order to satisfy a query. As discussed in the previous section, other dynamic algorithms [23,31] improve the quality of the R-tree, but still are not competitive with regard to query time when compared to loading algorithms that are allowed to pre-process the data to be stored. When done properly, preprocessing results in R-trees with nearly 100% space utilization and improved query times (due to the fact that fewer nodes need to be accessed while performing a query). Such *packing algorithms* were first proposed by Roussopoulos [27] and later by Kamel and Faloutsos [25], and Leutenegger et al. [26]. An approach that is intermediary between inserting a tuple at a time and constructing the entire tree by bulk loading is followed by [36], where an entire batch of input values is processed by partitioning the input into clusters and then inserting R-trees for the clusters into the existing R-tree.

The general approach to bulk loading an R-tree is similar to building a B-tree from a collection of keys by creating the leaf level first and then creating each successively higher level until the root node is created. The general approach is outlined below.

General Algorithm:

1. Sort the n rectangles and partition them into $\lceil n/B \rceil$ consecutive groups of B rectangles. Each group of B rectangles is eventually placed in the same leaf level node. Note that the last group may contain fewer than B rectangles.
2. Load the $\lceil n/B \rceil$ groups of rectangles into nodes and output the (MBR, address) for each leaf level node into a temporary file. The addresses are used as the child pointer fields for the nodes of the next higher level.
3. Recursively pack these MBRs into nodes at the next level, proceeding upwards, until the root node is created.

The three algorithms differ only in how the rectangles are sorted at each level. These differences are described below.

1. *Nearest-X (NX):*

This algorithm was proposed in Reference 27. The rectangles are sorted by the x -coordinate of a designated point such as the center. Once sorted, the rectangles are packed into nodes, in groups of size B , using this ordering. While our description is in terms of x , a different coordinate can clearly be used.

2. *Hilbert Sort (HS):*

The algorithm of [25] orders the rectangles using the Hilbert space filling curve. The center points of the rectangles are sorted based on their distance from the origin, measured along the curve. This process determines the order in which the rectangles are placed into the nodes of the R-Tree.

3. *Sort-Tile-Recursive (STR):*

STR [26] is best described recursively with $d = 2$ providing the base case. (The case $d = 1$ is already handled well by regular B-trees.) Accordingly, we first consider a set of rectangles in the plane. The basic idea is to “tile” the data space using $\sqrt{n/B}$ vertical slices so that each slice contains enough rectangles to pack roughly $\sqrt{n/B}$ nodes. Once again we assume coordinates are for the center points of the rectangles. Determine the number of leaf level pages $P = \lceil n/B \rceil$ and let $S = \lceil \sqrt{P} \rceil$. Sort the rectangles by x -coordinate and partition them into S vertical slices. A slice consists of a run of $S \cdot B$ consecutive rectangles from the sorted list. Note that the last slice may contain fewer than $S \cdot B$ rectangles. Now sort the rectangles of each slice by y -coordinate and pack them into nodes by grouping them into runs of length B (the first B rectangles into the first node, the next n into the second node, and so on).

The case $d > 2$ is a simple generalization of the approach described above. First, sort the hyper-rectangles according to the first coordinate of their center. Then divide the input set into $S = \lceil P^{\frac{1}{d}} \rceil$ slabs, where a slab consists of a run of $B \cdot \lceil P^{\frac{d-1}{d}} \rceil$ consecutive hyper-rectangles from the sorted list. Each slab is now processed recursively using the remaining $d - 1$ coordinates (i.e., treated as a $(d - 1)$ -dimensional data set).

Figure 22.5 illustrates the results from packing a set of segments from a Tiger file corresponding to the city of Long Beach. The figure shows the resultant leaf level MBRs for the same data set for each of the three algorithms using a value of $B = 100$ to bulk load the trees.

As reported in Reference 26, both Hilbert and STR significantly outperform NX packing on all types of data except point data, where STR and NX perform similarly. For tests conducted with both synthetic and actual data sets, STR outperformed Hilbert on all but one set, by factors of up to 40%. In one instance (VLSI data), Hilbert packing performed up to 10% faster. As expected, these differences decrease rapidly as the query size increases.

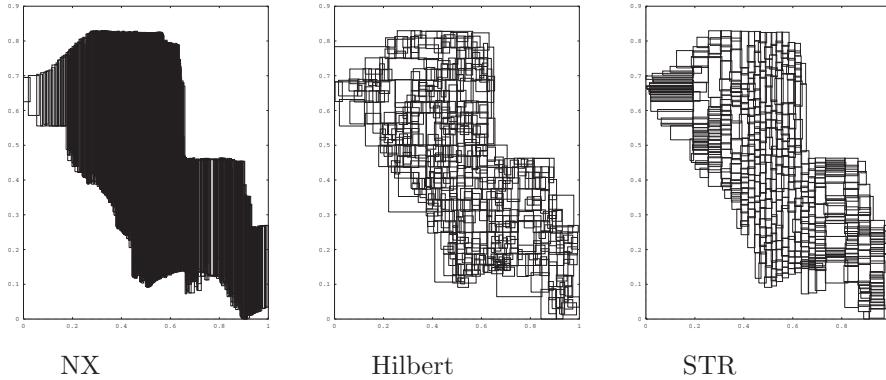

FIGURE 22.5 Leaf level nodes for three packing algorithms.

22.4 Advanced Operations

Even though R-trees were originally designed to perform intersections queries, it did not take long before R-trees were being used for other types of operations, such as nearest neighbor, both simple [37–39] and constrained to a range [40], reverse nearest neighbor [41–43], regular and bichromatic closest pairs [44–46], incremental nearest neighbors [38], topological queries [47], spatial joins [48–56] and distance joins [45,57]. Some of the proposals work on an ordinary R-tree while others require that the tree be modified or augmented in various ways. Because of space limitations we concentrate our attention on two problems: nearest neighbors and spatial joins.

22.4.1 Nearest Neighbor Queries

We discuss the problem of finding the input object closest to an arbitrary query point Q . We assume the standard Euclidean metric, that is, if $a = (a_1, \dots, a_d)$ and $b = (b_1, \dots, b_d)$ are arbitrary points then $\text{dist}(a, b) = (\sum_{i=1}^d (a_i - b_i)^2)^{1/2}$. For a general object O , such as a rectangle or polygon, we define $\text{dist}(Q, O) = \min_{p \in O} \text{dist}(Q, p)$ (Figure 22.6).

The first proposal to solve this problem using R-trees is from [39]. Roussopoulos et al. define two bounding functions of Q and an arbitrary rectangle r :

$$\text{mindist}(Q, r) = \text{dist}(Q, r), \text{ the distance from } Q \text{ to the closest point in } r.$$

$$\text{minmaxdist}(Q, r) = \min_f \max_{p \in f} (\text{dist}(Q, p)), \text{ where } f \text{ ranges over all } (d-1)\text{-dimensional facets of } r.$$

Notice that $\text{mindist}(Q, r) = 0$ if Q is inside r and that for any object or rectangle s that is a descendant of r , $\text{mindist}(Q, r) \leq \text{dist}(Q, s) \leq \text{minmaxdist}(Q, r)$. This last fact follows from the fact that each of the facets of r must share a point with at least one input object, but this object can be as far as possible within an incident face. Thus, the bounding functions serve as optimistic and pessimistic estimates of the distance from Q to the nearest object inside r .

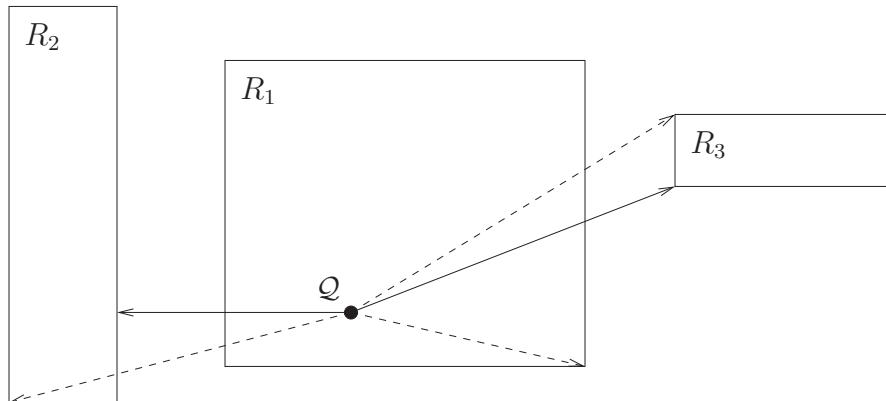

FIGURE 22.6 Illustration of mindist (solid) and minmaxdist (dashed) for three rectangles. Notice that $\text{mindist}(Q, R_1) = 0$ because $Q \in R_1$.

```

findNearestNeighbor(Q,v)
  if v is a leaf then
    foreach rectangle r in v do
      if dist(Q,r) < bestDistance then
        bestDistance ← dist(Q,r)
  else
    produce a list L of all entries (of the form (r,w)) in v
    sort L according to sorting criterion
    prune L using property P1
    while L is not empty do
      retrieve and remove next entry (r,w) from L
      findNearestNeighbor(Q,w)
      prune L using property P2
end

```

FIGURE 22.7 Nearest neighbor algorithm of [39].

The following properties of the bounding functions readily follow:

- P1** For any object or MBR r and MBR s , if $\text{mindist}(Q,r) > \text{minmaxdist}(Q,s)$ then r cannot be or contain the nearest neighbor of Q .
- P2** For any MBR r and object s , if $\text{mindist}(Q,r) > \text{dist}(Q,s)$ then r cannot contain the nearest neighbor of Q .

The authors describe a branch-and-bound algorithm that performs a depth-first traversal of the tree and keeps track of the best distance so far. The two properties above are used to identify and prune branches that are guaranteed not to contain the answer. For each call the algorithm keeps a list of active nodes, that is, nodes that tentatively need to be explored in search of a better estimate. No node of the list is explored until the subtrees corresponding to nodes appearing earlier in the active list have been processed or pruned. Thus, a sorting policy to determine the order in which rectangles stored in a node are processed is also required. In practice one would like to examine first those nodes that lower the best distance estimate as quickly as possible, but this order is difficult to determine a priori. Two criteria considered include sorting by mindist and by minmaxdist. Experimental results suggest that sorting by mindist results in slightly better performance. The algorithm is summarized in Figure 22.7. Global variable bestDistance stores the estimate of the distance to the nearest neighbor. The initial call uses the query and root of the tree as arguments.

A simple modification to the above algorithm allows [39] to report the $k > 1$ nearest neighbors of Q . All is needed is to keep track of the best k distances encountered so far and to perform the pruning with respect to the k -th best.

Cheung and Fu [37] show that pruning based on P1 is not necessary and do away with computing minmaxdist altogether. They simplify the algorithm by pruning with P2 exclusively, and by rearranging the code so that the pruning step occurs before, and not after, each recursive call.

Hjaltason and Samet [45] also describe an algorithm that avoids using P1. Furthermore, unlike [39] which keeps a local list of active entries for each recursive call, their algorithm uses a global priority queue of active entries sorted by the optimistic distance from Q to that entry. This modification minimizes the number of R-tree nodes retrieved and results in an incremental algorithm, that is, one that reports answers in increasing order of distance, a desirable characteristic when the value of k is not known a priori.

22.4.2 Spatial Joins

We consider the problem of calculating the intersection of two sets $R = \{r_1, r_2, \dots, r_n\}$ and $S = \{s_1, s_2, \dots, s_m\}$ of spatial objects. The spatial join, $R \bowtie S$, is the set of all pairs (r_i, s_j) such that $r_i \cap s_j \neq \emptyset$. The join of two spatial data sets is a useful and common operation. Consider, for example, the rivers and roads of a region, both represented using line segments. The spatial join of the river and road data sets yields the set of likely bridge locations. If the subset of river segments whose level is above a given threshold has been previously selected, the same spatial join now computes likely locations for road flooding.

Methods to compute spatial joins without R-trees exist but are not covered in this chapter. We consider the case where R-trees have been constructed for one or both data sets and hence can be used to facilitate the join computation. Unless otherwise stated, we will assume that the r_i 's and s_j 's refer to the MBRs enclosing the actual data objects.

```

SpatialJoin( $v_1, v_2$ )
  foreach entry  $E_{1j} \in v_1$  do
    foreach entry  $E_{2j} \in v_2$  such that  $R_{1j} \cap R_{2j} \neq \emptyset$  do
      if  $v_1$  and  $v_2$  are leaf nodes then
        output entries  $E_{1j}$  and  $E_{2j}$ 
      else
        Read the nodes pointed to by  $p_{1j}$  and  $p_{2j}$ 
        SpatialJoin( $p_{1j}, p_{2j}$ )
  End

```

FIGURE 22.8 Spatial join algorithm of [49] for two R-trees.

In Reference 49, Brinkhoff et al. proposed the “canonical” spatial join algorithm based on R-trees. A similar join algorithm was proposed at the same time by Gunther [50]. Gunther’s algorithm is applicable for general trees and includes R-trees as a special case. In Figure 22.8 we paraphrase the algorithm of [49]. Let v_1 and v_2 be nodes of R-trees T_1 and T_2 , respectively. Let E_{ij} be an entry of v_i of the form (r_{ij}, p_{ij}) , where r_{ij} and p_{ij} denote the MBR and child pointer, respectively. To join data sets R and S , indexed by R-trees T_1 and T_2 , invoke the SpatialJoin algorithm in Figure 22.8, passing as arguments the roots of T_1 and T_2 .

In Reference 49 the authors generalize the algorithm for the case where the two R-trees have different heights. They also improve upon the basic algorithm by reducing CPU computation and disk accesses. The CPU time is improved by reducing the number of rectangle intersection checks. One method to accomplish this is to first calculate the subset of entries within nodes v_1 and v_2 that intersect $\text{MBR}(v_1) \cap \text{MBR}(v_2)$, and then do full intersection tests among this subset. A second approach is to sort the entries and then use a sweep-line algorithm. In addition, the paper considers reduction of page I/O by ordering the accesses to pages so as to improve the buffer hit ratio. This is done by accessing the data in sweep-line order or Z-order.

In Reference 48 Brinkhoff et al. suggest the following 3-step approach for joining complex polygonal data sets: (1) use the R-trees and MBRs of the data sets to reduce the set to a list of potential hits; (2) use a lightweight approximation algorithm to further reduce the set, leaving in some “false positives”; (3) conduct the exact intersection tests on the remaining polygons using techniques from computational geometry (see Chapter 2 of [58], for example).

Often only one of the data sets to be joined will be indexed by an R-tree. This is the case when the DBA decides that maintaining an index is too expensive, when the data set being joined is the result of a series of non-spatial attribute selections, or for multi-step joins where intermediate results are not indexed.

To join two data sets when only one is indexed by an R-tree, Lo and Ravishankar [52] propose the idea of *seeded tree join*. The main idea is to use the existing R-tree to “seed” the creation of a new index, called the seeded tree, for the non-indexed data set, and then perform a join using the method of [49].

Consider the example shown in Figure 22.9 (similar to the example in Reference 52). Assume that the existing tree has four entries in the root node. The four rectangles, R1 to R4, in the left hand side represent the bounding rectangles of these entries. The dark filled squares do not belong to the existing R-tree but, rather, correspond to some of the data items in the non-indexed data set. Assuming a node capacity of four (i.e., $B = 4$) and using the normal insertion or loading algorithms which minimize area and perimeter, the dark rectangles would likely be grouped as shown by the dark MBRs in Figure 22.9b. A spatial join would then require that each node of each tree be joined with two nodes from the other tree, for a total of eight pairs. On the other hand, if the second R-tree was structured as show in Figure 22.9c, then each node would be joined with only one node from the other tree, for a total of four pairs. Hence, when performing a spatial join, it might be better to structure the top levels of the tree in a fashion that is sub-optimal for general window queries.

The general algorithm for seeded tree creation is to copy the top few levels of the existing tree and use them as the top levels for the new tree. These top levels are called the seed levels. The entries at the lowest seed level are called “slots”. Non-indexed data items are then inserted into the seeded tree by inserting them into an R-tree that is built under the appropriate slot. In Reference 52 the authors experimentally compare three join algorithms: (1) R-tree join, where an R-tree is first built on the non-indexed data set and then joined; (2) brute force, where the non-indexed data set is read sequentially and a region query is run against the existing R-tree for each data item in the non-indexed data set; (3) seeded tree join, where a seeded tree is built and then joined. The authors consider several variants of the seeded tree creation algorithm and compare the performance. Experimental studies show that the seeded tree method significantly reduces I/O. Note that if the entire seeded tree does not fit in memory significant I/O can occur during the building process. The authors propose to minimize this I/O by buffering runs for the slots and then building the tree for each slot during a second pass.

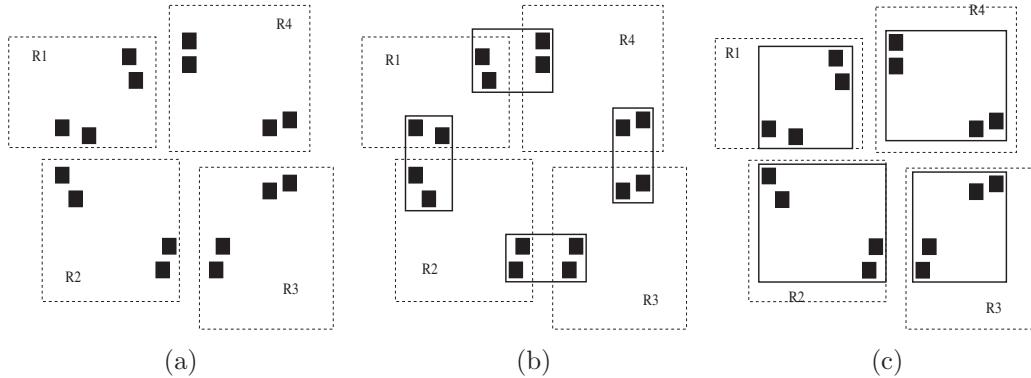

FIGURE 22.9 Seeded Tree Example. (a) Existing R-tree and non-indexed data (dark squares); (b) Normal R-tree structure for non-indexed data; (c) Seeded structure.

Another approach [51] for the one-index case is to sort the non-indexed data using the MBR lower endpoints for one of the dimensions, sort the leaf level MBRs from the existing R-tree on the same dimension, and finally join the two sorted data sets using a sweep-line algorithm. The authors analytically demonstrate that as long as the buffer size is sufficient to merge-sort efficiently, their algorithm results in less I/O than creating any type of index followed by a join. Experimental results also show a significant I/O reduction.

In Reference 56 a relational hash-based join approach is used. Although mostly hash-based, the method does need to default to R-trees in some cases. A sampled subset of R is partitioned into N buckets, $R_1 \dots R_N$, for some N . Each non-sampled object from R is then added to the bucket that requires the least enlargement. Set S is then partitioned in N corresponding buckets, $S_1 \dots S_N$ by testing each object o_S of S and placing a copy of it into S_i , for each bucket R_i such that $o_S \cap R_i \neq \emptyset$. If an object in S does not intersect any of the R_i buckets the object is discarded. The bucket pairs (R_i, S_i) are then read into memory and pairwise joined. If a bucket pair is too large to fit in memory, an R-tree index is built for one of the two buckets and an index-loop join is used.

In References 53 and 55 a method that combines the seeded tree and the hash-join approach is proposed. The proposed method, *slot index spatial join*, chooses a level from the existing tree and uses the MBRs of the entries as the buckets for the hashing. The chosen level is determined by the number of entries at that level and the number of buffer pages available for the bucket joining algorithm. Since R-trees have a wide fan out, the optimal number of buckets to use usually falls between level sizes. The paper considers several heuristics for combining MBRs from the next level down to tune the number of buckets. Overall performance is shown to be better than all previously existing methods in all but a few cases.

A method to join multiple spatial relations together is discussed in Reference 53 and 54. The authors propose a multi-way join algorithm called *synchronous traversal* and develop cost models to use for query optimization. They consider using only pairwise joins, only the synchronous traversal method, and combinations of the two approaches. They show that, in general, a combination of the two results in the best performance.

The concept of spatial join has been further generalized to *distance joins*, where a distance based ordering of a subset of the Cartesian product of the two sets is returned. In References 45 and 57, distance join algorithms using R-trees are proposed.

22.5 Analytical Models

Analytical models of R-trees provide performance estimates based on the assumptions of the model. Such models can be useful for gaining insight, comparing algorithms, and for query optimization.

Early analytical models for range queries were proposed by Kamel and Faloutsos [25], and Pagel et al. [59]. The models are similar and use the MBRs of all nodes in the tree as inputs to the model. They derive the probability that Q intersects a given MBR, and use this estimate to compute the expected number of MBRs intersected by Q . In References 60 and 61 the basic model was modified to correct for an error that may arise for MBRs near the boundary of the query sample space. In order to do this, [61] assumes that all queries fall completely within the data space. The changes necessary to handle different sample spaces are straightforward.

The models provide good insight into the problem, especially by establishing a quantitative relationship between performance and the total area and perimeter of MBRs of the tree nodes. We describe the model as presented in Reference 61.

Consider a 2-dimensional data set consisting of rectangles to be stored in an R-tree T with $h + 1$ levels, labeled 0 through h . Assume all input rectangles have been normalized to fit within the unit square $U = [0, 1] \times [0, 1]$. Queries are rectangles Q of size

$q_x \times q_y$. (A point query corresponds to the case $q_x = q_y = 0$.) Initially assume that queries are uniformly distributed over the unit square. Although this description concentrates on 2-d, generalizations to higher dimensions are straightforward.

Assume the following notation:

- m_i = number of nodes at the i th level of T
- m = Total number nodes in T , that is, $\sum_{i=0}^h m_i$
- R_{ij} = j th rectangle at the i th level of T
- X_{ij} = x -extent (width) of R_{ij}
- Y_{ij} = y -extent (height) of R_{ij}
- A_{ij} = area of R_{ij} , that is, $A_{ij} = X_{ij} \cdot Y_{ij}$
- A_{ij}^Q = probability that R_{ij} is accessed by query Q
- B_{ij} = number of accesses to R_{ij}
- \mathcal{A} = Sum of the areas of all MBRs in T
- L_x = Sum of the x -extents of all MBRs in T
- L_y = Sum of the y -extents of all MBRs in T
- N = number of queries performed so far
- N^* = expected number of queries required to fill the buffer
- β = buffer size
- $D(N)$ = number of distinct nodes (at all levels) accessed in N queries
- $E_T^P(q_x, q_y)$ = expected number of nodes (buffer resident or not) of T accessed while performing a query of size $q_x \times q_y$
- $E_T^D(q_x, q_y)$ = expected number of disk accesses while performing a query of size $q_x \times q_y$

The authors of [25,59] assume that performance is measured by the number of nodes accessed (independent of buffering). They observe that for uniform point queries the probability of accessing R_{ij} is just the area of R_{ij} , namely, A_{ij} . They point out that the level of T in which R_{ij} resides is immaterial as all rectangles containing Q (and only those) need to be retrieved. Accordingly, for a point query, the expected number of nodes retrieved as derived in Reference 25 is the sum of node areas^{*}:

$$E_T^P(0, 0) = \sum_{i=0}^h \sum_{j=1}^{m_i} A_{ij} = \mathcal{A} \quad (22.1)$$

which is the sum of the areas of all rectangles (both leaf level MBRs as well as MBRs of internal nodes).

We now turn our attention to region queries. Let $\langle(a, b), (c, d)\rangle$ denote an axis-parallel rectangle with bottom left and top right corners (a, b) and (c, d) , respectively. Consider a rectangular query $Q = \langle Q_{bl}, Q_{tr} \rangle$ of size $q_x \times q_y$. Q intersects $R = \langle(a, b), (c, d)\rangle$ if and only if Q_{tr} (the top right corner of Q) is inside the *extended rectangle* $R' = \langle(a, b), (c + q_x, d + q_y)\rangle$, as illustrated in Figure 22.10.

Kamel and Faloutsos infer that the probability of accessing R while performing Q is the area of R' , as the region query Q is equivalent to a point query Q_{tr} where *all* rectangles in T have been extended as outlined above. Thus, the expected number of

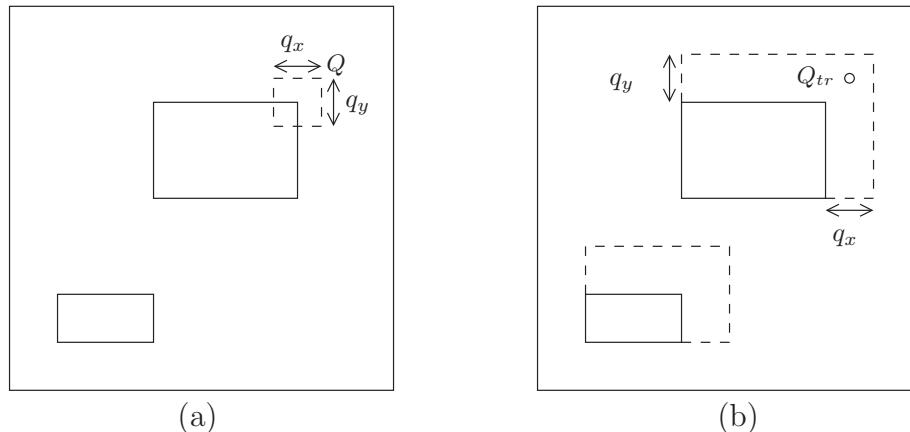

FIGURE 22.10 (a) Two data rectangles and region query Q . (b) Corresponding extended rectangles and equivalent point query Q_{tr} .

* We have modified the notation of [25] to make it consistent with the notation used here.

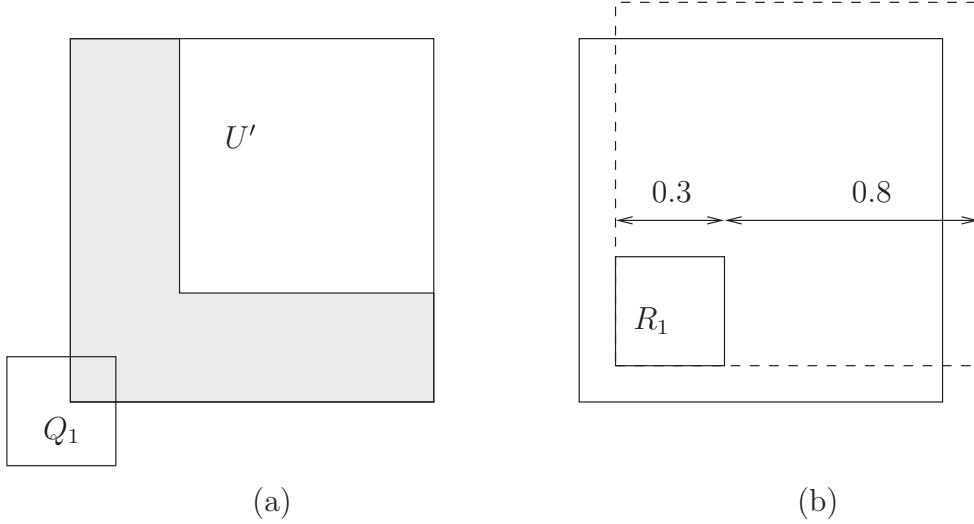

FIGURE 22.11 The domain of Q_{tr} for a query of size 0.3×0.3 is U' (area not shaded).

nodes retrieved (as derived in Reference 25) is:

$$\begin{aligned}
 E_T^P(q_x, q_y) &= \sum_{i=0}^h \sum_{j=1}^{m_i} (X_{ij} + q_x)(Y_{ij} + q_y) \\
 &= \sum_{i=0}^h \sum_{j=1}^{m_i} X_{ij} Y_{ij} + q_x \sum_{i=0}^h \sum_{j=1}^{m_i} Y_{ij} + q_y \sum_{i=0}^h \sum_{j=1}^{m_i} X_{ij} + mq_x q_y \\
 &= \mathcal{A} + q_x L_y + q_y L_x + mq_x q_y
 \end{aligned} \tag{22.2}$$

Equation 22.3 illustrates the fact that a good insertion/loading algorithm should cluster rectangles so as to minimize both the total area and total perimeter of the MBRs of all nodes. For point queries, on the other hand, $q_x = q_y = 0$, and minimizing the total area is enough.

In Reference 61 the model of [25] was modified to handle query windows that fall partially outside the data space as well as data rectangles close to the boundary of the data space, as suggested by Six et al. [59]. Specifically:

1. For uniformly distributed rectangular queries of size $q_x \times q_y$ the top right corner of the query region Q , cannot be an arbitrary point inside the unit square if the entire query region is to fit within the unit square. For example, if $q_x = q_y = 0.3$, a query such as Q_1 in Figure 22.11a should not be allowed. Rather, Q_{tr} must be inside the box $U' = [q_x, 1] \times [q_y, 1]$.
2. The probability of accessing a rectangle $R = ((a, b), (c, d))$ is *not always* the area of $R' = ((a, b), (c + q_x, d + q_y))$ as this value can be bigger than one. For example, in Figure 22.11b, the probability that a query of size 0.8×0.8 accesses rectangle R_1 should not be $1.1 \cdot 1.1 = 1.21$, which is the area of the extended rectangle R'_1 , obtained by applying the original formula. Rather, the access probability is the percentage of U' covered by the rectangle $R' \cap U'$.

Thus, we change the probability of accessing rectangle i of level j to:

$$\begin{aligned}
 A_{ij}^Q &= \frac{\text{area}(R' \cap U')}{\text{area}(U')} \\
 &= \frac{C \cdot D}{(1 - q_x)(1 - q_y)}
 \end{aligned} \tag{22.3}$$

where $C = [\min(1, c + q_x) - \max(a, q_x)]$ and $D = [\min(1, d + q_y) - \max(b, q_y)]$.

In Reference 62 the R-tree model was expanded to take into account the distribution of the input data. Specifically, rather than being uniformly distributed, the query regions were assumed to be distributed according to the input data distribution.

The above models do not consider the impact of the buffer. In Reference 62 a buffer model is integrated with the query model. Specifically, under uniformly distributed point queries, the probability of accessing rectangle R_{ij} while performing a query is

A_{ij} . Accordingly, the probability that R_{ij} is not accessed during the next N queries is $P[B_{ij} = 0|N] = (1 - A_{ij})^N$. Thus, $P[B_{ij} \geq 1|N] = 1 - (1 - A_{ij})^N$ and the expected number of *distinct* nodes accessed in N queries is,

$$D(N) = \sum_{i=0}^h \sum_{j=1}^{m_i} P[B_{ij} \geq 1|N] = m - \sum_{i=0}^h \sum_{j=1}^{m_i} (1 - A_{ij})^N \quad (22.4)$$

Note that $D(0) = 0 < \beta$ and $D(1) = \mathcal{A}$ (which may or may not be bigger than β). The buffer, which is initially empty, first becomes full after performing N^* queries, where N^* is the smallest integer that satisfies $D(N^*) \geq \beta$. The value of N^* can be determined by a simple binary search.

While the buffer is not full the probability that R_{ij} is in the buffer is equal to $P[B_{ij} \geq 1]$. The probability that a random query requires a disk access for R_{ij} is $A_{ij} \cdot P[B_{ij} = 0]$. Since the steady state buffer hit probability is approximately the same as the buffer hit probability after N^* queries, the expected number of disk accesses for a point query at steady state is

$$\sum_{i=0}^h \sum_{j=1}^{m_i} A_{ij} \cdot P[B_{ij} = 0|N^*] = \sum_{i=0}^h \sum_{j=1}^{m_i} A_{ij} \cdot (1 - A_{ij})^{N^*} \quad (22.5)$$

The above derivation also holds for region queries provided that A_{ij}^Q is used instead of A_{ij} , that is:

$$E_T^D(q_x, q_y) = \sum_{i=0}^h \sum_{j=1}^{m_i} A_{ij}^Q \cdot (1 - A_{ij}^Q)^{N^*}$$

In Reference 61 the authors compare the model to simulation and explore the I/O impact of pinning the top levels of an R-tree into the buffer.

Other analytical models include the following. Theodoridis and Sellis [63] provide a fully analytical model that does not require the R-tree MBRs as input. In Reference 64, a technique is developed for analyzing R-tree performance with skewed data distributions. The technique uses the concept of fractal dimension to characterize the data set and resultant R-tree performance. Analysis has also been used for estimating the performance of R-tree based spatial joins [65,66] and nearest neighbor queries [67,68].

23.1 Introduction and Background

The term spatiotemporal incorporates the two indispensable phenomena of space and time that characterize many objects in the real world. Spatial databases represent, store, and manipulate spatial data in the form of points, lines, areas, surfaces, and hyper-volumes in multidimensional space. Most of these databases suffer from, what is commonly called, the “Curse of Dimensionality” [1]. In the literature, curse of dimensionality refers to a performance degradation of similarity queries with increasing dimensionality of these databases. One way to reduce this curse is to develop data structures for indexing such databases for efficient similarity query handling. Specialized data structures such as R-trees and its variants (see [Chapter 22](#)) have been proposed for this purpose which have demonstrated multifold performance gains in access time on this data over sequential search. On the other hand, temporal databases store time-variant data.

Traditional spatial data structures can store only one “copy” of the data, latest at the “present time,” while we frequently encounter applications where we need to store more than one copy of the data. While spatial data structures typically handle objects having spatial components and temporal data structures handle time-variant objects, research in spatiotemporal data structures (STDS) and data models have concentrated around storing moving points and moving objects, or objects with geometries changing over time.

Some examples of domains generating spatiotemporal data include but are not limited to the following: geographical information systems, urban planning systems, communication systems, multimedia systems, and traffic planning systems. Moreover [2], advanced spatiotemporal analyses based on trajectory indexing techniques are used in such areas as behavioral pattern analysis and intelligent transportation decisions. While the assemblage of spatiotemporal data is growing, the development of efficient data structures for storage and retrieval of these data types has not kept pace with this increase. Research in spatiotemporal data abstraction is strewn but there are some important research results in this area that have laid elemental foundation for the development of novel structures for these data types. In this chapter, we will present an assortment of key modeling strategies for spatiotemporal data types.

In spatiotemporal databases (STB), two concepts of times are usually considered: *transaction* and *valid* time. According to Jensen et al. [3], transaction time is the time during which a piece of data is recorded in a relation and may be retrieved. Valid time is a time during which a fact is true in the modeled reality. The valid time can be in the future or in the past.

There are two major directions [4] in the development of STDS. The first direction is space-driven structures, which have indexing based upon the partitioning of the embedding multidimensional space into cells, independent of the distribution of

the data in this space. An example of such a space-driven data structure is multiversion linear quadtree (MVLQ) for storing spatiotemporal data. The other direction for storing spatiotemporal data is data-driven structures. These structures partition the set of the data objects rather than the embedding space. Examples of data-driven structures include those based upon R-trees and its variants.

23.1.1 Spatiotemporal Indexing Techniques

A key concept that is worth mentioning earlier in our discussion is indexing in STDS. Generally, indexing methods are influenced by a series of factors such as index generation efficiency, storage utilization, query performance, query type, and caching mechanisms. Theoretically, traditional indexing techniques can be used to access spatiotemporal data, for example, a one-dimensional compound indexes based on B-tree variants can be built for multidimensional data like spatiotemporal data where multidimensional spatiotemporal data are transformed into one-dimensional sorting codes. R-tree and Octree can be extended into spatiotemporal indexes, in which time is viewed as another dimension in addition to spatial dimensions. However, concerns over such issues as index generation performance degradation and overall query processing efficiency have led to the quest for hybrid type of indexing methods, such as HBSTR-tree [2], which combines Hash table, B*-tree, and spatiotemporal R-tree to handle trajectory data processing. Currently, three groups of indexes can be identified. The first group is based on multiversion structures in which each timestamp corresponds to a spatial index structure and unchanged nodes are shared between versions, such as HR-tree and MV3R-tree [5]; next are those based on spatial partition methods, such as SETI and CSE, in which trajectory points are firstly divided into respective spatial partitions and then a temporal index is generated for points in each partition [6]; and lastly, those indexes such as STR-tree and TB-tree that are extensions from traditional spatial indexes such as R-tree with the unique ability to adaptively adjust index structures according to generation performance [7]. A more recently proposed technique in Reference 8 utilizes a parallel indexing technique to extend a two-dimensional spatial interval representation of intervals to a multidimensional parallel space and uses a set of formulas to transform spatiotemporal queries into parallel interval set operations. This transformation results in reducing the problem of multidimensional object relationships to simpler two-dimensional spatial intersection problems. In their survey work on predictive spatiotemporal queries, Hendawi and Mokbel [9] mention a data structure-based spatiotemporal indexing as the most popular technique in the literature, with the following categories:

1. *R-tree based*: These include time parameterized R-tree, TPR-tree, and TPR*-tree which are formed by the addition of a time parameter that supports querying current and projected future positions of moving objects, and others based on convex hull property for indexing objects with nonlinear trajectories using a traditional index structure.
2. *B-tree based*: Examples here include B^x-tree that uses a linear technique to index changes in the underlying data values such as moving objects locations and utilized in algorithms for predictive range queries and KNN queries on near-future positions of the indexed objects; others in this category include the self-tunable spatiotemporal B + -tree (SP² B-tree) for handling frequent updates for objects locations by allowing automatic online rebuilding of its subtrees using a different set of reference points and different grid size without significant overhead.
3. *kd-tree based*: This category is based on the kd-tree data structure presented in Reference 7 and its main idea to create new indexes for the most updated pieces of the main index and then throw them away from the main memory after some short time period. An example of this is the MOVIES, for (MOVing objects Indexing using frequent Snapshots) technique [10,11] that is characterized as providing support for time-parameterized predictive queries with the qualities of being space-, query-, update-, and multi-CPU efficient.
4. *Quadtree based*: This is a dual scheme that is used to index the predicted trajectories of moving objects in a dual transformed space such that trajectories for objects in d -dimensional space become points in a higher 2D-dimensional space, where this dual transformed space is then indexed using a regular hierarchical grid decomposition indexing structure.

In this chapter, we will discuss both space-driven and data-driven data structures for storing spatiotemporal data. We will initiate our discussion with MVLQ space-driven data structure.

23.2 Overlapping Linear Quadtree

Tzouramanis et al. [12] proposed multiversion linear quadtrees (MVLQ), also called overlapping linear quadtrees, which are analogous to multiversion B-trees (MVBT) [13], but with significant differences. Instead of storing transaction time for each individual object in MVBT, an MVLQ consolidates object descriptors that share a common transaction time. As it will be evident from the following discussion, these object descriptors are code words derived from a linear representation of multiversion quadtrees.

The idea of storing temporal information about the objects is based upon including a parameter for transaction time for these objects. Each object is given a unique timestamp T_i (transaction time), where $i \in [1 \dots n]$ and n is the number of objects in the

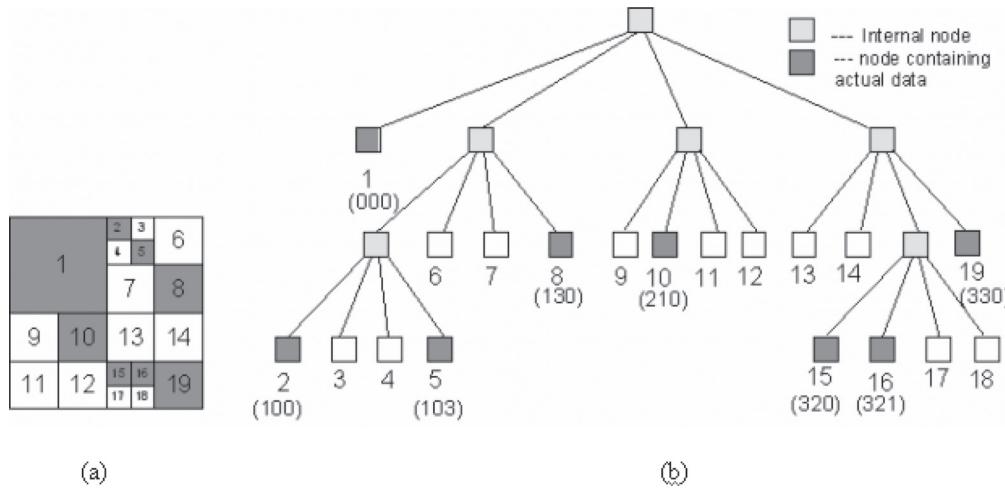

FIGURE 23.1 (a) A binary $2^3 \times 2^3$ image and (b) its corresponding region quadtree. The location codes for the homogeneous codes are indicated in brackets.

database. This timestamp implicitly associates a time value to each record representing the object. Initially, when the object is created in the database, this time interval is set equal to $[T_i, *]$. Here, “*” refers to *as-of-now*, a usage indicating that the current object is valid until a unspecified time in the future, when it would be terminated (at that time, * will be replaced by the T_j , $j \in [1 \dots n]$ and $j > i$, the timestamp for when the object is terminated).

Before we proceed further, let us gather some brief background in regional Quadtrees, commonly called quadtrees, a spatial data structure. In the following discussion, it is assumed that an STDS is required to be developed for a sequence of evolving regional images, which are stored in an image database. Each image is assumed to be represented as a $2^N \times 2^N$ matrix of pixel values, where N is a positive integer.

Quadtree is a modification of T-pyramid. Every node of the tree, except the leaves, has four children (NW: north-western, NE: north-eastern, SW: south-western, SE: south-eastern). The image is divided into four equal quadrants at each hierarchical level, but it is not necessary to store nodes at all levels. If a parent node has four children of the same homogeneous (e.g., intensity) value, it is not necessary to record them. Figure 23.1 represents an image and its corresponding quadtree representation. Quadtree is a memory-resident data structure, with each node being stored as a record pointing to its children. However, when the represented object becomes too large it may not be possible to store the entire quadtree in the main memory. The strategy that is followed at this point is that the homogeneous components of the quadtrees are stored in a B+ tree, a secondary memory data structure, eliminating the need of pointers in quadtree representation. In this case, addresses representing the location of the homogeneous node and its size constitute a record. Such a version of Quadtree is called linear region quadtree [14].

Several linear representations of regional quadtrees have been proposed, but fixed length (FL), fixed length-depth (FD), and variable length (VL) versions have attracted most attention. We refer the interested reader to Reference 14 for details on these representations, while we concentrate on the FD representation. In this representation, each homogeneous node is represented by a pair of two codes, *location code* and *level number*. Location node C denotes the correct path to this node when traversing the Quadtree from its root till the appropriate leaf is reached and a level number L refers to the level at which the node is located. This makes up the FD linear implementation of Quadtree. The quadrants NW, NE, SW, and SE are represented as 0, 1, 2, and 3, respectively. The location codes for the homogeneous nodes of a quadtree are presented in Figure 23.1.

A persistent data structure (see Chapter 33) [15] is one in which a change to the structure can be made without eliminating the old version, so that all versions of the structure persist and can at least be accessed (the structure is said to be partially persistent) or even modified (the structure is said to be fully persistent). MVLQ is an example of a persistent data structure, in contrast to Linear Quadtree, a transient data structure. In MVLQ, each object in the database is labeled with a time for maintaining the past states. MVLQ couples time intervals with spatial objects in each node.

The leaf of the MVLQ contains the data records of the format:

$$<(C, L), T, EndTime>$$

where

C is the location code of the homogeneous node of the region quadtree,

L is the level of the region quadtree at which the homogeneous node is present,

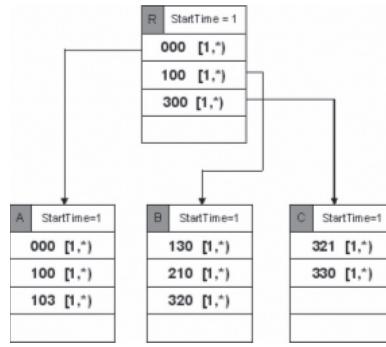

FIGURE 23.2 MVLQ structure after the insertion of image given in Figure 23.1a.

T represents the time interval when the homogeneous node appears in the image sequence, $EndTime$ is transaction time when the homogeneous leaf node becomes historical.

The nonleaf nodes contain entries of the form [12]:

$$< C', P', ptr, StartTime >$$

where

C' is the smallest C recorded in that descendant node,

P' is the time interval that expresses the lifespan of the latter node,

Ptr is a pointer to a descendant node,

$StartTime$ is the time instant when the node was created.

The MVLQ structure after the insertion of image given in Figure 23.1a is given in Figure 23.2.

In addition to the main memory structure of the MVLQ described earlier, it also contains two additional main memory substructures: $Root^*table$ and Depth First expression (DF -expression) of the last inserted object.

$Root^*table$: MVLQ has one tree for each version of the data. Consequently, each version can be reached through its root which can be identified by the time interval of the version that it represents and a pointer to its location. If T'' is the time interval of the root, given by $T'' = [T_i, T_j]$, where $i, j \in [1 \dots n]$, $i < j$, and ptr' is a pointer to the physical address of the root, then each record in the $Root^*table$ identifying a root is represented in the following form:

$$< T'', ptr' >$$

DF -expression of the last inserted object [12,16]: The purpose of Depth first expression (DF -expression) is to contain the prefetched location of the homogeneous nodes of last insert data object. The advantage of this storage is that when a new data object is being inserted, the stored information can be used to calculate the cost of deletions, insertions, and/or updates. If the DF -expression is not stored, then there is an input/output cost associated with locating the last insert object's homogeneous nodes locations. The DF -expression is an array representation of preorder traversal of the last inserted object's Quadtree.

23.2.1 Insertion of an Object in MVLQ

The first step in insertion of a quadcode of a new object involves identifying the corresponding leaf node. If the corresponding leaf node is full, then a node overflow [12] occurs. Two possibilities may arise at this stage, and depending on the $StartTime$ field of the leaf, a split may be initiated. If NC is the node capacity, k and c are integer constants (greater than zero), then the insertion is performed based on the algorithm presented in Figure 23.3.

23.2.2 Deletion of an Object in MVLQ

The algorithm for the deletion of an object from MVLQ is straightforward. If $T_i = StartTime$, then *physical deletion* occurs and the appropriate entry of the object is deleted from the leaf. If number of entries in the leaf $< \lceil NC/k \rceil$ (threshold), then a *node-underflow* is handled as in B+ tree with an additional step of checking for a sibling's $StartTime$ for key redistribution. If $T_i > StartTime$, then *logical deletion* occurs and the temporal information of an entry between range $([T_i, *), [T_i, T_j))$ is updated. If an entry is logically deleted in a leaf with exactly $\lceil NC/k \rceil$ present quadcode versions, then a *version underflow* [13] occurs that causes a version split of the node, copying the present versions of its quadcodes into a new node. After version split, the number of present versions of quadcodes is below $(1 + e) \lceil NC/k \rceil$ and a merge is then attempted with a sibling or a copy of that sibling.

```

If  $T_i = StartTime$ 
    // Key-split Old-leaf into Old-leaf and New-leaf
    Old-leaf = First  $\lceil NC/2 \rceil$  entries of Old-leaf
    New-Leaf = Remaining entries for the corresponding leaf
If  $T_i > StartTime$ 
    // Version-Split the node: Make copy of the old leaf and remove
    // all past entries from the copy leaf. Number of present versions
    // of the quadcodes after version split is within range
    //  $[(1+c)*(NC/k), (k-c)*(NC/k)]$ .
    If Number of versions after version-split <  $(1+c)*(NC/k)$ 
        Attempt merging with a sibling or a copy of a sibling
        containing present version of the quadcode.
    If Number of versions after version-split >  $(k-e)*(NC/k)$ 
        Key-Split the node.

```

FIGURE 23.3 Algorithm for an insertion of an object in MVLQ.

23.2.3 Updating an Object in MVLQ

Updating a leaf entry refers to update of the field L (level) of the object's code. This is implemented in a two-step fashion. First, a logical deletion of the entry is performed. Second, the new version is inserted in place of that entry through the steps outlined above.

23.3 3D R-Tree

In the previous section, a space-driven, MVLQ-based STDS was presented. In this section, we discuss a data-driven data structure that partitions the set of objects for efficient spatiotemporal representation.

Theodoridis et al. [17] have proposed a data structure termed 3D R-tree for indexing spatiotemporal information for large multimedia applications. The data structure is a derivation of R-trees (see Chapter 22) whose variants have been demonstrated to be an efficient indexing schema for high-dimensional spatial objects.

Theodoridis et al. [17] have adopted a set of operators defined by Papadias and Theodoridis [18] to represent possible topological-directional spatial relationships between two 2-dimensional objects. An anthology of 169 relationships $R_{i,j}$ ($i \in [1 \dots 13], j \in [1 \dots 13]$) can represent a complete set of spatial operators. Figure 23.4 represents these relations. An interested reader can find a complete illustration of these topographical relationships in Reference 18. To represent the temporal relationships, a set of temporal operators defined in Reference 19 are employed. Any spatiotemporal relationships among objects can be found using these operators. For example, object Q to appear 7 seconds after the object P, 14 cm to the right and 2 cm down the right bottom vertex of object P can be represented as the following composition tuple:

$$R_t = P[(r_{13_13}, v3, v4, 14, 2), (-7 - >)]Q$$

where r_{13_13} is the corresponding spatial relationship, $(-7 - >)$ is the temporal relationship between the objects, $v3$ and $v4$ are the named vertices of the objects while $(14, 2)$ are their spatial distances on the two axes.

Theodoridis et al. have employed the following typical spatiotemporal relationships to illustrate their indexing schema [17]. These relationships can be defined as *spatiotemporal operators*.

- *overlap_during(a, b)*: returns the catalogue of objects a that spatially overlap object b during its execution.
- *overlap_before(a, b)*: returns the catalogue of objects a that spatially overlap object b and their execution terminates before the start of execution of b .
- *above_during(a, b)*: returns the catalogue of objects a that spatially lie above object b during the course of its execution.

FIGURE 23.4 Spatial relationships between two objects covering directional-topological information. (From M. Abdelguerfi et al., ACM-GIS, pp. 29–34, 2002.)

- *above_before(a, b)*: returns the catalogue of objects *a* that spatially lie above object *b* and their execution terminates before the start of execution of *b*.

Spatial and temporal features of objects are typically identified by six dimensions (each spatiotemporal object can be perceived as a point in a six-dimensional space):

$(x_1, x_2, y_1, y_2, t_1, t_2)$, where

(x_1, x_2) : Projection of the object on the horizontal plane

(y_1, y_2) : Projection of the object on the vertical plane

(t_1, t_2) : Projection of the object on the time plane.

In a naïve approach, these object descriptors coupled by the object *id* (unique for the object that they represent) can be stored sequentially in a database. An illustration of such an organization is demonstrated in Figure 23.5.

Such a sequential schema has obvious demerits. Answering of spatial-temporal queries, such as one described earlier, would require a full scan of the data organization, at least once. As indicated before, most STB suffer from the curse of dimensionality and sequential organization of data exhibits this curse through depreciated performance, rather than reducing it.

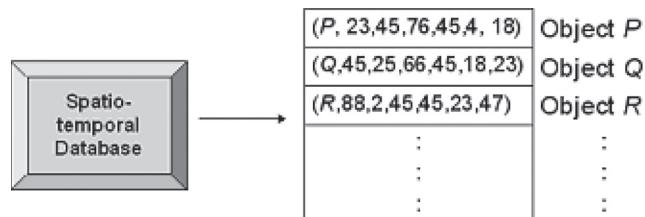

FIGURE 23.5 Schema for sequential organization of spatiotemporal data.

In another schema, two indices can be maintained to store spatial and temporal components separately. Specifically, they can be organized as follows.

1. Spatial index: an index to store the size and coordinates of the objects in two dimensions;
2. Temporal index: a one-dimensional index for storing the duration and start/stop time for objects in one dimension.

R-trees and their variants have been demonstrated to be efficient for storing n -dimensional data. Generally speaking, they could be used to store the spatial space components in a 2D R-tree and temporal components in a 1D R-tree. This schema is better than sequential search, since a tree structure provides a hierarchical organization of data leading to a logarithmic time performance. More details on R-trees and its variants can be found in [Chapter 22](#).

Although this schema is better than sequential searching, it still suffers from a limitation [17]. Consider the query *overlap_during*, which would require that both the indices (spatial 2D R-tree and temporal 1D R-tree) are searched individually (in the first phase) and then the intersection of the recovered answer sets from each of the indices is reported as the index's response to the query. Access to both the indices individually and then postintersection can cumulatively be a computationally expensive procedure, especially when each of these indices is dense. Spatial joins [17,20] have been proposed to handle queries on two indexes, provided these indexing schemas adopt the same spatial data structure. It is not straightforward to extend these to handle joins in two varieties of spatial data structures. Additionally, there might be possible inherent relationships between the spatial descriptors and the temporal descriptors resident in two different indexes which can be learned and exploited for enhanced performance. Arranging and searching these descriptors separately may not be able to exploit these relationships. Hence, a unified framework is needed to present spatiotemporal components preferably in a same indexing schema.

Before we proceed further, let us briefly discuss the similarity search procedure in R-trees. In R-trees, minimum bounding boxes (MBB or minimum bounding rectangles in two dimensions) are used to assign geometric descriptors to objects for similarity applications, especially in data mining [21]. The idea behind the usage of MBB in R-trees is the following. If two objects are disjoint, then their MBBs should be disjoint, and if two objects overlap, then their MBB should definitely overlap. Typically, a spatial query on an MBB-based index involves the following steps.

(1) Searching the index: This step is used to select the answer and some possible false alarms from a given data set, ignoring those records that cannot possibly satisfy the query criterion. (2) Dismissals of false alarms: The input to this step is the resultant of the index searching step. In this step, the false alarms are eliminated to identify correct answers, which are reported as the query response. Designing an indexing schema for a multimedia application requires design of a spatiotemporal indexing structure to support spatiotemporal queries. Consider the following scenario.

EXAMPLE 23.1

An application starts with a video clip A located at point (1,7) relative to the application origin Θ . After 2 minutes, an image B appears inside A with 1 unit above its lower horizontal edge and 3 units after its left vertical edge. B disappears after 2 minutes of its presence, while A continues. After 2 minutes of B's disappearance, an text window C appears 3 units below the lower edge of A and 4 units to the right of left edge of it. A then disappears after 1 minute of C's appearance. The moment A disappears, a small image D appears 2 units to the right of right edge of C and 3 units above the top edge of C. C disappears after 2 minutes of D's appearance. As soon as C disappears, a text box E appears 2 units below the lower edge of D and left aligned with it. E lasts for 4 minutes after which it disappears. D disappears 1 minute after E's disappearance. The application ends with D's disappearance. The spatial layout of the above scenario is presented in [Figure 23.6a](#) and the temporal layout is presented in [Figure 23.6b](#).

A typical query that can be posed on such a database of objects described earlier is “Which objects overlap the object A during its presentation?” In Reference 17, the authors have proposed a unified schema to handle queries on an STB, such as the one stated above. The schema amalgamates the spatial and temporal components in a single data structure such as R-trees to exhibit advantages and performance gains over the other schemas described earlier. This schema amalgamates need of spatial joins on two spatial data structures besides aggregating both attributes under a unified framework. The idea for representation of spatiotemporal attributes is as follows. If an object which initially lies at point (x_a, y_a) during time $[t_a, t_b]$ and at (x_b, y_b) during $[t_b, t_c]$, it can be modeled by two lines $\overline{[(x_a, y_a, t_a), (x_a, y_a, t_b)]}$ and $\overline{[(x_b, y_b, t_b), (x_b, y_b, t_c)]}$. These lines can be presented in a hierarchical R-tree index in three dimensions. [Figure 23.7](#) presents the unified spatial-temporal schema for the spatial and temporal layouts of the example presented above.

23.3.1 Answering Spatiotemporal Queries Using the Unified Schema

Answering queries on the above presented unified schema is similar to handling similarity queries using R-trees. Consider the following queries [17]:

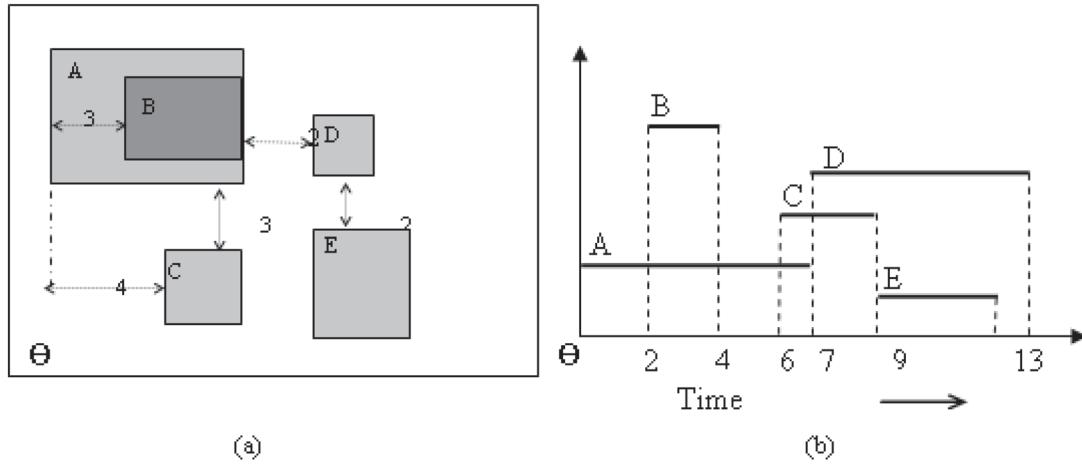

FIGURE 23.6 (a) Spatial layout of the multimedia database and (b) temporal layout of the multimedia database.

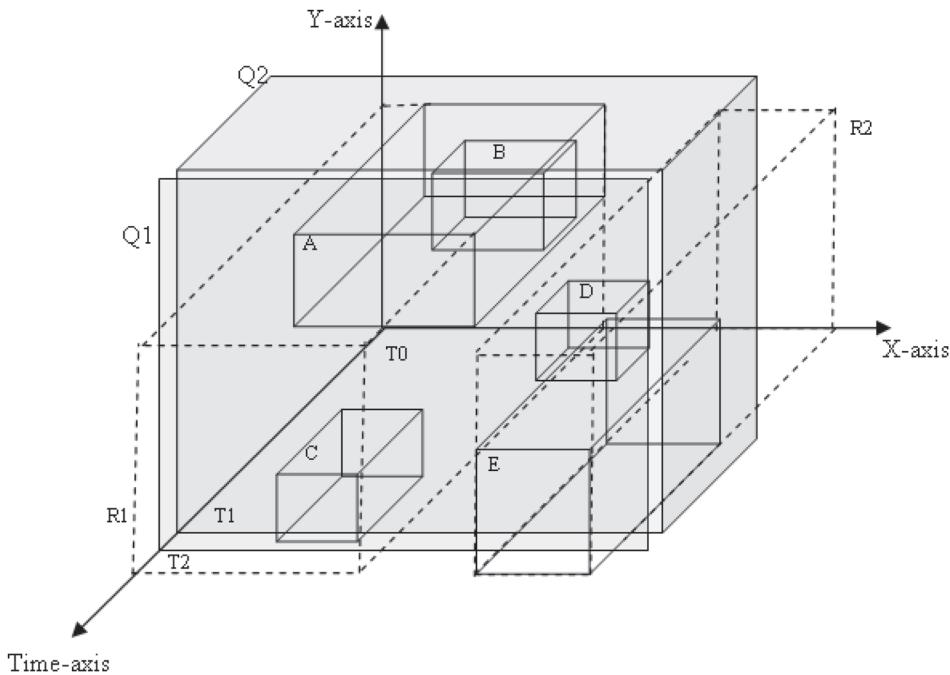

FIGURE 23.7 A unified R-tree-based schema for storing spatial and temporal components.

Query 1: “Find all the objects on the screen at time T_2 ” (spatial layout query). This query can be answered by considering a rectangle Q_1 (Figure 23.7) intersecting the time axis at exactly one point, T_2 .

Query 2: “Find all the objects and their corresponding temporal duration between the time interval (T_0, T_1) ” (temporal layout query). This query can be answered by considering a box Q_2 (Figure 23.7) intersecting the time axis between the intervals (T_0, T_1) .

After we have obtained the objects enclosed by the rectangle Q_1 and box Q_2 , these objects are filtered (in main memory) to obtain the answer set.

Query 3: “Find all the objects and their corresponding spatial layout at time $T = 3$ minutes.” This query can be answered by looking at the screenshot of spatial layout of objects that were present at the given instant of time. The resultant would be the list of objects and their corresponding spatial descriptors. The response to this query is given in Figure 23.8a.

Query 4: Find the temporal layout of all the objects between the time interval $(T_1 = 2, T_2 = 9)$. This query can be answered by drawing a rectangle on the unified index with dimensions $(X_{\max} - 0) \times (Y_{\max} - 0) \times (T_2 - T_1)$. The response of the query is shown in Figure 23.8b.

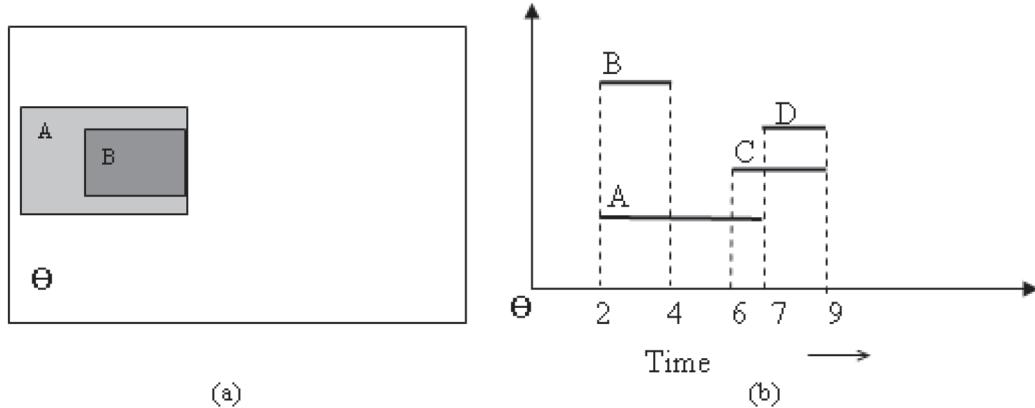

FIGURE 23.8 (a) Response to Query 3 and (b) response to Query 4.

23.3.2 Spatiotemporal Query Types

Here, we consider some major query types that are commonly performed on spatiotemporal data. Existing algorithms for these are mostly predictive in nature [9].

- *Range queries* [22,23]: This has a query range R and a future time t , and requests about the objects expected to be inside R after time t . This utilizes a mobility model that is based on a time parameterized bounding rectangle as a moving region that intersects or otherwise, a moving circle that represents a range query.
- *K-nearest-neighbor queries* [23,24]: This has a location point P , a future time t , and requests about the K objects expected to be closest to P after time t . Two algorithms, RangeSearch and KNNSearchBF, work by traversing spatiotemporal index tree (TPR/TPR*-tree) to find the nodes that intersect with the query circular region for Range and KNN queries, respectively.
- *Reverse-nearest-neighbor queries* [23,25]: Contrary to the predictive KNN query, predictive reverse-nearest-neighbor query finds out the objects expected to have the query region as their nearest neighbor.
- *Aggregate queries* [26]: This type has a query region R , future time t , and requests about the number of objects N predicted to be inside R after time t . Sun et al. [26] present a comprehensive technique that employs adaptive multidimensional histogram (AMH), historical synopsis, and stochastic method to provide approximate answers for aggregate spatiotemporal queries for the future, in addition to the past, and the present.
- *Continuous queries* [27,28]: Continuous query Q , mostly server-side algorithm that is stored until the end of its life, could be any of the above discussed types but with the additional condition that it needs to be continuously reevaluated many times throughout its life in the underlying system. The rate of reevaluation depends on the time gap, t_{gap} between each two consecutive reported answers specified in the received query Q .

23.3.3 Performance Analysis of 3D R-Trees

Theodoridis et al. [17] analyzed the performance of the proposed R-trees using the expected retrieval cost metric that they presented in Reference 15. An interested reader is referred to References 17 and 29 for details on this metric. Based on the analytical model of this metric, it is asserted that one can estimate the retrieval cost of an *overlap query* based on the information attainable from the query window and data set only. In the performance analysis, it was demonstrated that since the expected retrieval cost metric expresses the expected performance of R-trees on overlapping queries, the retrieval of spatiotemporal operators using R-trees is cost equivalent to the cost of retrieval of an overlap query using an appropriate query window Q . Rigorous analysis with 10,000 objects asserted the following conclusions as described in Reference 17:

1. For the operators with high selectivity (*overlap*, *during*, *overlap_during*), the proposed 3D R-trees outperformed sequential search at a level of 1 to 2 orders of magnitude.
2. For operators with low selectivity (*above*, *before*, *above_before*), the proposed 3D R-trees outperformed sequential search by factors ranging between 0.25 and 0.50 fraction of the sequential cost.

23.3.4 Handling Queries with Open Transaction Times

In the previous section although 3D R-trees were demonstrated to be very efficient compared to sequential search, it suffers from a limitation. The transaction times presented as creation and termination time of an object are expected to be known *a priori*

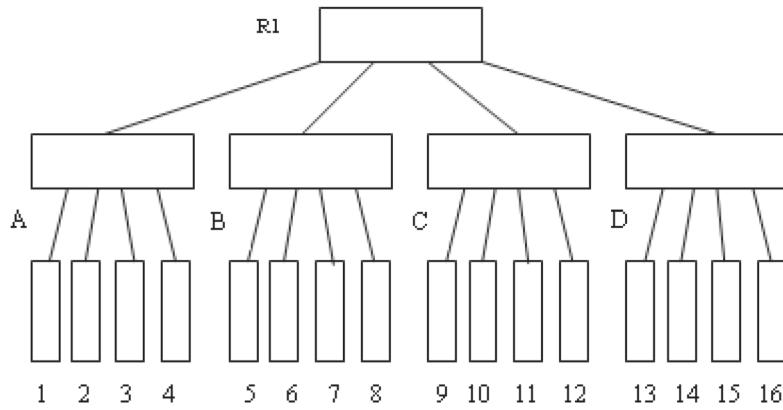

FIGURE 23.9 An R-tree at time T_0 .

before they can be stored and queried from the index. However, in most practical circumstances, the duration of existence of an object is not known. In other words, when the object is created, all we know is that it would remain valid *until changed*. The concept of *until changes* is a well-discussed issue [30,31]. Data structures like R-trees and also its modified form of 3D R-tree are typically not capable of handling such queries having open transaction times. In the following section, we discuss two STDS capable of handling queries with open transaction times.

23.4 2+3 R-Tree

Nascimento et al. [31] have proposed a solution to the problem of handling objects with open transaction times. The idea is to split the indexing of these objects into two parts: one for two-dimensional points and other for three-dimensional lines. Two-dimensional points store the spatial information about the objects and their corresponding start time. Three-dimensional lines store the historical information about the data. Once the “started” point stored in 2D R-tree becomes closed, a corresponding line is constructed to be stored in the 3D R-tree and the point entry is deleted from the 2D R-tree. It should be understood that both trees are expected to be searched depending on the timestamp at which the query is posed. If the end times for each of the spatial points is known *a priori*, then the need of a 2D can be completely eliminated reducing the structure to a 3D R-tree.

23.5 HR-Trees

One possible way to index spatiotemporal data is to build one R-tree for each timestamp, which is certainly space inefficient. The demerit of 2 + 3 R-tree is that it requires two stores to be searched to answer a query. The HR-tree [32] or Historical R-tree “compresses” multiple R-trees, so that R-tree nodes which are common in two timestamps are shared by the corresponding R-trees. The main idea is based on the expectation that a vast majority of indexed points do not change their positions at every timestamp. In other words, it is reasonable to expect that a vast majority of spatial points will “share” common nodes in respective R-trees. The HR-tree exploits this property by keeping a “logical” linkage to a previously present spatial point if it is referenced again in the new R-tree. Consider two R-trees in Figures 23.9 and 23.10 at two different timestamps (T_0, T_1). An HR-tree for these R-trees is given in Figure 23.11.

Recently, Ni and Ravishankar [33] proposed the PA-tree as an indexing scheme for historical trajectory data. PA-tree is a parametric space indexing method that uses approximating sequence of movement functions with single continuous polynomial approximations, and demonstrated how this could support both offline and online query processing of historical trajectories. Their work showed that although existing schemes such as MVR-trees and SETI are faster for index construction and timestamp queries, PA-trees are an order of magnitude faster to construct and incur lower I/O cost for spatiotemporal range queries which makes it an excellent choice for both offline and online processing of historical trajectories.

23.6 MV3R-Tree

The MV3R-tree was proposed by Tao and Papadias [34] and is demonstrated to process timestamp and interval queries efficiently. Timestamp queries discover all objects that intersect a window query at a particular timestamp. On the other hand, interval

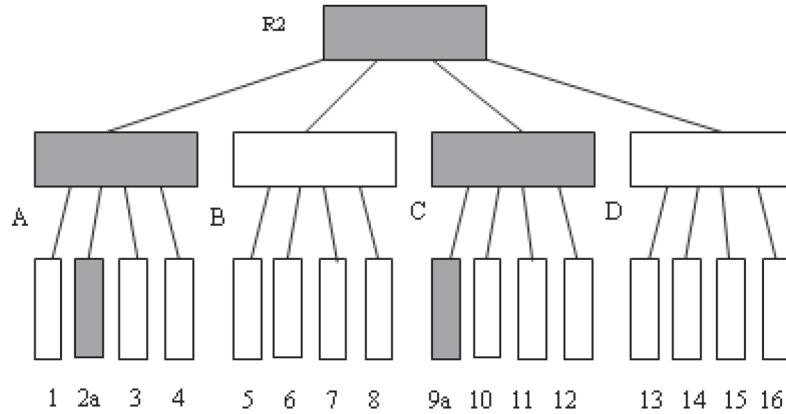

FIGURE 23.10 An R-tree at time T_1 . The modified nodes are in dark boxes.

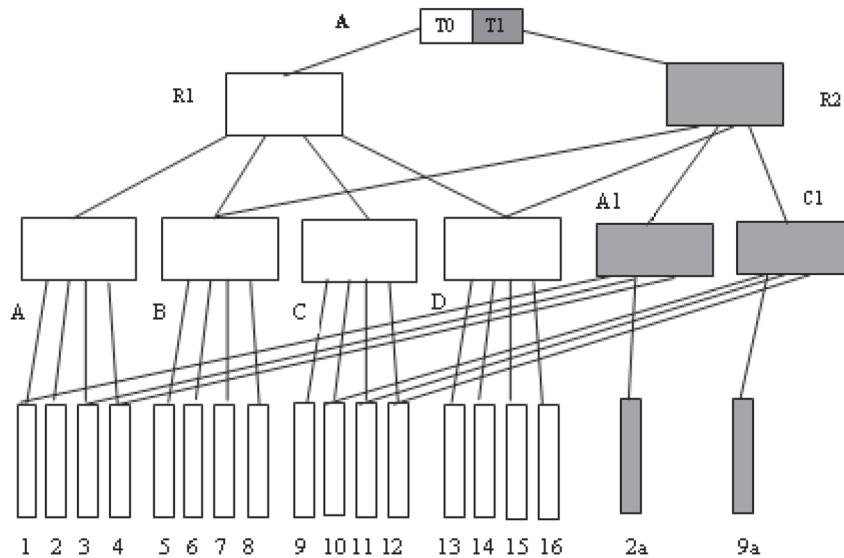

FIGURE 23.11 The HR-tree.

queries include multiple timestamps in the discovered response. While the spatial data structures proposed before have been demonstrated [17,34] to be suitable for either of these queries (or a subset of it), none of them have been established to process both timestamp and interval queries efficiently. MV3R-tree has addressed limitations in terms of efficiency of the above trees in handling both of these queries. MV3R-tree consists of a multiversion R-tree (MVR-tree) and an auxiliary 3D R-tree built on the leaves of the MVR-tree. Although the primary motivation behind the development of MV3R-tree is MVBT [13] (which are extended from B+ trees), they are significantly different from these versions. Before we proceed further, let us understand the working of an MVBT.

A typical entry of an MVBT takes the following form: $< id, time_{start}, time_{end}, P >$. For nonleaf nodes, $time_{start}$ and $time_{end}$ are the minimum and maximum values, respectively, in this node and P is a pointer to the next level node. For a leaf node, the timestamps $time_{start}$ and $time_{end}$ indicate when the object was inserted and deleted from the index and pointer P points to the actual record with a corresponding id value. At time $time_{current}$, the entry is said to be *alive* if $time_{start} < time_{current}$, otherwise *dead* [34]. There can be multiple roots in an MVBT, where each root has a distinguishing time range it represents. A search on the tree begins at identifying the root within which the timestamp of the query belongs. The search is continued based on the id , $time_{start}$, and $time_{end}$. A *weak version condition* specifies that for each node, except the root, at least $K \cdot T$ entries are alive at time t , where K is the node capacity and T is the tree parameter. This condition ensures that entries alive at the identical timestamps are in a majority of the cases assembled together to allow easy timestamp queries.

3D R-trees are very space efficient and can handle long interval queries efficiently. However, timestamp and short-interval queries using 3D R-trees are expensive. In addition to this, 3D R-trees do not include a methodology such as the weak version

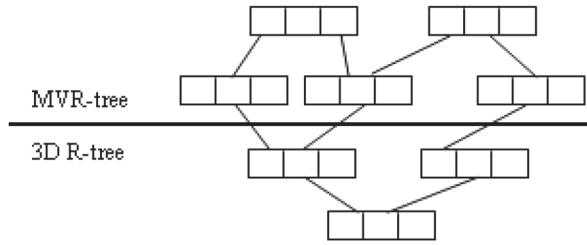

FIGURE 23.12 An MV3R-tree.

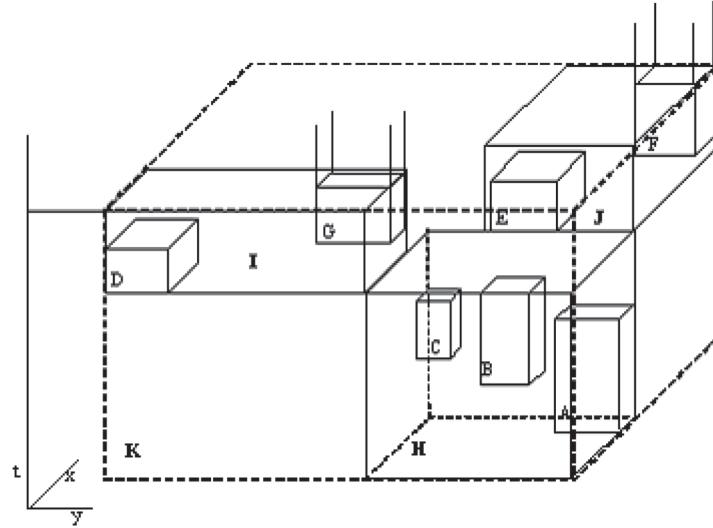

FIGURE 23.13 A 3D visualization of MVR-tree.

condition to ensure that each node has a minimum number of live entries at a given timestamp. HR-trees [32], on the other hand, maintain an R-tree (or its derivative) for each timestamp and the timestamp query is directed to the corresponding R-tree to be searched within it. In other words, the query disintegrates into an ordinary window query and is handled very efficiently. However, in case of an interval query, several timestamps should search the corresponding trees of all the timestamps constituting the interval. The original work in HR-tree did not present a schema for handling interval queries; however, Tao and Papadias [34] have proposed a solution to this problem by the use of negative and positive pointers. The performance of this schema is then compared with MV3R-tree in Reference 34. It is demonstrated that MV3R-trees outperform HR-trees and 3D R-trees even in extreme cases of only timestamp and interval-based queries.

Multiversion 3D R-trees (MV3R-trees) combine a multiversion R-tree (MVR-tree) and a small auxiliary 3D R-tree built on the leaf nodes of the MVR-tree as shown in Figure 23.12. MVR-trees maintain multiple R-trees and have entries of the form $\langle MBR, time_{start}, time_{end}, P \rangle$, where MBR refers to minimum bounding rectangle and other entries are similar to B+ trees. An example of a 3D visualization of an MVR-tree of height 2 is shown in Figure 23.13. The tree consists of Object cubes (A–G), leaf nodes (H–J) and root of the tree K. Detailed algorithms for insertion and deletion in these trees are provided in Reference 34. Timestamp queries can be answered efficiently using MVR-trees. An auxiliary 3D R-tree is built on the leaves of the MVR-tree in order to process interval queries. It is suggested that for a moderate node capacity, the number of leaf nodes in an MVR-tree is much lower than the actual number of objects, hence this tree is expected to be small compared to a complete 3D R-tree.

Performance analysis has shown that the MV3R-tree offers better trade-off between query performance and structure size than the HR-tree and 3D R-tree. For typical situations where workloads contain both timestamp and interval queries, MV3R-trees outperform HR-trees and 3D R-trees significantly. The incorporation of the auxiliary 3D R-tree not only accelerates interval queries but also provides flexibilities toward other query processing, such as spatiotemporal joins.

23.7 Indexing Structures for Continuously Moving Objects

Continuously moving objects pose new challenges to indexing technology for large databases. Sources for such data include GPS systems, wireless networks, air-traffic controls, and so on. In the previous sections, we have outlined some indexing schemas that

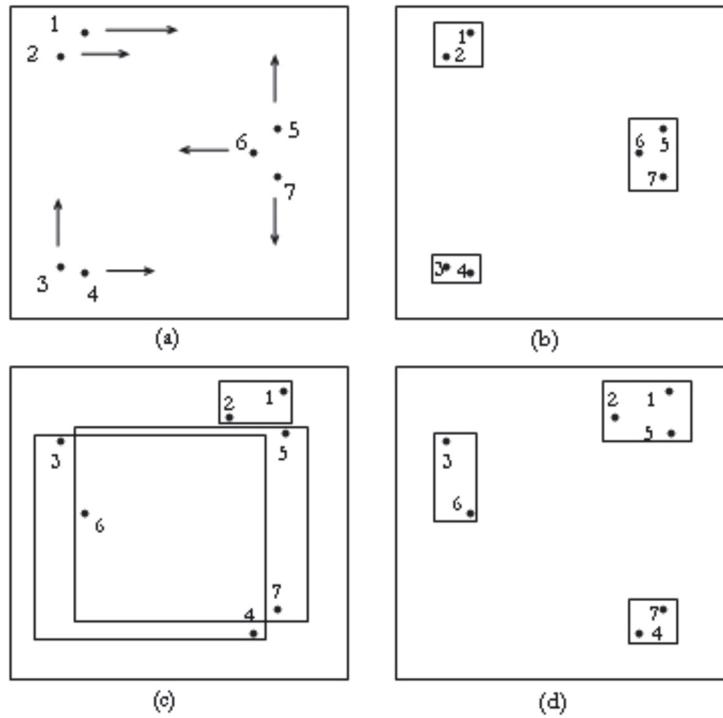

FIGURE 23.14 Moving data points and their leaf-level MBBs at subsequent points.

could efficiently index spatiotemporal data types but some other schemas have been developed specifically for answering predictive queries in a database of continuously moving objects. In this section, we discuss an assortment of such indexing schemas.

Databases of continuously moving objects have two kinds of indexing issues: storing the historical movements in time of objects and predicting the movement of objects based on previous positional and directional information. Such predictions can be made more reliably for a future time T_f , not far from the current timestamp T_j . As T_f increases, the predictions become less and less reliable since the change of trajectory by a moving object results in inaccurate prediction. Traditional indexing schemas such as R*-trees are successful in storing multidimensional data points but are not directly useful for storing moving objects. An example [35] of such kind of system is shown in Figure 23.14. For simplicity, a two-dimensional space is illustrated, but practical systems can have larger dimensions. First part of the figure shows multiple objects moving in different directions. If traditional R*-trees are used for indexing these data, the MBB for the leaf level of the tree are demonstrated in Figure 23.14b. But these objects might be following different trajectories (as shown by arrows in Figure 23.14a) and at subsequent timestamps, the leaf level MBB might change in size and position, as demonstrated in Figure 23.14c and d.

Since traditional indexing methods are not designed for such kind of applications, some novel indexing schemas are described in References 35–38 to handle such data types and queries imposed on them.

23.7.1 TPR-Tree

Saltenis et al. [35] proposed TPR-tree, an acronym for Time-Parameterized R*-tree, based on the underlying principles of R-tree. TPR-tree indexes the current and future anticipated positions of moving objects in one, two, and three dimensions. The basic algorithms of R*-trees are employed for TPR-tree with a modification that the leaf and nonleaf minimum bounding rectangles are now augmented with velocity vectors for these rectangles. The velocity vector for an edge of the rectangle is chosen so that the object remains inside the moving rectangle. TPR-tree can typically handle the following three types of queries:

- Timeslice Query: A query Q specified by hyperrectangle R located at time point t .
- Window Query: A query Q specified by hyperrectangle R covering an interval from $[T_a, T_b]$.
- Moving Query: A query Q specified by hyperrectangles R_a and R_b at different times T_a and T_b , forming a trapezoid.

Figure 23.15 shows objects o1, o2, o3, and o4 moving in time. The trajectories of these objects are shifting, as shown in the figure. The three types of queries as described earlier are illustrated in this figure. Q0 and Q1 are timeslice queries, Q2 and Q3 are window queries, and Q4 is a moving query.

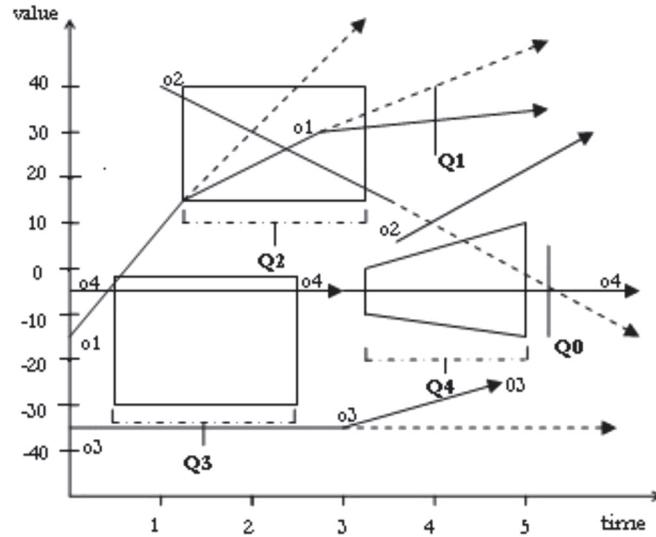

FIGURE 23.15 Types of queries on one-dimensional data.

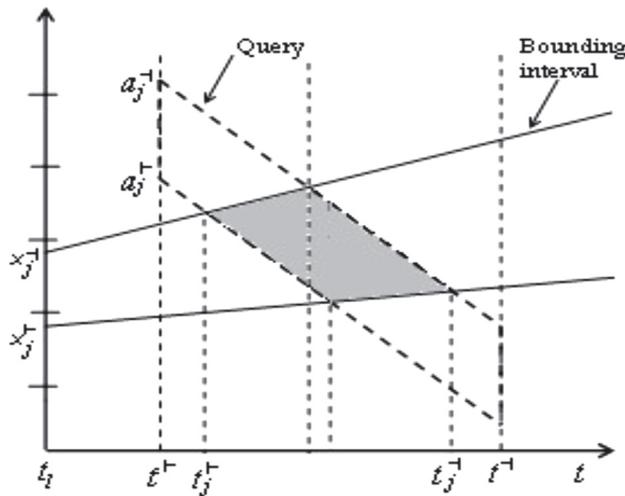

FIGURE 23.16 A bounding interval and a query imposed on the TPR-tree.

The structure of TPR-tree is very similar to R*-tree with leaves consisting of position and pointer of the moving object. The nodes of the tree consist of pointers to subtree and bounding rectangles for the entries in subtree. TPR-trees store the moving objects as linear function of time with time-parameterized bounding rectangles. The index does not consist of points and rectangles for timestamp older than current time. TPR-tree differs from the R*-trees in how its insertion algorithms group points into nodes. While in R*-trees, the heuristics of the minimized area, overlap, and margin of bounding rectangles are used to assign points to the nodes of the tree, in case of TPR-trees these heuristics are replaced by their respective integrals, which are representative of their temporal components. Given an objective function $F(t)$, the following integral is expected to be minimized [35].

$$\int_{t_c}^{t_c+H} F(t) dt, \text{ where } t_c \text{ is the current time and } H \text{ is the time horizon.}$$

The objective function can be area or perimeters of the bounding rectangles, or could represent the overlap between these rectangles. Figure 23.16 represents a bounding interval and a query in the TPR-tree. The area of the shaded region in Figure 23.16 represents the time integral of the length of the bounding interval.

Saltenis et al. [35] compared the performance of TPR-trees with load-time bounding rectangles, TPR-tree with update-time bounding rectangles, and R-tree with a set of experiments with varying workloads. The results demonstrated that TPR-tree outperforms other approaches by considerable improvement. It was also demonstrated that TPR-tree does not degrade severely in performance with increasing time and it can be tuned to take advantage of a specific update rate.

23.7.2 R^{EXP}-tree

Saltenis and Jensen [36] proposed R^{EXP}-tree as a balanced, multiway tree with a structure of R*-tree. R^{EXP}-tree is an improvement over TPR-tree, assuming that some objects used in indexing expires after a certain period. These trees can handle realistic scenario where certain objects are no longer required, that is when they expire. By removing the expired entries and recomputing bounding rectangles, the index organizes itself to handle subsequent queries efficiently. This tree structure finds its application where the objects do not report their positions for a certain period, possibly implying that they are no more interested in the service.

The index structure of R^{EXP}-tree differs from TPR-tree in insertion and deletion algorithms for disposing the expired nodes. R^{EXP}-tree uses a “lazy strategy” for deleting the expired entries. Another possible strategy is scheduled deletion of entries in TPR-trees. During the search, insertion, and deletion operations, only the live entries are searched and expired entries are physically removed when the content of the node is modified and is written to the disk. Whenever an entry in internal node is deleted, the entire subtree is reallocated. The performance results demonstrated in Reference 36 show that choosing the right bounding rectangles and corresponding algorithms for grouping entries is not straightforward and depends on the characteristics of the workloads.

23.7.3 STAR-Tree

Procopiu et al. [37] propose a Spatio-Temporal Self-Adjusting R-tree or STAR-tree. STAR-tree indexing schema is similar to TPR trees with few differences. Specifically, STAR-tree groups point according to their current locations and may result in points moving with different velocities being included in the same rectangle. Scheduled events are used to regroup points to control the growth of such bounding rectangles. It improves the structure of TPR-tree by self-adjusting the index, whenever index performance degrades. Intervention of user is not needed for adjustment of the index and the query time is kept low even without continuously updating the index by positions of the objects. STAR-tree does not need periodic rebuilding of indexing and estimation of time horizon. It provides trade-offs between storage and query performance and between time spent in updating the index and in answering queries. STAR-tree can handle not only the timeslice and range queries as those handled by TPR-trees but also nearest neighbor queries for continuously moving objects.

23.7.4 TPR^{*}-Tree

TPR^{*}-tree proposed by Tao et al. [38] is an optimized spatiotemporal indexing method for predictive queries. TPR-tree, described in the previous section, does not propose an analytical model for cost estimation and query optimization and quantification of its performance. TPR^{*}-tree assumes a probabilistic model that accurately estimates the number of disk accesses in answering a window query in a spatiotemporal index. Tao et al. [38] investigate the optimal performance of any data partition index using the proposed model.

The TPR^{*}-tree improves the performance of TPR-tree by employing a new set of insertion and deletion algorithms that minimize the average number of node accesses for answering a window query, whose MBB uniformly distributes in the data space. The static point interval query with the following constraints has been optimized [38] using the TPR^{*}-tree:

- MBB has a length $|Q^R| = 0$ on each axis.
- Velocity bounding rectangle is $\{0,0,0,0\}$.
- Query interval $Q_I = [0, H]$, where H is the horizon parameter.

It is demonstrated that the above choice of parameters leads to nearly optimal performance independently of the query parameters. The experiments have also shown that TPR^{*}-trees significantly outperform the conventional TPR-tree under all conditions.

24.1 Introduction

Motion is ubiquitous in the physical world, yet its study is much less developed than that of another common physical modality, namely shape. While we have several standardized mathematical shape descriptions, and even entire disciplines devoted to that area—such as *Computer-Aided Geometric Design* (CAGD)—the state of formal motion descriptions is still in flux. This in part because motion descriptions span many levels of detail; they also tend to be intimately coupled to an underlying physical process generating the motion (dynamics). Thus, until recently, proper abstractions were lacking and there was only limited work on algorithmic descriptions of motion and their associated complexity measures. This chapter aims to show how an algorithmic study of motion is intimately tied via appropriate data structures to more classical theoretical disciplines, such as discrete and computational geometry. After a quick survey of earlier work (Sections 24.2 and 24.3), we devote the bulk of this chapter to discussing the framework of *Kinetic Data Structures* (Section 24.4) [1,2] and its many applications (Section 24.5). We also briefly discuss methods for querying moving objects (Section 24.6).

24.2 Motion in Computational Geometry

Motion has not been studied extensively within the context of theoretical computer science. Until recently, there were only sporadic investigations of moving objects in the computational geometry literature. *Dynamic computational geometry* refers to the study of combinatorial changes in a geometric structure, as its defining objects undergo prescribed motions. For example, we may have n points moving linearly with constant velocities in \mathcal{R}^2 , and may want to know the time intervals during which a particular point appears on their convex hull, the steady-state form of the hull (after all changes have occurred), or get an upper bound on how many times the convex hull changes during this motion. Such problems were introduced and studied in Reference 3.

A number of other authors have dealt with geometric problems arising from motion, such as collision detection or minimum separation determination [4–6]. See also Chapter 57. For instance, [6] shows how to check in subquadratic time whether two collections of simple geometric objects (spheres, triangles) collide with each other under specified polynomial motions.

24.3 Motion Models

An issue with the above research is that object motion(s) are assumed to be known in advance, sometimes in explicit form (e.g., points moving as polynomial functions of time). Indeed, the proposed methods reduce questions about moving objects to other questions about derived static objects.

* This chapter has been reprinted from first edition of this Handbook, without any content updates. A version of this chapter has also appeared in the *CRC Handbook of Discrete and Computational Geometry* (Chapter 50: Modeling Motion), 2nd Edition.

While most evolving physical systems follow known physical laws, it is also frequently the case that discrete events occur (such as collisions) that alter the motion law of one or more of the objects. Thus motion may be predictable in the short term, but becomes less so further into the future. Because of such discrete events, algorithms for modeling motion must be able to adapt in a dynamic way to motion model modifications. Furthermore, the occurrence of these events must be either predicted or detected, incurring further computational costs. Nevertheless, any truly useful model of motion must accommodate this *on-line* aspect of the temporal dimension, differentiating it from spatial dimensions, where all information is typically given at once.

In real-world settings, the motion of objects may be imperfectly known and better information may only be obtainable at considerable expense. The model of *data in motion* of [7] assumes that upper bounds on the rates of change are known, and focuses on being selective in using sensing to obtain additional information about the objects, in order to answer a series of queries.

24.4 Kinetic Data Structures

Suppose we are interested in tracking high-level attributes of a geometric system of objects in motion such as, for example, the convex hull of a set on n points moving in \mathcal{R}^2 . Note that as the points move continuously, their convex hull will be a continuously evolving convex polygon. At certain discrete moments, however, the combinatorial structure of the convex hull will change (i.e., the circular sequence of a subset of the points that appear on the hull will change). In between such moments, tracking the hull is straightforward: its geometry is determined by the positions of the sequence of points forming the hull. How can we know when the combinatorial structure of the hull changes? The idea is that we can focus on certain elementary geometric relations among the n points, a set of *cached assertions*, which altogether certify the correctness of the current combinatorial structure of the hull. If we have short-term information about the motion of the points, then we can predict failures of these assertions in the near future. Furthermore, we can hope to choose these certifying relations in such a way so that when one of them fails because of point motion, both the hull and its set of certifying relations can be updated locally and incrementally, so that the whole process can continue.

- *Kinetic data structure*: A kinetic data structure (KDS) for a geometric attribute is a collection of simple geometric relations that certifies the combinatorial structure of the attribute, as well as a set of rules for repairing the attribute and its certifying relations when one relation fails.
- *Certificate*: A certificate is one of the elementary geometric relations used in a KDS.
- *Motion plan*: An explicit description of the motion of an object in the near future.
- *Event*: An event is the failure of a KDS certificate during motion. If motion plans are available for all objects in a certificate, then the future time of failure for this certificate can be predicted. Events are classified as *external* when the combinatorial structure of the attribute changes, and *internal*, when the structure of the attribute remains the same, but its certification needs to change.
- *Event queue*: In a KDS, all certificates are placed in an event queue, according to their earliest failure time.

The inner loop of a KDS consists of repeated certificate failures and certification repairs, as depicted in Figure 24.1.

We remark that in the KDS framework, objects are allowed to change their motions at will, with appropriate notification to the data structure. When this happens all certificates involving the object whose motion has changed must re-evaluate their failure times.

24.4.1 Convex Hull Example

Suppose we have four points a , b , c , and d in \mathcal{R}^2 , and wish to track their convex hull. For the convex hull problem, the most important geometric relation is the CCW predicate: $\text{CCW}(a, b, c)$ asserts that the triangle abc is oriented counterclockwise. Figure 24.2 shows a configuration of four points and four CCW relations that hold among them. It turns out that these four relations

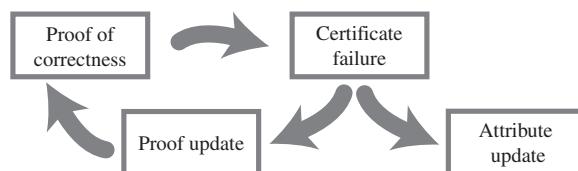

FIGURE 24.1 The inner loop of a kinetic data structure.

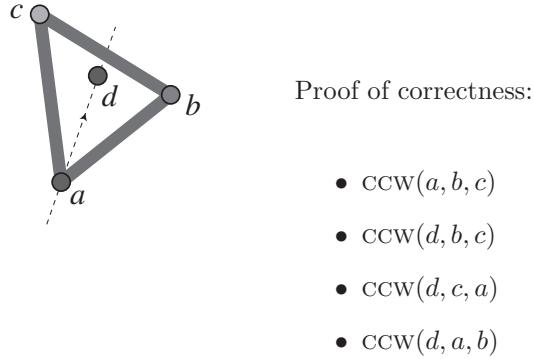

FIGURE 24.2 Determining the convex hull of the points.

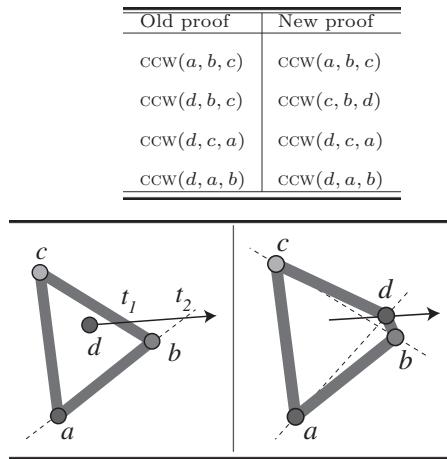

FIGURE 24.3 Updating the convex hull of the points.

are sufficient to prove that the convex hull of the four points is the triangle abc . Indeed the points can move and form different configurations, but as long as the four certificates shown remain valid, the convex hull must be abc .

Now suppose that points a , b , and c are stationary and only point d is moving with a known plan, as shown in Figure 24.3. At some time t_1 the certificate $\text{CCW}(d, b, c)$ will fail, and at a later time t_2 $\text{CCW}(d, a, b)$ will also fail. Note that the certificate $\text{CCW}(d, c, a)$ will never fail in the configuration shown even though d is moving. So the certificates $\text{CCW}(d, b, c)$ and $\text{CCW}(d, a, b)$ schedule events that go into the event queue. At time t_1 , $\text{CCW}(d, b, c)$ ceases to be true and its negation, $\text{CCW}(c, b, d)$, becomes true. In this simple case the three old certificates, plus the new certificate $\text{CCW}(c, b, d)$ allow us to conclude that convex hull has now changed to $abdc$.

If the certificate set is chosen wisely, the KDS repair can be a local, incremental process—a small number of certificates may leave the cache, a small number may be added, and the new attribute certification will be closely related to the old one. A good KDS exploits the continuity or coherence of motion and change in the world to maintain certifications that themselves change only incrementally and locally as assertions in the cache fail.

24.4.2 Performance Measures for KDS

Because a KDS is not intended to facilitate a terminating computation but rather an on-going process, we need to use somewhat different measures to assess its complexity. In classical data structures there is usually a tradeoff between operations that interrogate a set of data and operations that update the data. We commonly seek a compromise by building indices that make queries fast, but such that updates to the set of indexed data are not that costly as well. Similarly in the KDS setting, we must at the same time have access to information that facilitates or trivializes the computation of the attribute of interest, yet we want information that is relatively stable and not so costly to maintain. Thus, in the same way that classical data structures need to balance the efficiency of access to the data with the ease of its update, kinetic data structures must tread a delicate path between “knowing

“too little” and “knowing too much” about the world. A good KDS will select a certificate set that is at once economical and stable, but also allows a quick repair of itself and the attribute computation when one of its certificates fails.

- *Responsiveness:* A KDS is *responsive* if the cost, when a certificate fails, of repairing the certificate set and updating the attribute computation is small. By “small” we mean polylogarithmic in the problem size—in general we consider small quantities that are polylogarithmic or $O(n^c)$ in the problem size.
- *Efficiency:* A KDS is *efficient* if the number of certificate failures (total number of events) it needs to process is comparable to the number of required changes in the combinatorial attribute description (external events), over some class of allowed motions. Technically, we require that the ratio of total events to external events is small. The class of allowed motions is usually specified as the class of *pseudo-algebraic* motions, in which each KDS certificate can flip between true and false at most a bounded number of times.
- *Compactness:* A KDS is *compact* if the size of the certificate set it needs is close to linear in the degrees of freedom of the moving system.
- *Locality:* A KDS is *local* if no object participates in too many certificates; this condition makes it easier to re-estimate certificate failure times when an object changes its motion law. (The existence of local KDSs is an intriguing theoretical question for several geometric attribute functions.)

24.4.3 The Convex Hull, Revisited

We now briefly describe a KDS for maintaining the convex hull of n points moving around in the plane [1].

The key goal in designing a KDS is to produce a *repairable certification* of the geometric object we want to track. In the convex hull case it turns out that it is a bit more intuitive to look at the dual problem, that of maintaining the upper (and lower) envelope of a set of moving lines in the plane, instead of the convex hull of the primal points. Such dualities represent a powerful toolkit in computational geometry; readers are referred to any standard computational geometry textbook for details, for example [8]. For simplicity we focus only on the upper envelope of the moving lines from now on; the lower envelope case is entirely symmetric. Using a standard divide-and-conquer approach, we partition our lines into two groups of size roughly $n/2$ each, and assume that recursive invocations of the algorithm maintain the upper envelopes of these groups. For convenience call the groups red and blue.

In order to produce the upper envelope of all the lines, we have to merge the upper envelopes of the red and blue groups and also certify this merge, so we can detect when it ceases to be valid as the lines move; see Figure 24.4.

Conceptually, we can approach this problem by sweeping the envelopes with a vertical line from left to right. We advance to the next red (blue) vertex and determine if it is above or below the corresponding blue (red) edge, and so on. In this process we determine when red is above blue or vice versa, as well as when the two envelopes cross. By stitching together all the upper pieces, whether red or blue, we get a representation of the upper envelope of all the lines.

The certificates used in certifying the above merge are of three flavors:

- x -certificates ($<_x$) are used to certify to x -ordering among the red and blue vertices; these involve four original lines.
- y -certificates ($<_y$) are used to certify that a vertex is above or below an edge of the opposite color; these involve three original lines and are exactly the duals of the ccw certificates discussed earlier.
- s -certificates ($<_s$) are slope comparisons between pairs of original lines; though these did not arise in our sweep description above, they are needed to make the KDS local [1].

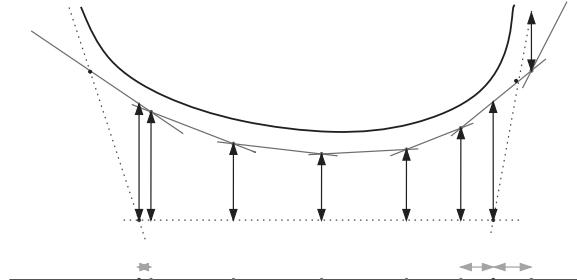

FIGURE 24.4 Merging the red and blue upper envelopes. In this example, the red envelope (solid line) is above the blue (dotted line), except at the extreme left and right areas. Vertical double-ended arrows represent y -certificates and horizontal double-ended arrows represent x -certificates, as described below.

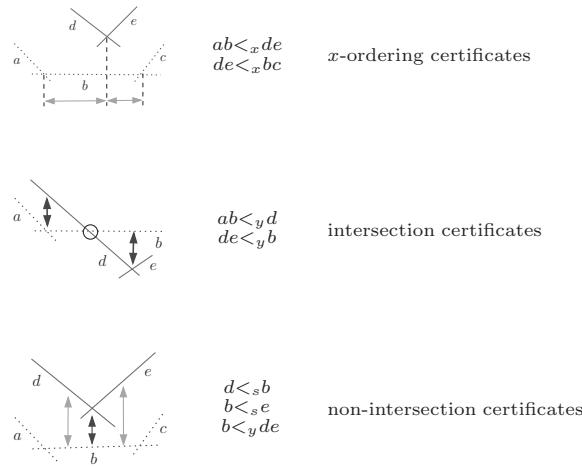

FIGURE 24.5 Using the different types of certificates to certify the red-blue envelope merge.

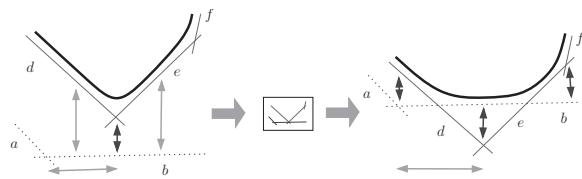

FIGURE 24.6 Envelope repair after a certificate failure. In the event shown lines b , d , and e become concurrent, producing a red-blue envelope intersection

Figure 24.5 shows examples of how these types of certificates can be used to specify x -ordering constraints and to establish intersection or non-intersection of the envelopes.

A total of $O(n)$ such certificates suffices to verify the correctness of the upper envelope merge.

Whenever the motion of the lines causes one of these certificates to fail, a local, constant-time process suffices to update the envelope and repair the certification. Figure 24.6 shows an example where an y -certificate fails, allowing the blue envelope to poke up above the red.

It is straightforward to prove that this kinetic upper envelope algorithm is responsive, local, and compact, using the logarithmic depth of the hierarchical structure of the certification. In order to bound the number of events processed, however, we must assume that the line motions are polynomial or at least pseudo-algebraic. A proof of efficiency can be developed by extruding the moving lines into space-time surfaces. Using certain well-known theorems about the complexity of upper envelopes of surfaces [9] and the overlays of such envelopes [10] it can be shown that in the worst case the number of events processed by this algorithm is near quadratic ($O(n^{2+\epsilon})$). Since the convex hull of even linearly moving points can change $\Omega(n^2)$ times [11], the efficiency result follows.

No comparable structure is known for the convex hull of points in dimensions $d \geq 3$.

24.5 A KDS Application Survey

Even though we have presented kinetic data structures in a geometric setting, there is nothing intrinsically geometric about KDS. The idea of cached assertions that help track an attribute of interest can be applied to many other settings where there is continuous evolution over time punctuated by discrete events, beyond motion in the physical world. For example, consider a graph whose edge weights or capacities are functions of time, as might arise in an evolving communications network. Then the problem of tracking various substructures of interest, such as the minimum spanning tree (MST) of the graph, or a shortest path tree from a source node, can be formulated and studied within the KDS framework.

We present below a quick summary of some of the areas to which kinetic data structures have been applied so far. The are mostly geometric in nature, but several non-geometric examples appear as well.

24.5.1 Extent Problems

A number of the original problems for which kinetic data structures were developed are aimed at different measures of how “spread out” a moving set of points in \mathcal{R}^2 is—one example is the convex hull, whose maintenance was discussed in the previous subsection. Other measures of interest include the diameter, width, and smallest area or perimeter bounding rectangle for a moving set S of n points. All these problems can be solved using the kinetic convex hull algorithm above; the efficiency of the algorithms is $O(n^{2+\epsilon})$, for any $\epsilon > 0$. There are also corresponding $\Omega(n^2)$ lower bounds for the number of combinatorial changes in these measures. Surprisingly, the best known upper bound for maintaining the smallest enclosing disk containing S is still near-cubic. Extensions of these results to dimensions higher than two are also lacking.

These costs can be dramatically reduced if we consider approximate extent measures. If we are content with $(1 + \epsilon)$ approximations to the measures, then an approximate smallest orthogonal rectangle, diameter, and smallest enclosing disk can be maintained with a number of events that is a function ϵ only and not of n [12]. For example, the bound of the number of approximate diameter updates in \mathcal{R}^2 under linear motion of the points is $O(1/\epsilon)$.

24.5.2 Proximity Problems

The fundamental proximity structures in computational geometry are the Voronoi Diagram and the Delaunay triangulation ([Chapters 65](#) and [66](#)). The edges of the Delaunay triangulation contain the closest pair of points, the closest neighbor to each point, as well as a wealth of other proximity information among the points. From the kinetic point of view, these are nice structures, because they admit completely local certifications. Delaunay’s 1934 theorem [13] states that if a local empty sphere condition is valid for each $(d - 1)$ -simplex in a triangulation of points in \mathcal{R}^d , then that triangulation must be Delaunay. This makes it simple to maintain a Delaunay triangulation under point motion: an update is necessary only when one of these empty sphere conditions fails. Furthermore, whenever that happens, a local retiling of space (of which the classic “edge-flip” in \mathcal{R}^2 is a special case) easily restores Delaunayhood. Thus the KDS for Delaunay (and Voronoi) that follows from this theorem is both responsive and efficient—in fact, each KDS event is an external event in which the structure changes. Though no redundant events happen, an exact upper bound for the total number of such events in the worst-case is still elusive even in \mathcal{R}^2 , where the best known upper bound is nearly cubic, while the best lower bound only quadratic [14].

This principle of a set of easily checked local conditions that implies a global property has been used in kinetizing other proximity structures as well. For instance, in the *power diagram* [15] of a set of disjoint balls, the two closest balls must be neighbors [16]—and this diagram can be kinetized by a similar approach. Voronoi diagrams of more general objects, such as convex polytopes, have also been investigated. For example, in \mathcal{R}^2 [17] shows how to maintain a compact Voronoi-like diagram among moving disjoint convex polygons; again, a set of local conditions is derived which implies the global correctness of this diagram. As the polygons move, the structure of this diagram allows one to know the nearest pair of polygons at all times.

In many applications the exact L_2 -distance between objects is not needed and more relaxed notions of proximity suffice. Polyhedral metrics (such as L_1 or L_∞) are widely used, and the normal unit ball in L_2 can be approximated arbitrarily closely by polyhedral approximants. It is more surprising, however, that if we partition the space around each point into a set of polyhedral cones and maintain a number of directional nearest neighbors to each point in each cone, then we can still capture the globally closest pair of points in the L_2 metric. By directional neighbors here we mean that we measure distance only along a given direction in that cone. This geometric fact follows from a packing argument and is exploited in Reference 18 to give a different method for maintaining the closest pair of points in \mathcal{R}^d . The advantage of this method is that the kinetic events are changes of the sorted order of the points along a set of directions fixed *a priori*, and therefore the total number of events is provably quadratic.

24.5.3 Triangulations and Tilings

Many areas in scientific computation and physical modeling require the maintenance of a triangulation (or more generally a simplicial complex) that approximates a manifold undergoing deformation. The problem of maintaining the Delaunay triangulation of moving points in the plane mentioned above is a special case. More generally, local re-triangulations are necessitated by collapsing triangles, and sometimes required in order to avoid undesirably “thin” triangles. In certain cases the number of nodes (points) may also have to change in order to stay sufficiently faithful to the underlying physical process; see, for example, [19]. Because in general a triangulation meeting certain criteria is not unique or canonical, it becomes more difficult to assess the efficiency of kinetic algorithms for solving such problems. The lower-bound results in Reference 20 indicate that one cannot hope for a subquadratic bound on the number of events in the worst case in the maintenance of any triangulation, even if a linear number of additional Steiner points is allowed.

There is large gap between the desired quadratic upper bound and the current state of art. Even for maintaining an arbitrary triangulation of a set of n points moving linearly in the plane, the best-known algorithm processes $O(n^{7/3})$ events [21] in the worst case. The algorithm actually maintains a pseudotriangulation of the convex hull of the point set and then a triangulation

of each pseudotriangle. Although there are only $O(n^2)$ events in the pseudotriangulation, some of the events change too many triangles because of high-degree vertices. Unless additional Steiner points are allowed, there are point configurations for which high-degree vertices are inevitable and therefore some of the events will be expensive. A more clever, global argument is needed to prove a near-quadratic upper bound on the total number of events in the above algorithm. Methods that choose to add additional points, on the other hand, have the burden of defining appropriate trajectories for these Steiner points as well. Finally, today no triangulation that guarantees certain quality on the shapes of triangles as well as a subcubic bound on the number of retiling events is known.

24.5.4 Collision Detection

Kinetic methods are naturally applicable to the problem of collision detection between moving geometric objects. Typically collisions occur at irregular intervals, so that fixed-time stepping methods have difficulty selecting an appropriate sampling rate to fit both the numerical requirements of the integrator as well as those of collision detection. A kinetic method based on the discrete events that are the failures of relevant geometric conditions can avoid the pitfalls of both oversampling and undersampling the system. For two moving convex polygons in the plane, a kinetic algorithm where the number of events is a function of the relative separation of the two polygons is given in Reference 22. The algorithm is based on constructing certain outer hierarchies on the two polygons. Analogous methods for 3D polytopes were presented in Reference 23, together with implementation data.

A tiling of the free space around objects can serve as a proof of non-intersection of the objects. If such a tiling can be efficiently maintained under object motion, then it can be the basis of a kinetic algorithm for collision detection. Several papers have developed techniques along these lines, including the case of two moving simple polygons in the plane [24], or multiple moving polygons [21,25]. These developments all exploit deformable pseudotriangulations of the free space—tilings which undergo fewer combinatorial changes than, for example, triangulations. An example from Reference 21 is shown in Figure 24.7. The figure shows how the pseudotriangulation adjusts by local retiling to the motion of the inner quadrilateral. The approach of [21] maintains a canonical pseudotriangulation, while others are based on letting a pseudotriangulation evolve according to the history of the motion. It is unclear at this point which is best. An advantage of all these methods is that the number of certificates needed is close to size of the min-link separating subdivision of the objects, and thus sensitive to how intertwined the objects are.

Deformable objects are more challenging to handle. Classical methods, such as bounding volume hierarchies [26], become expensive, as the fixed object hierarchies have to be rebuilt frequently. One possibility for mitigating this cost is to let the hierarchies themselves deform continuously, by having the bounding volumes defined implicitly in terms of object features. Such an approach was developed for flexible linear objects (such as rope or macromolecules), using combinatorially defined sphere hierarchies in Reference 27. In that work a bounding sphere is defined not in the usual way, via its center and radius, but in an implicit combinatorial way, in terms of four feature points of the enclosed object geometry. As the object deforms these implicitly defined spheres automatically track their assigned features, and therefore the deformation. Of course the validity of the hierarchy has to be checked at each time step and repaired if necessary. What helps here is that the implicitly defined spheres change their

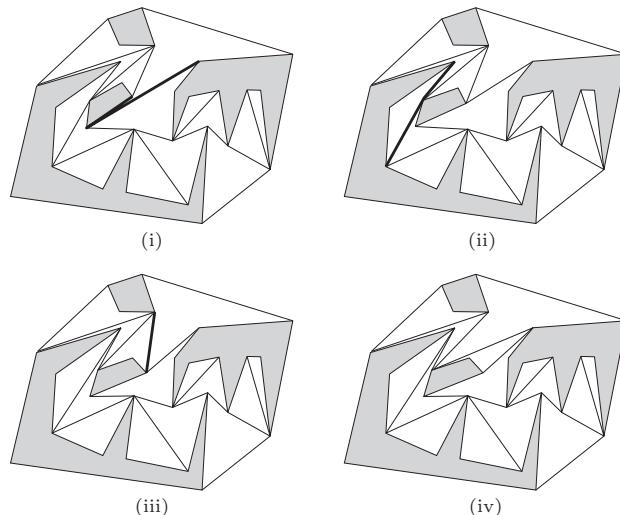

FIGURE 24.7 Snapshots of the mixed pseudotriangulation of [21]. As the center trapezoid-like polygon moves to the right, the edges corresponding to the next about-to-fail certificate are highlighted.

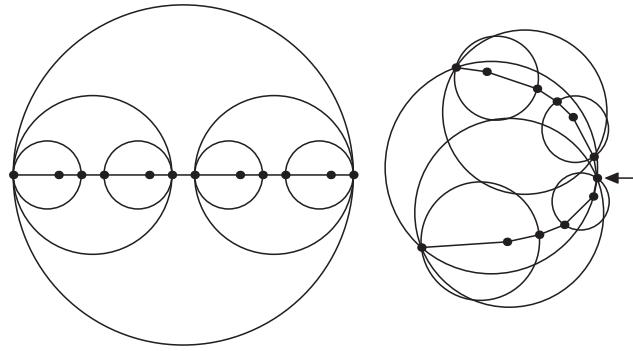

FIGURE 24.8 A thin rod bending from a straight configuration, and a portion of its associated bounding sphere hierarchy. The combinatorially defined sphere hierarchy is stable under deformation. Only the top level sphere differs between the two conformations.

combinatorial description rather infrequently, even under extreme deformation. An example is shown in Figure 24.8 where the rod shown is bent substantially, yet only the top-level sphere needs to update its description.

The pseudotriangulation-based methods above can also be adapted to deal with object deformation.

24.5.5 Connectivity and Clustering

Closely related to proximity problems is the issue of maintaining structures encoding connectivity among moving geometric objects. Connectivity problems arise frequently in *ad hoc* mobile communication and sensor networks, where the viability of links may depend on proximity or direct line-of-sight visibility among the stations desiring to communicate. With some assumptions, the communication range of each station can be modeled by a geometric region, so that two stations can establish a link if and only if their respective regions overlap. There has been work on kinetically maintaining the connected components of the union of a set of moving geometric regions for the case of rectangles [28] and unit disks [29].

Clustering mobile nodes is an essential step in many algorithms for establishing communication hierarchies, or otherwise structuring *ad hoc* networks. Nodes in close proximity can communicate directly, using simpler protocols; correspondingly, well-separated clusters can reuse scarce resources, such as the same frequency or time-division multiplexing communication scheme, without interference. Maintaining clusters of mobile nodes requires a tradeoff between the tightness, or optimality of the clustering, and its stability under motion. In Reference 30 a randomized clustering scheme is discussed based on an iterated leader-election algorithm that produces a number of clusters within a constant factor of the optimum, and in which the number of cluster changes is also asymptotically optimal. This scheme was used in Reference 31 to maintain a routing graph on mobile nodes that is always sparse and in which communication paths exist that are nearly as good as those in the full communication graph.

Another fundamental kinetic question is the maintenance of a minimum spanning tree (MST) among n mobile points in the plane, closely related to earlier work on parametric spanning trees [32] in a graph whose edge weights are functions of a parameter λ (λ is time in the kinetic setting). Since the MST is determined by the sorted order of the edge weights in the graph, a simple algorithm can be obtained by maintaining the sorted list of weights and some auxiliary data structures (such an algorithm is quadratic in the graph size, or $O(n^4)$ in our case). This was improved when the weights are linear functions of time to nearly $O(n^{11/6})$ (subquadratic) for planar graphs or other minor-closed families [33]. When the weights are the Euclidean distances between moving points, only approximation algorithms are known and the best event bounds are nearly cubic [18]. For many other optimization problems on geometric graphs, such as shortest paths for example, the corresponding kinetic questions are wide open.

24.5.6 Visibility

The problem of maintaining the visible parts of the environment when an observer is moving is one of the classic questions in computer graphics and has motivated significant developments, such as binary space partition trees, the hardware depth buffer, etc. The difficulty of the question increases significantly when the environment itself includes moving objects; whatever visibility structures accelerate occlusion culling for the moving observer, must now themselves be maintained under object motion.

Binary space partitions (BSP) are hierarchical partitions of space into convex tiles obtained by performing planar cuts (Chapter 21). Tiles are refined by further cuts until the interior of each tile is free of objects or contains geometry of limited complexity. Once a BSP tree is available, a correct visibility ordering for all geometry fragments in the tiles can be easily determined and incrementally maintained as the observer moves. A kinetic algorithm for visibility can be devised by maintaining a BSP tree as

STRUCTURE	BOUNDS ON EVENTS	SOURCE
Convex hull	$\Omega(n^{2+\epsilon})$	[16]
Pseudotriangulation	$O(n^2)$	[5]
Triangulation (arb.)	$\Omega(n^{7/3})$	[5]
MST	$O(n^{11/6} \log^{3/2} n)$	[6]
BSP	$\tilde{O}(n^2)$	[7, 11]

FIGURE 24.9 Bounds on the number of combinatorial changes.

the objects move. The key insight is to certify the correctness of the BSP tree through certain combinatorial conditions, whose failure triggers localized tree rearrangements—most of the classical BSP construction algorithms do not have this property. In \mathcal{R}^2 , a randomized algorithm for maintaining a BSP of moving disjoint line segments is given in Reference 34. The algorithm processes $O(n^2)$ events, the expected cost per tree update is $O(\log n)$, and the expected tree size is $O(n \log n)$. The maintenance cost increases to $O(n\lambda_{s+2}(n) \log^2 n)$ [35] for disjoint moving triangles in \mathcal{R}^3 (s is a constant depending on the triangle motion). Both of these algorithms are based on variants on vertical decompositions (many of the cuts are parallel to a given direction). It turns out that in practice these generate “sliver-like” BSP tiles that lead to robustness issues [36].

As the pioneering work on the visibility complex has shown [37], another structure that is well suited to visibility queries in \mathcal{R}^2 is an appropriate pseudotriangulation. Given a moving observer and convex moving obstacles, a full radial decomposition of the free space around the observer is quite expensive to maintain. One can build pseudotriangulations of the free space that become more and more like the radial decomposition as we get closer to the observer. Thus one can have a structure that compactly encodes the changing visibility polygon around the observer, while being quite stable in regions of the free space well-occluded from the observer [38].

24.5.7 Result Summary

We summarize in Figure 24.9 the efficiency bounds on the main KDSs discussed above.

24.5.8 Open Problems

As mentioned above, we still lack efficient kinetic data structures for many fundamental geometric questions. Here is a short list of such open problems:

1. Find an efficient (and responsive, local, and compact) KDS for maintaining the convex hull of points moving in dimensions $d \geq 3$.
2. Find an efficient KDS for maintaining the smallest enclosing disk in $d \geq 2$. For $d = 2$, a goal would be an $O(n^{2+\epsilon})$ algorithm.
3. Establish tighter bounds on the number of Voronoi diagram events, narrowing the gap between quadratic and near-cubic.
4. Obtain a near-quadratic bound on the number of events maintaining an arbitrary triangulation of linearly moving points.*
5. Maintain a kinetic triangulation with a guarantee on the shape of the triangles, in subcubic time.
6. Find a KDS to maintain the MST of moving points under the Euclidean metric achieving subquadratic bounds.

Beyond specific problems, there are also several important structural issues that require further research in the KDS framework. These include:

24.5.8.1 Recovery after Multiple Certificate Failures

We have assumed up to now that the KDS assertion cache is repaired after each certificate failure. In many realistic scenarios, however, it is impossible to predict exactly when certificates will fail because explicit motion descriptions may not be available. In such settings we may need to sample the system and thus we must be prepared to deal with multiple (but hopefully few) certificate failures at each time step. A general area of research that this suggests is the study of how to efficiently update common geometric structures, such as convex hulls, Voronoi and Delaunay diagrams, arrangements, etc., after “small motions” of the defining geometric objects.

There is also a related subtlety in the way that a KDS assertion cache can certify the value, or a computation yielding the value, of the attribute of interest. Suppose our goal is to certify that a set of moving points in the plane, in a given circular order, always form a convex polygon. A plausible certificate set for convexity is that all interior angles of the polygon are convex. See Figure

* While this handbook was going to print, Agarwal, Wang and Yu, gave a near-quadratic such algorithm [39].

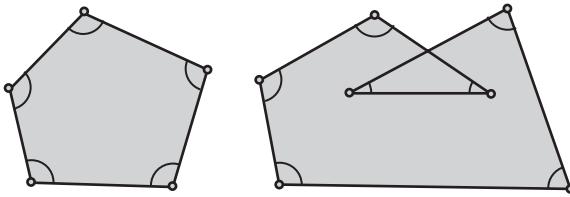

FIGURE 24.10 Certifying the convexity of a polygon.

24.10. In the normal KDS setting where we can always predict accurately the next certificate failure, it turns out that the above certificate set is sufficient, *as long as at the beginning of the motion the polygon was convex*. One can draw, however, nonconvex self-intersecting polygons all of whose interior angles are convex, as also shown in the same figure. The point here is that a standard KDS can offer a *historical* proof of the convexity of the polygon by relying on the fact that the certificate set is valid *and* that the polygon was convex during the prior history of the motion. Indeed the counterexample shown cannot arise under continuous motion without one of the angle certificates failing first. On the other hand, if an oracle can move the points when “we are not looking,” we can wake up and find all the angle certificates to be valid, yet our polygon need not be convex. Thus in this oracle setting, since we cannot be sure that no certificates failed during the time step, we must insist on *absolute* proofs—certificate sets that in any state of the world fully validate the attribute computation or value.

24.5.8.2 Hierarchical Motion Descriptions

Objects in the world are often organized into groups and hierarchies and the motions of objects in the same group are highly correlated. For example, though not all points in an elastic bouncing ball follow exactly the same rigid motion, the trajectories of nearby points are very similar and the overall motion is best described as the superposition of a global rigid motion with a small local deformation. Similarly, the motion of an articulated figure, such as a man walking, is most succinctly described as a set of relative motions, say that of the upper right arm relative to the torso, rather than by giving the trajectory of each body part in world coordinates.

What both of these examples suggest is that there can be economies in motion description, if the motion of objects in the environment can be described as a superposition of terms, some of which can be shared among several objects. Such hierarchical motion descriptions can simplify certificate evaluations, as certificates are often local assertions concerning nearby objects, and nearby objects tend to share motion components. For example, in a simple articulated figure, we may wish to assert CCW (A, B, C) to indicate that an arm is not fully extended, where \overline{AB} and \overline{BC} are the upper and lower parts of the arm respectively. Evaluating this certificate is clearly better done in the local coordinate frame of the upper arm than in a world frame—the redundant motions of the legs and torso have already been factored out.

24.5.8.3 Motion Sensitivity

As already mentioned, the motions of objects in the world are often highly correlated and it behooves us to find representations and data structures that exploit such motion coherence. It is also important to find mathematical measures that capture the degree of coherence of a motion and then use this as a parameter to quantify the performance of motion algorithms. If we do not do this, our algorithm design may be aimed at unrealistic worst-case behavior, without capturing solutions that exploit the special structure of the motion data that actually arise in practice—as already discussed in a related setting in Reference 40. Thus it is important to develop a class of kinetic *motion-sensitive* algorithms, whose performance can be expressed a function of how coherent the motions of the underlying objects are.

24.5.8.4 Non-Canonical Structures

The complexity measures for KDSs mentioned earlier are more suitable for maintaining *canonical* geometric structures, which are uniquely defined by the position of the data, for example, convex hull, closest pair, and Delaunay triangulation. In these cases the notion of external events is well defined and is independent of the algorithm used to maintain the structure. On the other hand, as we already discussed, suppose we want to maintain a triangulation of a moving point set. Since the triangulation of a point set is not unique, the external events depend on the triangulation being maintained, and thus depend on the algorithm. This makes it difficult to analyze the efficiency of a kinetic triangulation algorithm. Most of the current approaches for maintaining noncanonical structures artificially impose canonicality and maintain the resulting canonical structure. But this typically increases the number of events. So it is entirely possible that methods in which the current form of the structure may depend

on its past history can be more efficient. Unfortunately, we lack mathematical techniques for analyzing such history-dependent structures.

24.6 Querying Moving Objects

Continuous tracking of a geometric attribute may be more than is needed for some applications. There may be time intervals during which the value of the attribute is of no interest; in other scenarios we may be just interested to know the attribute value at certain discrete query times. For example, given n moving points in \mathcal{R}^2 , we may want to pose queries asking for all points inside a rectangle R at time t , for various values of R and t , or for an interval of time Δt , etc. Such problems can be handled by a mixture of kinetic and static techniques, including standard range-searching tools such as partition trees and range trees [8]. They typically involve tradeoffs between evolving indices kinetically, or prebuilding indices for static snapshots. An especially interesting special case is when we want to be able answer queries about the near future faster than those about the distant future—a natural desideratum in many real-time applications.

A number of other classical range-searching structures, such as k -d-trees and R -trees have recently been investigated for moving objects [41,42].

25.1 Introduction

Given an initially empty set S , the dictionary problem consists of executing online any sequence of operations of the form $S.\text{membership}(s)$, $S.\text{insert}(s)$, and $S.\text{delete}(s)$, where each element s is an object (or point in one-dimensional space). Each object can be stored in a single word, and it takes $O(1)$ time to store or retrieve it. It is well known that the set may be represented by using arrays (sorted or unsorted), linked lists (sorted or unsorted), hash tables, binary search trees, AVL-trees, B-trees, 2-3 trees, weighted balanced trees, or balanced binary search trees (i.e., 2-3-4 trees, symmetric B-trees, half balanced trees, or red-black trees).

The worst-case time complexity for performing each of these operations is $O(\log n)$, where n is the maximum number of elements in the set being represented, when using AVL-trees, B-trees (fixed order), 2-3 trees, weighted balanced trees, or balanced binary search trees. See [Chapters 2, 3, 9, 11](#) and [16](#) for details on these structures. The insertion or deletion of elements in these structures requires a set of additional operations to preserve certain properties of the resulting trees. For binary search trees, these operations are called *rotations*, and for m-way search trees they are called *splitting or combining* nodes. The balanced binary search trees are the only trees that require a constant number of rotations for both the *insert* and *delete* operations [\[1,2\]](#).

This chapter discusses several algorithms [\[3,4\]](#) for the generalized dictionary problem for the case when the data is multidimensional, rather than one dimensional. Each data element consists of d -ordered components which we call *ordered d-tuple* or simply *d-tuple*. Each component contains a value which can be stored in a memory word and which can be compared against another value to determine whether the values are identical, the first value is larger than the second one, or the first value is smaller than the second one. The comparison operation between components takes constant time. We show that the basic multidimensional dictionary operations can be implemented to take $O(d + \log n)$, where n is the number of d -tuples in the set. We also show that other common operations can also be executed within the same time complexity bounds.

Let us now discuss one of the many applications of multidimensional dictionaries. Given a set of n points in multidimensional space and an integer D , the problem is to find the least number of orthogonal hypersquares (or d -boxes) of size D to cover all the points, that is, each of the points must be in at least one of the d -boxes. This covering problem arises in image processing, as well as when locating emergency facilities so that all users are within a reasonable distance of one of the facilities [\[5\]](#). The problem has been shown to be NP-hard and several polynomial time approximation schemes for its solution have been developed [\[5\]](#). The simplest approximation algorithm defines d -boxes along a multidimensional grid with grid d -boxes of length D . The approximation algorithm takes every d -dimensional point and by using simple arithmetic operations, including the floor function, finds its appropriate (grid) d -box. The d -box, which is characterized by d integer components, is inserted into a multidimensional dictionary and the operation is repeated for each d -dimensional point. Then one just visits all the d -tuples in the set and the d -boxes they represent is the solution generated by this simple approximation algorithm. Note that when a d -tuple is inserted into a multidimensional dictionary that already contains it, the dictionary will not change because dictionaries store sets, that is, multiple copies of the d -tuples are not allowed. Other applications of multidimensional dictionaries are when accessing multiattribute data by value. These applications include the management of geometrical objects and the solution of geometry search problems.

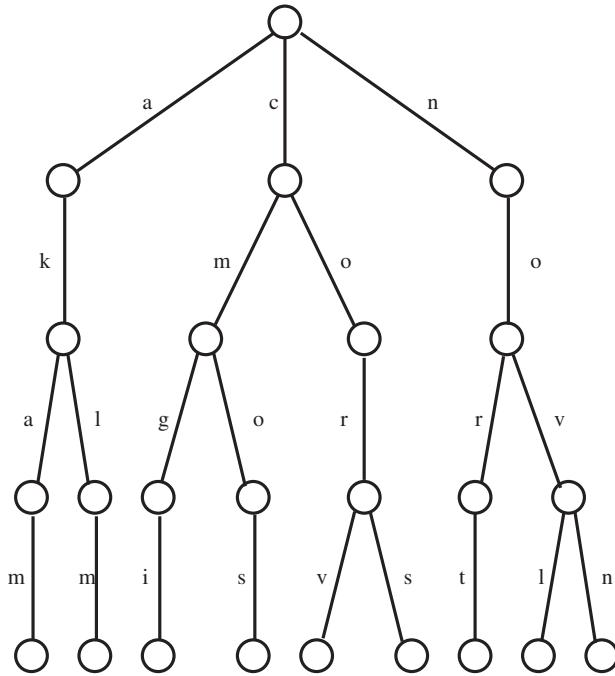

FIGURE 25.1 Trie for set T .

Given a d -tuple s in set S , one may access in constant time the i th element in the d -tuple by using the function $s.x(i)$. In other words, the d -tuple s is simply $(s.x(1), s.x(2), \dots, s.x(d))$. In this chapter, we examine the methods given in References 3 and 4 to represent the data set and their algorithms to perform online any sequence of the multidimensional dictionary operations. The most efficient of the implementations performs each of the three dictionary operations in $O(d + \log n)$ time, where n is the number of d -tuples and d is the number of dimensions. Each of the insert and delete operations requires no more than a constant number of rotations. The best of the algorithms requires dn words to represent the d -tuples, plus $O(n)$ additional space is required to keep additional pointers and data. Because we are using balanced binary search trees, we can also perform other operations efficiently. For example, find the (lexicographically) smallest or largest d -tuple ($O(\log n)$ time), print in lexicographic order ($O(dn)$ time), and concatenation ($O(d + \log n)$ time). By modifying slightly the representation and introducing additional information, one can also find the (lexicographically) k th smallest or largest d -tuple efficiently ($O(\log n)$ time). In Section 25.5, we show that the structure given in Reference 4 may also be used to implement the split operation in $O(d + \log n)$ time and that the approach can also be used with other balanced structures, such as AVL-trees, weight-balanced trees, and so on.

25.2 Trie Implementations

It is interesting to note that three decades ago balanced structures were written off for this type of applications. As noted in Reference 6, “balanced tree schemes based on key comparisons (e.g., AVL-trees, B-trees, etc.) lose some of their usefulness in this more general context.” At that time the approach was to use *tries* in conjunction with balanced tree schemes to represent multidimensional data. We will elaborate on these structures after defining some terms.

Given a set of strings over an alphabet Σ , the tree of all their prefixes is called a *trie* (see Chapter 29). In Figure 25.1, we depict the trie for the set of strings over the English alphabet $T = \{akam, aklm, cmgi, cmos, cors, corv, nort, novl, novn\}$. In this case, all the elements in the trie have the same number of symbols, but in general a trie may contain string with different number of symbols. Each node x in a trie is the destination of all the strings with the same prefix (say p_x) and node x consists of a set of element–pointer pairs. The first component of the pair is an alphabet element and the second one is a pointer to a subtrie that contains all the strings with prefix p_x followed by the alphabet element. In Figure 25.1, the pairs for a trie node are represented by the edges emanating from the lower portion of the circle that represents a node. Note that no two element–pointer pairs for a trie node have the same first component or the same second component. The set of element–pointer pairs in a trie node may be represented in different ways. For example, one may store the element–pointer pairs for each internal node as follows:

1. An array of m pointers, where m is the number of elements in the alphabet Σ . In this case, one needs to define a function to translate each element in the alphabet to an integer in the range $[0, m - 1]$. The function can normally be implemented to take constant time;
2. A sorted linked list with all the symbols and corresponding pointers of the branches emanating from the node [7];
3. A binary search tree with all the symbols and corresponding pointers of the branches emanating from the node [8].

We shall refer to the resulting structures as trie-array, trie-list, and trie-bst, respectively. These are by no means all the possibilities. For example, later on we discuss hybrid representations that have some interesting properties.

For multidimensional dictionaries defined over the set of integers $[0, m)$, the trie method treats a point in d -space as a string with d elements defined over the alphabet $\Sigma = \{0, 1, \dots, m - 1\}$ (see [Figure 25.1](#)). For the trie-array representation, the element–pointer pairs in a trie node are represented by an m -element sequential array of pointers. The i th pointer corresponds to the i th alphabet symbol, and a null pointer is used when the corresponding alphabet element is not part of any element–pointer pair. The space required to represent n d -tuples in this structure is at most dnm pointers, but the total amount of information can be represented using $dn \log m$ bits. The insert and delete operations take $O(md)$ time, because either of these operations may add or delete $d - 1$ trie nodes and each node includes an m -component array of pointers. On the other hand, the membership operation takes only $O(d)$ time. This is the fastest way of implementing the membership operation no matter what structure is used to represent the set. The trie-array implementation is not possible when m is large because there will be too much space wasted. The trie-list representation mentioned above is much better for this scenario. In this case, the list of element–pointer pairs is stored in a sorted linked list. The list is sorted with respect to the alphabet elements, that is, the first component in the element–pointer pairs. In the trie-bst representation, the element–pointers are stored in a binary search tree. The ordering is with respect to the alphabet elements. In the former case, we use dn memory locations for the d -tuples, plus $2dn$ pointers, and in the latter case one needs $3dn$ pointers. The time complexity for insert, delete, and membership in both of these representations is $O(d + n)$. It is important to note that there are two types of pointers: the trie pointers and the linked list or binary search tree pointers.

In practice, one may use hybrid structures in which some nodes in the trie are trie-arrays and others are trie-lists, and depending on the number of element–pointer pairs one transforms from one representation to the other. For example, if the number of element–pointer pairs becomes more than some bound b_u one uses trie-array nodes, but if it is less than b_l then one uses the trie-list nodes. If it is some number between these two bounds, then either representation is fine to use. By using appropriate values for b_l and b_u in this approach, we can avoid “trashing” which means that the algorithm spends most of the time changing back and forth from one representation to the other.

Bentley and Saxe [9] used a modified version of the trie-bst implementation. In this case, the binary search tree is replaced by a completely balanced binary tree. That is, each binary search tree or subtree for trie node x with k element–pointer pairs has as root an element–pointer pair (y, ptr) such that the median of the ordered strings (with prefix equal to the prefix of the trie node x (denoted by p_x) plus any of the k alphabet elements in the k element–pointer pairs) has as prefix p_x followed by y . For example, the root of the trie in [Figure 25.1](#) has the pair with alphabet element c , and the root of the subtree for the prefix no is the pair with alphabet element v . This balanced structure is the best possible when the trie does not change or it changes very slowly like in multikey sorting or restricted searching [10,11]. Since the overall structure is rigid, it can be shown that rebalancing after inserting or deleting an element can be very expensive and therefore not appropriate in a dynamic environment.

Research into using different balanced strategies for the trie-bst structures has lead into structures that use fixed order B-trees [12], weight-balanced trees [6], AVL-trees [13], and balanced binary search trees [14]. It has been shown that insert, delete, and membership for multidimensional dictionaries for all of the above structures take $O(d + \log n)$ time in the worst case, except for weight-balanced trees in which case it is an expected time complexity bound. The above procedures are complex and require balancing criteria in addition to the obvious ones. Also, the number of rotations needed for these insert and delete operations is not bounded by a constant. Vaishnavi [14] used balanced binary search trees that require only a constant number of rotations, however, since one may encounter d trees, the total number of rotations are no longer bounded by a constant. He left it as an open problem to design a structure such that multidimensional dictionaries can be implemented so that only a constant number of rotations are performed after each insert and delete operation.

25.3 Binary Search Tree Implementations

As pointed out by Gonzalez [3,4], using a balanced binary search tree (without a trie) and storing each tuple at each node lead to membership (and also insert and delete) algorithms that take $O(d \log n)$ time, where n is the number of elements in the tree, because one needs to compare the element being searched with the d -tuples at each node. One can go further and claim that for some problem instances it actually requires $\Theta(d \log n)$ time. Gonzalez [4] also points out that simple shortcuts to the search process do not work. For example, if we reach a node in the search such that the first k components are identical, one may be tempted to conclude that in the subtree rooted at that node one needs to search only from position $k + 1$ to d in the d -tuples. This

is false because the k -component prefixes of all the d -tuples in a subtree may vary considerable in a binary search tree. One can easily show that even the membership operation cannot be implemented this way. However, this variation is more predictable when comparing against the smallest or largest d -tuple in a subtree. This is a key idea exploited in Reference 3.

Manber and Myers [15] developed an efficient algorithm that given an N symbol text it finds all the occurrences of any input word q . The scenario is that the text is static, but there will be many word searches. Their approach is to preprocess the text and generate a structure where the searching can be performed efficiently. In their preprocessing stage, they construct a sorted list with all the N suffixes of the text. Locating all the occurrences of a string q reduces to performing two binary search operations in the list of suffixes, the first for the first suffix that contains as prefix q and the second search is for the last suffix that contains as prefix q . Both searches are similar, so let's discuss the first one. This operation is similar to the membership operation discussed in this chapter. Manber and Myers [15] binary search process begins by letting L (R) be the largest (smallest) string in the list. Then l (r), the index of the first element where L (R) differs from q , is computed. Note that if two strings are identical the index of the first component where they differ is set to the length of string plus 1. We use this convention throughout this chapter. The middle entry M in the list is located and then they compute the index of the first component where M and q differ. If this value is computed the obvious way, then the procedure will not be efficient. To do this efficiently they compute it with l , r as well as the index of the first component where M and L , and M and R differ. These last two values are precomputed in the preprocessing stage. This indirect computation may take $O(|q|)$ time; however, overall the phases of the computation the process takes at most $O(|q|)$ time. The advantage of this approach is that it requires only $O(N)$ space, and the preprocessing can be done in $O(N)$ expected time [15]. The disadvantage is that it is not dynamic. Updating the text requires expensive recomputation of the precomputed data, that is, one needs to find the first component where many pairs in the list differ in order to carry out efficiently the binary search process. For their application [15], the text is static. The time required to do the search for q is $O(|q| + \log N)$ time. This approach results in a structure that is similar to the fully balanced tree strategy in Reference 9.

Gonzalez [3] solved Vaishnavi's open problem by designing a binary tree data structure where the multidimensional dictionary operations can be performed in $O(d + \log n)$ time while performing only a constant number of rotations. To achieve this goal the set of d -tuples S is represented in a balanced binary search tree that contains additional information at each node. This additional information is similar to the one in the lists of Manber and Myers [15], but it can be recomputed efficiently as we insert and delete elements. The disadvantage is that the membership operation is more complex. But all the procedures developed in Reference 3 are simpler than the ones given in References 6,12–14. One just needs to add a few instructions in addition to the normal code required to manipulate balanced binary search trees [2]. The additional information in Reference 3 includes for every node v in the tree the index of the first element where v and the smallest (largest) d -tuple in the subtree rooted at v differ as well as a pointer to this d -tuple. As mentioned above, testing for membership is more complex. At each iteration in the search process [3], we are at the tree node t and we know that if q is in the tree then it is in the subtree rooted at t . The algorithm knows either the index of a component where q and the smallest d -tuple in the subtree t differ, or the index of a component where q and the largest d -tuple in the subtree t differ. Then the algorithm determines that q is in node t or it advances to the left or right subtrees of node t . In either case, it maintains the above invariant. It is important to point out that the invariant is: "the index of a component where q and the smallest d -tuple in the subtree differ" rather than the "the first index of a ..." It does not seem possible to find "the first index ..." in this structure efficiently with the information stored in the tree. This is not a big problem when q is in the tree since it will be found quickly, but if it is not in the tree then in order to avoid reporting that it is in the tree one must perform an additional verification step at the end that takes $O(d)$ time. Gonzalez [3] calls this search strategy "assume, verify, and conquer" (AVC). That is, in order to avoid multiple expensive verification steps one assumes that some prefixes of strings match. The outcome of the search depends on whether or not these assumptions were valid. This can be determined by performing one simple verification step that takes $O(d)$ time. The elimination of multiple verification steps is very important because in the worst case there are $\Omega(\log n)$ of such steps, and each one could take $\Omega(d)$ time. The difference between this approach and the one in Reference 15 is that Manber and Myers compute the first element where M and q differ, whereas Gonzalez [3] computes an element where M and q differ. As we said before, in Gonzalez [3] structure one cannot compute efficiently the first element where M and q differ, whereas in Reference 15 this is possible because it is a static structure.

Gonzalez [4] modified the structure in Reference 3 to one that follows the search process in Reference 15. The new structure, which we discuss in Section 25.4, is in general faster to update because for every node t one keeps the index of the first component where the d -tuple stored at node t and the smallest (largest) d -tuple greater (smaller) than all the d -tuples in the subtree rooted at t (if any) differ, rather than the one between node t and the smallest (largest) d -tuple in its subtree rooted at t as in Reference 3. In this structure, only several nodes have to be modified when inserting a node or deleting a leaf node, but in the structure in Reference 3 one may need to update $O(\log n)$ nodes. Deleting a nonleaf node from the tree requires more work in this structure than in Reference 3, but membership testing is simpler in the structure in Reference 4. To summarize, the membership algorithm in Reference 4 mimics the search procedure in Reference 15, but follows the update approach developed in Reference 3. Gonzalez [4] established that the dictionary operations can be implemented to take $O(d + \log n)$ time while performing only a constant

number of rotations for both insert and delete. Other operations which can be performed efficiently in this multidimensional balanced binary search trees are: finding the (lexicographically) smallest (largest) d -tuple ($O(\log n)$ time), print in lexicographic order ($O(dn)$ time), and concatenation ($O(d + \log n)$ time). Finding the (lexicographically) k th smallest (largest) d -tuple can also be implemented efficiently ($O(\log n)$ time) by adding to each node the number of nodes in its left subtree. The asymptotic time complexity bound for the procedures in Reference 4 is identical to the ones in Reference 3, but the procedures in Reference 4 are simpler. To distinguish this new type of balanced binary search trees from the classic ones and the ones in Reference 3, we refer to these trees as *multidimensional balanced binary search trees*. In this article, we follow the notation in Reference 4.

In Section 25.5, we show that the rotation operation in Reference 4 can be implemented to take only constant time by making some rather simple operations that were first discussed in Reference 16. The implication of this, as pointed out in Reference 16, is that the split operation can also be implemented to take $O(d + \log n)$. Also, the efficient implementation of the rotation operation allows us to use the technique in Reference 4 on many other balanced structures, such as AVL, weight balanced, and so on, since performing $O(\log n)$ rotations does not limit the applicability of the techniques in Reference 4. These observations were first reported in Reference 16, where they present a similar approach, but in a more general setting.

25.4 Balanced BST Implementation

Let us now discuss the data structure and algorithms for the multidimensional dictionaries given in Reference 4. The representation is based on balanced binary search trees, without external nodes, that is, each node represents one d -tuple. Balanced binary search trees and their algorithms [2] are like the typical “bottom-up” algorithms for the Red-Black trees. The ordering of the d -tuples is lexicographic. Each node t in the tree rooted at r has the following information in addition to the color bit required to manipulate balanced binary search trees [2]. Note that if two d -tuples are identical the index of the first component where they differ is set to $d + 1$. We use this convention throughout this chapter.

<i>s:</i>	The d -tuple represented by the node. The individual components may be accessed as $s.x(1), s.x(2), \dots, s.x(d)$
<i>lchild:</i>	Pointer to the left subtree of t
<i>rchild:</i>	Pointer to the right subtree of t
<i>lptr:</i>	Pointer to the node with largest d -tuple in r with value smaller than all the d -tuples in the subtree rooted at t , or null if no such d -tuple exists
<i>hptr:</i>	Pointer to the node with smallest d -tuple in r with value larger than all the d -tuples in the subtree rooted at t , or null if no such d -tuple exists
<i>lj:</i>	Index of first component where s and the d -tuple at the node pointed at by <i>lptr</i> differ, or one if <i>lptr = null</i>
<i>hj:</i>	Index of first component where s and the d -tuple at the node pointed at by <i>hptr</i> differ, or one if <i>hptr = null</i>

The insert, delete, and membership procedures perform the operations required to manipulate balanced binary search trees, and some new operations to update the structure. The basic operations to manipulate balanced binary search trees are well known [1,2]; so we only discuss in detail the new operations.

To show that membership, insert, and delete can be implemented to take $O(d + \log n)$ time, we only need to show that the following (new) operations can be performed $O(d + \log n)$ time.

- A. Given the d -tuple q determine whether or not it is stored in the tree
- B. Update the structure after adding a node (just before rotation(s), if any)
- C. Update the structure after performing a rotation
- D. Update the structure after deleting a leaf node (just before rotation(s), if any)
- E. Transform the deletion problem to deletion of a leaf node.

The membership operation that tests whether or not the d -tuple q given by $(q.x(1), q.x(2), \dots, q.x(d))$ is in the multidimensional binary search tree (or subtree) rooted at r appears in [4] and implements (A). The basic steps are as follows. Let t be any node encountered in the search process in the multidimensional balanced binary search tree rooted at r . Let $prev(t)$ to be the d -tuple in r with largest value but whose value is smaller than all the d -tuples stored in the subtree rooted at t , unless no such tuple exists in which case its value is $(-\infty, -\infty, \dots, -\infty)$, and let $next(t)$ be the d -tuple in r with smallest value but whose value is larger than all the d -tuples stored in the subtree rooted by t , unless no such tuple exists in which case its value is $(+\infty, +\infty, \dots, +\infty)$. The following invariant is maintained throughout the search process. During the search we will be visiting node t which is initially the root of the tree. The value of d_{low} is the index of the first component where q and $prev(t)$ differ, and variable d_{high} is the index of the first component where q and $next(t)$ differ. The d -tuple being search for, q , has value (lexicographically) greater than $prev(t)$ and (lexicographically) smaller than $next(t)$.

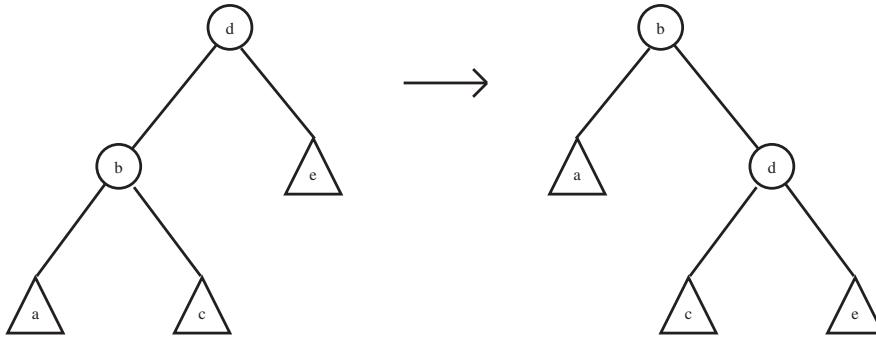

FIGURE 25.2 Rotation.

The computation of j , the index of the first component where $t.s$ and q differ is performed as follows: when $d_{low} \geq d_{high}$, then either (1) $d_{low} = t.lj$ in which case j is just $\min\{d_{low}, t.lj\}$, or (2) $d_{low} = t.lj$ in which case j is set to the index of the first component starting at position d_{low} where q and $t.s$ differ. The case when $d_{low} < d_{high}$ is similar and appears in Reference 4. Gonzalez [4] proved that by setting j by the above procedure will set it to the index of the first component where $t.s$ and q differ. When j is equal to $d + 1$, then q is the d -tuple stored in t and the procedure returns the value of **true**. Otherwise by comparing the j th element of q and t , the procedure decides whether to search in the left or right subtrees of t . In either case d_{high} or d_{low} is set appropriately and the invariant holds at the next iteration. The time complexity at each level is not bounded by a constant; however, it is bounded by 1 plus the difference between the new and old values of $\max\{d_{low}, d_{high}\}$. Since $\max\{d_{low}, d_{high}\}$ does not decrease and it is at most $d + 1$ at the end of each operation, it follows that the total number of operations performed is of order d plus the height of the tree ($O(\log n)$). Correctness and efficiency are established in the following lemma whose proof appears in Reference 4.

Lemma 25.1

Given a d -tuple q , the formal procedure membership (q, r) given in Reference 4 determines whether or not q is in the multidimensional balanced binary search tree rooted at r in $O(d + \log n)$ time [4].

For operation (B), a node is added as a leaf node, the information that needs to be set for that node are the pointers $lptr$ and $hptr$ which can be copied from the parent node, unless there is no parent in which case they are set to null. The values lj and hj can be computed directly in $O(d)$ time. A predecessor of the node added also needs its $lptr$ and lj , or $hptr$ and hj values changed. This can be easily done in $O(d)$, by remembering the node in question during the search process, that is, the last node where one makes a left turn (moving to the leftchild) or the last one where one makes a right turn (moving to the rightchild).

Lemma 25.2

After inserting a node q in a multidimensional balanced binary search tree and just before rotation, the structure can be updated as mentioned above in $O(d + \log n)$ time [4].

The implementation of operation (D) is similar to the one for (B), therefore, it will not be discussed further. The rotation operation (C) can be reduced to a simple rotation, as a double or triple rotation can be reduced to two and three simple rotations, respectively. A simple rotation is shown in Figure 25.2. It is simpler to implement the rotation operation by moving the nodes rather than just their values, because this reduces the number of updates that need to be performed. Clearly, the only nodes whose information needs to be updated are b , d and the parent of d . This can be implemented to take $O(d)$ time.

Lemma 25.3

After a rotation in a multidimensional balanced binary search tree, the structure can be updated as mentioned above in $O(d)$ time [4].

Operation (E) is more complex to implement. It is well known [17] that the problem of deleting an arbitrary node from a balanced binary search tree can be reduced to deleting a leaf node by applying a simple transformation. Since all cases are similar, let's just discuss the case shown in Figure 25.3. The node to delete is a which is not a leaf node. In this case, node b contents are moved to node a , and now we delete the old node b which is labeled x . As pointed out in Reference 4, updating the resulting

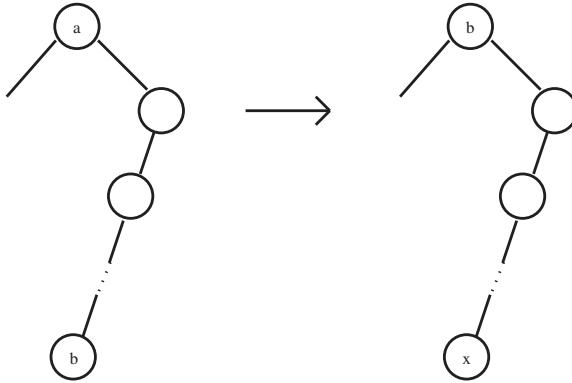

FIGURE 25.3 Transforming deletion of an arbitrary node to deletion of a leaf node.

structure takes $O(d + \log n)$ time. Since the node labeled x will be deleted, we do not need to update it. For the new root (the one labeled b), we need to update the lj and hj values. Since we can use directly the old $lptr$ and $hptr$ pointers, the update can be done in $O(d)$ time. The lj (hj) value of the nodes (if any) in the path that starts at the right (left) child of the new root that continues through the leftchild (rightchild) pointers until the null pointer is reached needs to be updated. There are at most $O(\log n)$ of such nodes. However, the d -tuples stored at each of these nodes are decreasing (increasing) in lexicographic order when traversing the path top down. Therefore, the lj (hj) values appear in increasing (decreasing) order. The correct values can be easily computed in $O(d + \log n)$ time by reusing previously computed lj (hj) values while traversing the path top down. The following lemma, whose proof is omitted, summarizes these observations. Then we state the main result in Reference 4 which is based on the above discussions and the lemmas.

Lemma 25.4

Transforming the deletion problem to deleting a leaf node can be performed, as mentioned above, in $O(d + \log n)$ time [4].

Theorem 25.1

Any online sequence of operations of the form insert, delete, and membership, for any d -tuple can be carried out on a multidimensional balanced binary search tree in $O(d + \log n)$ time, where n is the current number of points, and each insert and delete operation requires no more than a constant number of rotations [4].

25.5 Additional Operations

With respect to other operations, one can easily find the smallest or largest d -tuple in $O(\log n)$ time by just taking all the leftchild or rightchild pointers. By traversing the tree in inorder one can print all the d -tuples in increasing in $O(dn)$ time. An $O(d + \log n)$ time algorithm to concatenate two sets represented by the structure can be easily obtained by using standard procedures provided that all the d -tuples in one set are in lexicographic order smaller than the ones in the other set. The k th smallest or largest d -tuple can be found in $O(\log n)$ time after adding to each node in the tree the number of nodes in its left subtree.

The split operation is given a d -tuple q and a set represented by a multidimensional balanced binary search tree t , split t into two multidimensional balanced binary search trees: one containing all the d -tuples in lexicographic order smaller than or equal to q and the other one containing the remaining elements. At first glance, it seems that the split operation cannot be implemented within the $O(d + \log n)$ time complexity bound. The main reason is that there could be $\Omega(\log n)$ rotations and each rotation takes time proportional to d . However, the analysis in Reference 4 for the rotation operation which is shown in Section 25.4 can be improved and one can show that it can be easily implemented to take constant time. The reason for this is that for a simple rotation, see Figure 25.2, the lj or hj value needs to be updated for the node labeled b , and we know the $lptr$ and $hptr$ pointers. This value can be computed from previous values before the rotation, that is, the lj and hj values for node b and the fact that the $rptr$ value for b is node d before the rotation. The other value to be updated is the lj value for node d after the rotation, but this is simply the lj value for node d before the rotation.

The efficient implementation of the rotation operation allows us to use the same technique on many other balanced structures, such as AVL-trees, weight-balanced trees, and so on, since having $O(\log n)$ rotations does not limit its applicability.

25.6 Discussion

On average, the trie-bst approach requires less space to represent the d -tuples than our structures. However, multidimensional balanced binary search trees have simple procedures that take only $O(d + \log n)$ time, and only a constant number of rotations are required after each insert and delete operations. Furthermore, operations like finding the (lexicographically) smallest or largest d -tuple ($O(\log n)$ time), print in lexicographic order ($O(dn)$ time), concatenation ($O(d + \log n)$ time), and split ($O(d + \log n)$ time) can also be performed efficiently in this new structure. This approach can also be used in other balanced structures, such as AVL-trees, weight-balanced trees, and so on.

26.1 Introduction

For divide-and-conquer purposes, it is often desirable to organize a set S of n numbers into a sorted list, or perhaps to partition it into two equal-sized groups with no element in one group exceeding any element in the other one. More generally, we might wish to break up S into k groups of size roughly n/k , with again a total ordering among the distinct groups. In the first case we sort; in the second one we compute the median; in the third one we compute quantiles. This is all well known and classical. Is it possible to generalize these ideas to higher dimension? Surprisingly the answer is yes. A geometric construction, known as an ε -cutting, provides a space partitioning technique that extends the classical notion of selection to any finite dimension. It is a powerful, versatile data structure with countless applications in computational geometry.

Let H be a set n hyperplanes in \mathbf{R}^d . Our goal is to divide up \mathbf{R}^d into simplices, none of which is cut by too many of the n hyperplanes. By necessity, of course, some of the simplices need to be unbounded. We choose a parameter $\varepsilon > 0$ to specify the coarseness of the subdivision. A set \mathcal{C} of closed full-dimensional simplices is called an ε -cutting for H (Figure 26.1) if:

1. The union of the simplices is \mathbf{R}^d , and their interiors are mutually disjoint;
2. The interior of any simplex is intersected by at most εn hyperplanes of H .

Historically, the idea of using sparsely intersected simplices for divide and conquer goes back to Clarkson [1] and Haussler and Welzl [2], among others. The definition of an ε -cutting given above is essentially due to Matoušek [3]. Efficient but suboptimal constructions were given by Agarwal [4,5] for the two-dimensional case and Matoušek [3,6,7] for arbitrary dimension. The optimal ε -cutting construction cited in the theorem below, due to Chazelle [8], is a simplification of an earlier design by Chazelle and Friedman [9].

Theorem 26.1

Given a set H of n hyperplanes in \mathbf{R}^d , for any $0 < \varepsilon < 1$, there exists an ε -cutting for H of size $O(\varepsilon^{-d})$, which is optimal. The cutting, together with the list of hyperplanes intersecting the interior of each simplex, can be found deterministically in $O(n\varepsilon^{1-d})$ time.

26.2 The Cutting Construction

This section explains the main ideas behind the proof of Theorem 26.1. We begin with a quick overview of geometric sampling theory. For a comprehensive treatment of the subject, see References 10 and 11.

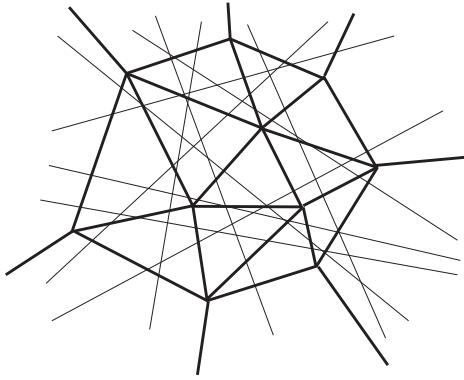

FIGURE 26.1 A two-dimensional cutting.

26.2.1 Geometric Sampling

A *set system* is a pair $\Sigma = (X, \mathcal{R})$, where X is a set and \mathcal{R} is a collection of subsets of X . In our applications, $X \subset \mathbf{R}^d$ and each $R \in \mathcal{R}$ is of the form $X \cap f(K)$, where K is a fixed region of \mathbf{R}^d and f is any member of a fixed group F of transformations. For example, we might consider n points in the plane, together with the subsets lying inside any triangle congruent to a fixed triangle.

Given $Y \subseteq X$, we define the set system “induced by Y ” to be $(Y, \mathcal{R}|_Y)$, with $\mathcal{R}|_Y = \{ Y \cap R \mid R \in \mathcal{R} \}$. The *VC-dimension* (named for Vapnik and Chervonenkis [12]) of Σ is defined as the maximum size of any Y such that $\mathcal{R}|_Y = 2^Y$. For example, the VC-dimension of the infinite geometric set system formed by points in the plane and halfplanes is 3. The *shatter function* $\pi_{\mathcal{R}}(m)$ of the set system $\Sigma = (X, \mathcal{R})$ is the maximum number of subsets in the set system $(Y, \mathcal{R}|_Y)$ induced by any $Y \subseteq X$ of size m . If $\pi_{\mathcal{R}}(m)$ is bounded by cm^d , for some constants $c, d > 0$, then the set system is said to have a *shatter function exponent* of at most d . It was shown in References 12–14 that, if the shatter function exponent is $O(1)$, then so is the VC-dimension. Conversely, if the VC-dimension is $d \geq 1$ then, for any $m \geq d$, $\pi_{\mathcal{R}(m)} < (em/d)^d$.

We now introduce two fundamental notions: ε -nets and ε -approximations. For any $0 < \varepsilon < 1$, a set $N \subseteq X$ is called an ε -net for a finite set system (X, \mathcal{R}) if $N \cap R \neq \emptyset$ for any $R \in \mathcal{R}$ with $|R|/|X| > \varepsilon$. A finer (but more costly) sampling mechanism is provided by an ε -*approximation* for (X, \mathcal{R}) , which is a set $A \subseteq X$ such that, given any $R \in \mathcal{R}$,

$$\left| \frac{|R|}{|X|} - \frac{|A \cap R|}{|A|} \right| \leq \varepsilon.$$

Some simple structural facts about nets and approximations:

Lemma 26.1

If X_1, X_2 are disjoint subsets of X of the same size, and A_1, A_2 are same-size ε -approximations for the subsystems induced by X_1, X_2 (respectively), then $A_1 \cup A_2$ is an ε -approximation for the subsystem induced by $X_1 \cup X_2$.

Lemma 26.2

If A is an ε -approximation for (X, \mathcal{R}) , then any ε' -approximation (resp. -net) for $(A, \mathcal{R}|_A)$ is also an $(\varepsilon + \varepsilon')$ -approximation (resp. -net) for (X, \mathcal{R}) .

In the absence of any restrictive assumption on the set system, it is natural to expect the sample size to depend on both the desired accuracy and the size of the set system itself.

Theorem 26.2

Given a set system (X, \mathcal{R}) , where $|X| = n$ and $|\mathcal{R}| = m$, for any $1/n \leq \varepsilon < 1$, it is possible to find, in time $O(nm)$, an ε -net for (X, \mathcal{R}) of size $O(\varepsilon^{-1} \log m)$ and an ε -approximation for (X, \mathcal{R}) of size $O(\varepsilon^{-2} \log m)$.

If we assume bounded VC-dimension, everything changes. In fact the key result in geometric sampling theory is that, for any given level of accuracy, the sample size need not depend on the size of the set system.

In practice, geometric set systems often are “accessible” via an *oracle* function that takes any $Y \subseteq X$ as input and returns the list of sets in $\mathcal{R}|_Y$ (each set represented explicitly). We assume that the time to do that is $O(|Y|^{d+1})$, which is linear in the maximum possible size of the oracle’s output, where d is the shatter function exponent. For example, in the case of points and disks in the plane, we have $d = 3$, and so this assumes that, given n points, we can enumerate all subsets enclosed by a disk in time $O(n^4)$. To do this, enumerate all k -tuples of points ($k \leq 3$) and, for each tuple, find which points lie inside the smallest disk enclosing the k points. The main result below is stated in terms of the shatter function exponent d , but the same results hold if d denotes the VC-dimension.

Theorem 26.3

Given a set system (X, \mathcal{R}) of shatter function exponent d , for any $\varepsilon \leq 1/2$, an ε -approximation for (X, \mathcal{R}) of size $O(d\varepsilon^{-2} \log d\varepsilon^{-1})$ and an ε -net for (X, \mathcal{R}) of size $O(d\varepsilon^{-1} \log d\varepsilon^{-1})$ can be computed in time $O(d^{3d}(\varepsilon^{-2} \log d\varepsilon^{-1})^d |X|)$.

Vapnik and Chervonenkis [12] described a probabilistic construction of ε -approximations in bounded VC-dimension. The deterministic construction stated above is due to Chazelle and Matoušek [15], and builds on earlier work [3,6,7,9]. Hausler and Welzl [2] proved the upper bound on the size of ε -nets. The running time for computing an ε -net was improved to $O(d^{3d}(\varepsilon^{-1} \log d\varepsilon^{-1})^d |X|)$ by Brönnimann, Chazelle, and Matoušek [16], using the concept of a *sensitive ε -approximation*. Komlós, Pach, and Woeginger [17] showed that, for any fixed d , the bound of $O(\varepsilon^{-1} \log \varepsilon^{-1})$ for ε -nets is optimal in the worst case (see also Reference 18). The situation is different with ε -approximations: if $d > 1$ is the VC dimension, then there exists an ε -approximation for (X, \mathcal{R}) of size $O(\varepsilon^{-2+2/(d+1)})$ [19,20].

An important application of ε -approximations is for estimating how many vertices in an arrangement of hyperplanes in \mathbb{R}^d lie within a given convex region. Let $\Sigma = (H, \mathcal{R})$ be the set system formed by a set H of hyperplanes in \mathbb{R}^d , where each $R \in \mathcal{R}$ is the subset of H intersected by an arbitrary line segment. Let σ be a convex body (not necessarily full-dimensional). In the arrangement formed by H within the affine span of σ , let $V(H, \sigma)$ be the set of vertices that lie inside σ . The following was proven in References 8 and 16.

Theorem 26.4

Given a set H of hyperplanes in \mathbb{R}^d in general position, let A be an ε -approximation for $\Sigma = (H, \mathcal{R})$. Given any convex body σ of dimension $k \leq d$,

$$\left| \frac{|V(H, \sigma)|}{|H|^k} - \frac{|V(A, \sigma)|}{|A|^k} \right| \leq \varepsilon.$$

26.2.2 Optimal Cuttings

For convenience of exposition, we may assume that the set H of n hyperplanes in \mathbb{R}^d is in general position. Let $\mathcal{A}(H)$ denote the arrangement formed by H . Obviously, no simplex of an ε -cutting can enclose more than $O(\varepsilon n)^d$ vertices. Since $\mathcal{A}(H)$ itself has exactly $\binom{n}{d}$ vertices, we should expect to need at least on the order of ε^{-d} simplices. But this is precisely the upper bound claimed in Theorem 26.1, which therefore is asymptotically tight.

Our starting point is an ε -net N for H , where the underlying set system (X, \mathcal{R}) is formed by a set X of hyperplanes and the collection \mathcal{R} of subsets obtained by intersecting X with all possible open d -simplices. Its VC-dimension is bounded, and so by Theorem 26.3 an ε -net N of size $O(\varepsilon^{-1} \log \varepsilon^{-1})$ can be found in $n\varepsilon^{-O(1)}$ time.

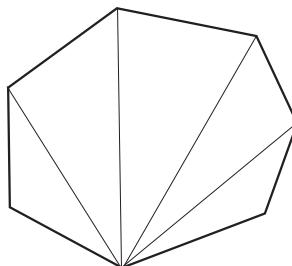

FIGURE 26.2 A canonical triangulation.

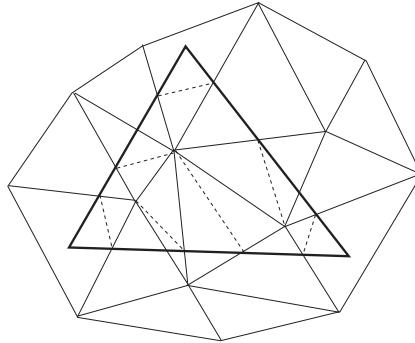

FIGURE 26.3 Clip and retriangulate.

We need to use a systematic way to triangulate the arrangement formed by the ε -net. We build a *canonical triangulation* of $\mathcal{A}(N)$ by induction on the dimension d (Figure 26.2). The case $d = 1$ is trivial, so we assume that $d > 1$.

1. Rank the vertices of $\mathcal{A}(N)$ by the lexicographic order of their coordinate sequences.
2. By induction, form a canonical triangulation of the $(d - 1)$ -dimensional arrangement made by each hyperplane with respect to the $n - 1$ others.
3. For each cell (i.e., full-dimensional face) σ of $\mathcal{A}(N)$, lift toward its lowest-ranked vertex v each k -simplex ($k = 0, \dots, d - 2$) on the triangulated boundary of σ that does not lie in a $(d - 1)$ -face of $\mathcal{A}(N)$ that is incident to v .

It is not hard to see that the combinatorial complexity (i.e., number of all faces of all dimensions) of the canonical triangulation of $\mathcal{A}(N)$ is asymptotically the same as that of $\mathcal{A}(N)$, which is $O(\varepsilon^{-1} \log \varepsilon^{-1})^d$. Therefore, the closures of its cells constitute an ε -cutting for H of size $O(\varepsilon^{-1} \log \varepsilon^{-1})^d$, which is good but not perfect. For optimality we must remove the log factor.

Assume that we have at our disposal an optimal method for building an ε_0 -cutting of size $O(\varepsilon_0^{-d})$, for some suitably small constant ε_0 . To bootstrap this into an optimal ε -cutting construction for any ε , we might proceed as follows: Beginning with a constant-size cutting, we progressively refine it by producing several generations of finer and finer cuttings, $\mathcal{C}_1, \mathcal{C}_2, \dots$, where \mathcal{C}_k is an ε_0^k -cutting for H of size $O(\varepsilon^{-dk})$. Specifically, assume that we have recursively computed the cutting \mathcal{C}_k for H . For each $\sigma \in \mathcal{C}_k$, we have the incidence list H_σ of the hyperplanes intersecting the interior of σ . To compute the next-generation cutting \mathcal{C}_{k+1} , consider refining each σ in turn as follows:

1. Construct an ε_0 -cutting for H_σ , using the algorithm whose existence is assumed.
2. Retain only those simplices that intersect σ and clip them outside of σ .
3. In case the clipping produces nonsimplicial cells within σ , retriangulate them “canonically” (Figure 26.3).

Let \mathcal{C}_{k+1} denote the collection of new simplices. A simplex of \mathcal{C}_{k+1} in σ is cut (in its interior) by at most $\varepsilon_0 |H_\sigma|$ hyperplanes of H_σ , and hence of H . By induction, this produces at most $n\varepsilon_0^{k+1}$ cuts; therefore, \mathcal{C}_{k+1} is an ε_0^{k+1} -cutting. The only problem is that \mathcal{C}_{k+1} might be a little too big. The reason is that excess in size builds up from generation to generation. We circumvent this difficulty by using a global parameter that is independent of the construction; namely, the total number of vertices.

Note that we may assume that $|H_\sigma| > n\varepsilon_0^{k+1}$, since σ would otherwise already satisfy the requirement of the next generation. We distinguish between *full* and *sparse* simplices. Given a set X of hyperplanes and a d -dimensional (closed) simplex σ , let $v(X, \sigma)$ be the number of vertices of $\mathcal{A}(X)$ in the interior of σ .

- The simplex $\sigma \in \mathcal{C}_k$ is *full* if $v(H, \sigma) \geq c_0 |H_\sigma|^d$, where $c_0 = \varepsilon_0^2$. If so, we compute an ε_0 -net for H_σ , and triangulate the portion of the net’s arrangement within σ to form an ε_0 -cutting of size $O(\varepsilon_0^{-1} \log \varepsilon_0^{-1})^d$. Its simplices form the elements of \mathcal{C}_{k+1} that lie within σ .
- A simplex σ that is not full is *sparse*. If so, we find a subset H_σ^o of H_σ that satisfies two conditions:
 - i. The canonically triangulated portion of $\mathcal{A}(H_\sigma^o)$ that lies inside σ consists of a set \mathcal{C}_σ^o of at most $\frac{1}{2}\varepsilon_0^{-d}$ full-dimensional (closed) simplices.
 - ii. Each simplex of \mathcal{C}_σ^o is intersected in its interior by at most $\varepsilon_0 |H_\sigma|$ hyperplanes of H .

The elements of \mathcal{C}_{k+1} within σ are precisely the simplices of \mathcal{C}_σ^o .

Lemma 26.3

\mathcal{C}_{k+1} is an ε_0^{k+1} -cutting of size $O(\varepsilon_0^{-d(k+1)})$.

Next, we explain how to enforce conditions (i) and (ii) for sparse simplices. To be able to distinguish between full and sparse simplices, we use a $c_0/2$ -approximation A_σ for H_σ of constant size, which we can build in $O(|H_\sigma|)$ time (Theorem 26.3). It follows from Theorem 26.4 that

$$\left| \frac{v(H, \sigma)}{|H_\sigma|^d} - \frac{v(A_\sigma, \sigma)|}{|A_\sigma|^d} \right| \leq \frac{c_0}{2}; \quad (26.1)$$

therefore, we can estimate $v(H, \sigma)$ in constant time with an error of at most $\frac{c_0}{2}|H_\sigma|^d$, which for our purposes here is inconsequential.

How do we go about refining σ and how costly is it? If σ is a full simplex, then by Theorem 26.3, we can compute the required ε_0 -net in $O(|H_\sigma|)$ time. Within the same amount of time, we can also find the new set of simplices in σ , together with all of their incidence lists.

The refinement of a sparse simplex σ is a little more involved. We begin with a randomized construction, from which we then remove all the randomness. We compute H_σ^0 by choosing a random sample from A_σ of size $c_1 \varepsilon_0^{-1} \log \varepsilon_0^{-1}$, for some constant c_1 large enough (independent of ε_0). It can be shown that, with probability at least 2/3, the sample forms an $(\varepsilon_0/2)$ -net for A_σ . By Lemma 26.2, H_σ^0 is a $(c_0/2 + \varepsilon_0/2)$ -net for H_σ ; therefore, we ensure that (ii) holds with probability at least 2/3. A slightly more complex analysis shows that (i) also holds with probability at least 2/3; therefore (i,ii) are both true with probability at least 1/3. We derandomize the construction in a trivial manner by trying out all possible samples, which takes constant time; therefore, the running time for refining σ is $O(|H_\sigma|)$.

Putting everything together, we see that refining any simplex takes time proportional to the total size of the incidence lists produced. By Lemma 26.3, the time needed for building generation $k+1$ is $O(n\varepsilon_0^{-(d-1)(k+1)})$. The construction goes on until we reach the first generation such that $\varepsilon_0^k \leq \varepsilon$. This establishes Theorem 26.1.

From the proof above it is not difficult to derive a rough estimate on the constant factor in the $O(\varepsilon^{-d})$ bound on the size of an ε -cutting. A thorough investigation into the smallest possible constant was undertaken by Har-Peled [21] for the two-dimensional case.

26.3 Applications

Cuttings have numerous uses in computational geometry. We mention just a handful: point location, Hopcroft's problem, convex hulls, Voronoi diagrams, and range searching. In many cases, cuttings allow us to derandomize existing probabilistic solutions, that is, to remove any need for random bits and thus produce deterministic algorithms. Many other applications are described in the survey [5].

26.3.1 Point Location

How do we preprocess n hyperplanes in \mathbf{R}^d , so that, given a query point q , we can quickly find the face of the arrangement formed by the hyperplanes that contains the point? For an answer, simply set $\varepsilon = 1/n$ in Theorem 26.1, and use the nesting structure of $\mathcal{C}_1, \mathcal{C}_2, \dots$, to locate q in \mathcal{C}_k . Note that this can be done in constant time once we know the location in \mathcal{C}_{k-1} .

Theorem 26.5

Point location among n hyperplanes can be done in $O(\log n)$ query time, using $O(n^d)$ preprocessing.

Observe that if we only wish to determine whether the point q lies on one of the hyperplanes, it is possible to cut down the storage requirement a little. To do that, we use an ε -cutting for $\varepsilon = (\log n)/n$. The cells associated with the bottom of the hierarchy are each cut by $O(\log n)$ hyperplanes, which we can therefore check one by one. This reduces the storage to $O(n^d/(\log n)^{d-1})$.

26.3.2 Hopcroft's Problem

Given n points and n lines in \mathbf{R}^2 , is there any incidence between points and lines? This is *Hopcroft's problem*. It is self-dual; therefore dualizing it won't help. A classical arrangement of n lines due to Erdős has the property that its n highest-degree vertices are each incident to $\Omega(n^{1/3})$ edges. By picking these n lines as input to Hopcroft's problem and positioning the n points in the near vicinity of these high-degree vertices, we get a sense (not a proof) that to solve the problem should require checking each point against the $\Omega(n^{1/3})$ lines incident to their nearby vertex. This leads to an $\Omega(n^{4/3})$ running time, which under some realistic (though restrictive) conditions, can be made into a rigorous lower bound [22]. At the very least this line of reasoning suggests that to beat $\Omega(n^{4/3})$ is unlikely to be easy. This bound has almost been achieved by an algorithm of Matoušek [23] with, at its heart, a highly intricate and subtle use of cuttings.

Theorem 26.6

To decide whether n points and n lines in the plane are free of any incidence can be done in $n^{4/3} 2^{O(\log^* n)}$ time.

26.3.3 Convex Hulls and Voronoi Diagrams

Cuttings play a key role in computing convex hulls in higher dimension. Given n points in \mathbf{R}^d , their convex hull is a bounded convex polytope with $O(n^{\lfloor d/2 \rfloor})$ vertices. Of course, it may have much fewer of them: for example, $d+1$, if $n-d-1$ points lie strictly inside the convex hull of the $d+1$ others. It is notoriously difficult to design *output-sensitive* algorithms, the term designating algorithms whose running time is a function of both input and output sizes. In the “worst case” approach our goal is a simpler one: to design an optimal convex hull algorithm that runs in $O(n \log n + n^{\lfloor d/2 \rfloor})$ time. (The extra term $n \log n$ is unavoidable because sorting is easily embedded as a convex hull problem.)

Computing the convex hull of n points is equivalent by duality to computing the intersection of n halfspaces. A naive approach to this problem is to insert each halfspace one after the other while maintaining the intersection of previously inserted halfspaces incrementally. This can be done without difficulty if we maintain a canonical triangulation of the current intersection polyhedron and update a bipartite graph indicating which hyperplane intersects which cell of the triangulation. A surprising fact, first proven by Clarkson and Shor [24], is that if the halfspaces are inserted in random order, then the expected running time of the algorithm can be made optimal. By using an elaborate mix of ε -nets, ε -approximations, and ε -cuttings, Chazelle [25] showed how to compute the intersection deterministically in optimal time; his algorithm was subsequently simplified by Brönnimann, Chazelle, and Matoušek [16]; a complete description is also given in the book [10]. This implies the two theorems below.

Theorem 26.7

The polyhedron formed by the intersection of n halfspaces in \mathbf{R}^d can be computed in $O(n \log n + n^{\lfloor d/2 \rfloor})$ time.

Not only does this result give us an optimal deterministic solution for convex hulls, but it also solves the Voronoi diagram problem. Indeed, recall [26,27] that a Voronoi diagram of n points in \mathbf{R}^d can be “read off” from the facial structure of the convex hull of a lift of the n points into \mathbf{R}^{d+1} .

Theorem 26.8

The convex hull of a set of n points in \mathbf{R}^d can be computed deterministically in $O(n \log n + n^{\lfloor d/2 \rfloor})$ time. By duality, the Voronoi diagram (or Delaunay triangulation) of a set of n points in \mathbf{E}^d can be computed deterministically in $O(n \log n + n^{\lceil d/2 \rceil})$ time.

26.3.4 Range Searching

Simplex range searching refers to the problem of preprocessing a set P of n points in \mathbf{R}^d so that, given a query (closed) simplex σ , the size of $P \cap \sigma$ can be quickly evaluated. Variants of the problem include reporting the points of $P \cap \sigma$ explicitly or, assuming that each point p has a weight $w(p) \in \mathbf{R}$, computing $\sum \{ w(p) \mid p \in P \cap \sigma \}$. The most powerful data structure for solving simplex range searching, the *simplicial partition*, vividly illustrates the power of ε -cuttings. A collection $\{(P_i, R_i)\}$ is called a *simplicial partition* if

- The collection $\{P_i\}$ forms a partition of P ; and
- Each R_i is a relatively open simplex that contains P_i .

The simplices R_i can be of any dimension and, in fact, need not even be disjoint; furthermore the P_i ’s need not be equal to $P \cap R_i$. A hyperplane is said to *cut* R_i if it intersects, but does not contain, R_i . The *cutting number* of the simplicial partition refers to the maximum number of R_i ’s that can be cut by a single hyperplane. Matoušek [28] designed an optimal construction, which happens to be crucially based on ε -cuttings.

Lemma 26.4

Given a set P of n points in \mathbf{R}^d ($d > 1$), for any integer $1 < r \leq n/2$, there exists a simplicial partition of cutting number $O(r^{1-1/d})$ such that $n/r \leq |P_i| < 2n/r$ for each (P_i, R_i) in the partition.

To understand the usefulness of simplicial partitions for range searching, one needs to learn about *partition trees*. A partition tree for P is a tree T whose root is associated with the point set P . The set P is partitioned into subsets P_1, \dots, P_m , with each P_i

associated with a distinct child v_i of the root. To each v_i corresponds a convex open set R_i , called the *region* of v_i , that contains P_i . The regions R_i are not necessarily disjoint. If $|P_i| > 1$, the subtree rooted at v_i is defined recursively with respect to P_i .

Armed with a partition tree, it is a simple matter to handle range search queries. In preprocessing, at each node we store the sum of the weights of the points associated with the corresponding region. To answer a query σ , we visit all the children v_i of the root and check whether σ intersects the region R_i of v_i : (i) if the answer is yes, but σ does not completely enclose the region R_i of v_i , then we visit v_i and recurse; (ii) if the answer is yes, but σ completely encloses R_i , we add to our current weight count the sum of the weights within P_i , which happens to be stored at v_i ; (iii) if the answer is no, then we do not recurse at v_i .

It is straightforward to see that Lemma 26.4 can be used to construct partition trees. It remains for us to choose the branching factor. If we choose a large enough constant r , we end up with a partition tree that lets us answer simplex range search queries in $O(n^{1-1/d+\varepsilon})$ time for any fixed $\varepsilon > 0$, using only $O(n)$ storage. A more complex argument by Matoušek [28] removes the ε term from the exponent.

With superlinear storage, various space-time tradeoffs can be achieved. For example, as shown by Chazelle, Sharir, and Welzl [29], simplex range searching with respect to n points in \mathbb{R}^d can be done in $O(n^{1+\varepsilon}/m^{1/d})$ query time, using a data structure of size m , for any $n \leq m \leq n^d$. Matoušek [23] slightly improved the query time to $O(n(\log m/n)^{d+1}/m^{1/d})$, for m/n large enough. These bounds are essentially optimal under highly general computational models [10].

27.1 Introduction

Specialized data structures are useful for answering specific kinds of geometric queries. Such structures are tailor-made for the kinds of queries that are anticipated and even then there are cases when producing an exact answer is only slightly better than an exhaustive search. For example, Chazelle and Welzl [1] showed that triangle range queries can be solved in $O(\sqrt{n} \log n)$ time using linear space but this holds only in the plane. In higher dimensions, the running times go up dramatically, so that, in general, the time needed to perform an exact simplex range query and still use small linear space is roughly $\Omega(n^{1-1/d})$, ignoring logarithmic factors [2]. For orthogonal range queries, efficient query processing is possible if superlinear space is allowed. For example, range trees (Chapter 19) can answer orthogonal range queries in $O(\log^{d-1} n)$ time but use $O(n \log^{d-1} n)$ space [3].

In this chapter, we focus instead on general-purpose data structures that can answer nearest-neighbor queries and range queries using linear space. Since the lower-bound of Chazelle [2] applies in this context, in order to get query bounds that are significantly faster than exhaustive search, we need to compromise somewhat on the exactness of our answers. That is, we will answer all queries *approximately*, giving responses that are within an arbitrarily small constant factor of the exact solution. As we discuss, such responses can typically be produced in logarithmic or polylogarithmic time, using linear space. Moreover, in many practical situations, a good approximate solution is often sufficient.

In recent years several interesting data structures have emerged that efficiently solve several general kinds of geometric queries approximately. We review three major classes of such structures in this chapter. The first one we discuss is a structure introduced by Arya et al. [4] for efficiently approximating nearest-neighbor queries in low-dimensional space. Their work developed a new structure known as the balanced box decomposition (BBD) tree. The BBD tree is a variant of the quadtree and octree [5] but is most closely related to the fair-split tree of Callahan and Kosaraju [6]. In Reference 7, Arya and Mount extend the structure to show that it can also answer approximate range queries. Their structure is based on the decomposition of space into “boxes” that may have a smaller box “cut out;” hence, the boxes may not be convex. The second general purpose data structure we discuss is the balanced aspect ratio (BAR) tree of Duncan et al. [8–10], which is a structure that has similar performance as the BBD tree but decomposes space into convex regions. Finally, we discuss an analysis of a type of k -d tree [11] that helps to explain why k -d trees have long been known to exhibit excellent performance bounds in practice for general geometric queries. In particular, we review a result of Dickerson et al. [8,12], which shows that one of the more common variants, the maximum-spread k -d tree, exhibits properties similar to BBD trees and BAR trees; we present efficient bounds on approximate geometric queries for this variant. Unfortunately, the bounds are not as efficient as the BBD tree or BAR tree but are comparable.

^{*} This chapter has been reprinted from first edition of this Handbook, without any content updates.

27.2 General Terminology

In order to discuss approximate geometric queries and the efficient structures on them without confusion, we must cover a few fundamental terms. We distinguish between general points in \mathbb{R}^d and points given as input to the structures.

For a given metric space \mathbb{R}^d , the coordinates of any point $p \in \mathbb{R}^d$ are (p_1, p_2, \dots, p_d) . When necessary to avoid confusion, we refer to points given as input in a set S as *data points* and general points in \mathbb{R}^d as *real points*. For two points $p, q \in \mathbb{R}^d$, the L_m metric distance between p and q is

$$\delta(p, q) = \left(\sum_{i=1}^d |p_i - q_i|^m \right)^{\frac{1}{m}}.$$

Although our analysis will concentrate on the Euclidean L_2 metric space, the data structures mentioned in this chapter work in all of the L_m metric spaces.

In addition, we use the standard notions of (convex) regions R , rectangular boxes, hyperplanes H , and hyperspheres B . For each of these objects we define two distance values. Let P and Q be any two regions in \mathbb{R}^d , the *minimum* and *maximum* metric distances between P and Q are

$$\begin{aligned} \delta(P, Q) &= \min_{p \in P, q \in Q} \delta(p, q) \text{ and} \\ \Delta(P, Q) &= \max_{p \in P, q \in Q} \delta(p, q) \text{ respectively.} \end{aligned}$$

Notice that this definition holds even if one or both regions are simply points.

Let S be a finite data set $S \subset \mathbb{R}^d$. For a subset $S_1 \subseteq S$, the *size* of S_1 , written $|S_1|$, is the number of distinct data points in S_1 . More importantly, for any region $R \subset \mathbb{R}^d$, the size is $|R| = |R \cap S|$. That is, the *size* of a region identifies the number of data points in it. To refer to the physical size of a region, we define the *outer radius* as $O_R = \min_{R \subseteq B_r} r$, where B_r is defined as the hypersphere with radius r . The *inner radius* of a region is $I_R = \max_{B_r \subseteq R} r$. The outer radius, therefore, identifies the smallest ball that contains the region R whereas the inner radius identifies the largest ball contained in R .

In order to discuss balanced aspect ratio, we need to define the term.

Definition 27.1

A convex region R in \mathbb{R}^d has aspect ratio $\text{asp}(R) = O_R/I_R$ with respect to some underlying metric. For a given balancing factor α , if $\text{asp}(R) \leq \alpha$, R has *balanced aspect ratio* and is called an α -balanced region. Similarly, a collection of regions \mathcal{R} has balanced aspect ratio for a given factor α if each region $R \in \mathcal{R}$ is an α -balanced region.

For simplicity, when referring to rectangular boxes, we consider the aspect ratio as simply the ratio of the longest side to the shortest side. It is fairly easy to verify that the two definitions are equal within a constant factor. As is commonly used, we refer to regions as being either *fat* or *skinny* depending on whether their aspect ratios are balanced or not.

The class of structures that we discuss in this chapter are all derivatives of binary space partition (BSP) trees, see for example [13]. See also Chapter 21. Each node u in a BSP tree T represents both a *region* R_u in space and the *data subset* $S_u \subseteq S$ of objects, points, lying inside R_u . For simplicity, regions are considered closed and points falling on the boundary of two regions can be in either of the two regions but not both. Each leaf node in T represents a region with a constant number of data objects, points, from S . Each internal node in T has an associated cut partitioning the region into two subregions, each a child node. The root of T is associated with some bounding (rectangular box) region containing S . In general, BSP trees can store any type of object, points, lines, solids, but in our case we focus on points. Typically, the partitioning cuts used are hyperplanes resulting in convex regions. However, the BBD tree presented in Section 27.5 is slightly different and can introduce regions with a single interior hole. Therefore, we have generalized slightly to accommodate this in our definition.

27.3 Approximate Queries

Before elaborating on the structures and search algorithms used to answer certain geometric queries, let us first introduce the basic definitions of approximate nearest-neighbor, farthest-neighbor, and range queries, see [4,7,8,10,14].

Definition 27.2

Given a set S of points in \mathbb{R}^d , a query point $q \in \mathbb{R}^d$, a (connected) query region $Q \subset \mathbb{R}^d$, and $\epsilon > 0$, we define the following queries (see Figure 27.1):

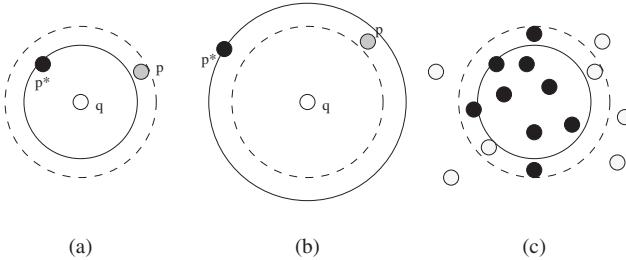

FIGURE 27.1 Examples of (a) an approximate nearest-neighbor p to q with the exact neighbor p^* , (b) an approximate farthest-neighbor p to q with the exact neighbor p^* , and (c) an approximate range query; here the dark points are reported or counted and the lighter points are not.

- A point $p^* \in S$ is a *nearest neighbor* of q if $\delta(p^*, q) \leq \delta(p, q)$ for all $p \in S$.
- A point $p^* \in S$ is a *farthest neighbor* of q if $\delta(p^*, q) \geq \delta(p, q)$ for all $p \in S$.
- A point $p \in S$ is a $(1 + \epsilon)$ -*nearest neighbor* of q if $\delta(p, q) \leq (1 + \epsilon)\delta(p^*, q)$, where p^* is the true nearest neighbor of q .
- A point $p \in S$ is a $(1 - \epsilon)$ -*farthest neighbor* of q if $\delta(p, q) \geq \delta(p^*, q) - \epsilon O_S$, where p^* is the true farthest neighbor of q .
- An ϵ -*approximate range query* returns or counts a subset $S' \subseteq S$ such that $S \cap Q \subseteq S'$ and for every point $p \in S'$, $\delta(p, Q) \leq \epsilon O_Q$.

To clarify further, a point p is a $(1 + \epsilon)$ -approximate nearest neighbor if its distance is within a constant error factor of the true nearest distance. Although we do not discuss it here, we can extend the definitions to report a sequence of k $(1 + \epsilon)$ -nearest (or $(1 - \epsilon)$ -farthest) neighbors. One may also wonder why the approximate farthest neighbor is defined in absolute terms instead of relative terms as with the nearest version. By observing that the distance from any query point to its farthest neighbor is always at least the radius of the point set O_S , one can see that the approximation is as good as the relative approximation. Moreover, if the query point is extremely far from the point set, then a relative approximation could return any point in S , whereas an absolute approximation would require a much more accurate distance.

Although we do not modify our definition here, one can extend this notion and our later theorems to compensate for the problem of query points distant from the point set in nearest-neighbor queries as well. In other words, when the query point is relatively close to the entire data set, we can use the relative error bound, and when it is relatively far away from the entire data set, we can use the absolute error bound.

The approximate range searching problem described above has one-sided false-positive errors. We do not miss any valid points, but we may include erroneous points near the range boundary. It is a simple modification of the query regions to instead get false-negative errors. That is, we could instead require including only points that are inside of Q but allow missing some points that are inside of Q if they are near the border. In fact, for any region Q one could define two epsilon ranges ϵ_i and ϵ_o for both interior and exterior error bounds and then treat the approximation factor as $\epsilon = \epsilon_i + \epsilon_o$.

There are numerous approaches one may take to solving these problems. Arya et al. [4] introduced a priority search algorithm for visiting nodes in a partition tree to solve nearest-neighbor queries. Using their BBD tree structure, they were able to prove efficient query times. Duncan et al. [10] show how this priority search could also solve farthest-neighbor queries. The nearest and farthest neighbor priority searching algorithms shown in Figures 27.2 and 27.3 come from [8]. In the approximate nearest-neighbor, respectively farthest-neighbor, search, nodes are visited in order of closest node, respectively farthest node. Nodes are extracted via an efficient priority queue, such as the Fibonacci heap [15,16].

Introduced by [7], the search technique used for the approximate range query is a modification to the standard range searching algorithm for regular partition trees. We present the algorithm from [8] in Figure 27.4. In this algorithm, we have two different query regions, the inner region Q and the outer region $Q' \supseteq Q$. The goal is to return all points in S that lie inside Q , allowing some points to lie inside Q' but none outside of Q' . That is $Q' - Q$ defines a buffer zone that is the only place allowed for erroneous points. Whenever a node u is visited, if u is a leaf node, we simply check all of u 's associated data points. Otherwise, if R_u does not intersect Q , we know that none of its points can lie in Q , and we ignore u and its subtree. If R_u lies completely inside Q' then all of the data points in its subtree must lie inside Q' , and we report all points. Otherwise, we repeat the process on u 's two child nodes. For an ϵ -approximate range search, we define $Q' = \{p \in \mathbb{R}^d | \delta(p, Q) \leq \epsilon O_Q\}$. We note that this search algorithm can also be modified to return the count or sum of the weights of the points inside the approximate range rather than explicitly reporting the points.

In all of these search algorithms, the essential criteria behind the running time is the observation that a non-terminating node in the search, one that requires expansion of its child nodes, is a node that must cross certain size boundaries. For example, in the approximate range searching algorithm, the only nodes expanded are those whose region lies partially inside Q , else it

```

APPROXIMATENEARESTNEIGHBOR( $T, q, \epsilon$ )
Arguments: BSP tree,  $T$ , query point  $q$ , and error factor  $\epsilon$ 
Returns: A  $(1+\epsilon)$ -nearest neighbor  $p$ 
 $Q \leftarrow \text{root}(T)$ 
 $p \leftarrow \infty$ 
do  $u \leftarrow Q.\text{extractMin}()$ 
  if  $\delta(u, q) > \delta(p, q)/(1+\epsilon)$ 
    return  $p$ 
  while  $u$  is not a leaf
     $u_1 \leftarrow \text{leftChild}(u)$ 
     $u_2 \leftarrow \text{rightChild}(u)$ 
    if  $\delta(u_1, q) \leq \delta(u_2, q)$ 
       $Q.\text{insert}(\delta(u_2, q), u_2)$ 
       $u \leftarrow u_1$ 
    else
       $Q.\text{insert}(\delta(u_1, q), u_1)$ 
       $u \leftarrow u_2$ 
  end while
  //  $u$  is now a leaf
  for all  $p'$  in  $\text{dataSet}(u)$ 
    if  $\delta(p', q) < \delta(p, q)$ 
       $p \leftarrow p'$ 
repeat

```

FIGURE 27.2 The basic algorithm to perform nearest-neighbor priority searching.

```

APPROXIMATESFARTHESTNEIGHBOR( $T, q, \epsilon$ )
Arguments: BSP tree,  $T$ , query point  $q$ , and error factor  $\epsilon$ 
Returns: A  $(1-\epsilon)$ -farthest neighbor  $p$ 
 $Q \leftarrow \text{root}(T)$ 
 $p \leftarrow q$ 
do  $u \leftarrow Q.\text{extractMax}()$ 
  if  $\Delta(u, q) \leq \delta(p, q) + \epsilon D$ 
    return  $p$ 
  while  $u$  is not a leaf
     $u_1 \leftarrow \text{leftChild}(u)$ 
     $u_2 \leftarrow \text{rightChild}(u)$ 
    if  $\Delta(u_1, q) \geq \Delta(u_2, q)$ 
       $Q.\text{insert}(\Delta(u_2, q), u_2)$ 
       $u \leftarrow u_1$ 
    else
       $Q.\text{insert}(\Delta(u_1, q), u_1)$ 
       $u \leftarrow u_2$ 
  end while
  //  $u$  is now a leaf
  for all  $p'$  in  $\text{dataSet}(u)$ 
    if  $\delta(p', q) > \delta(p, q)$ 
       $p \leftarrow p'$ 
repeat

```

FIGURE 27.3 The basic algorithm to perform farthest-neighbor priority searching.

```

APPROXIMATERANGESEARCH( $u, Q, Q'$ )
Arguments: Node  $u$  in a BSP tree, inner region  $Q$ , outer region  $Q'$ 
  Initially,  $u \leftarrow \text{root}(T)$ .
Reports: All points in the approximate range defined by  $Q$  and  $Q'$ 
if  $u$  is a leaf node
  for all  $p$  in  $\text{dataSet}(u)$ 
    if  $p \in Q$ 
      output  $p$ 
else if  $R_u \subseteq Q'$ 
  // The region lies completely inside  $Q'$ 
  output all points  $p$  in the subtree of  $u$ 
else if  $R_u \cap Q \neq \emptyset$ 
  // The region lies partially inside  $Q$ 
  call APPROXIMATERANGESEARCH(leftChild( $u$ ),  $Q, Q'$ )
  call APPROXIMATERANGESEARCH(rightChild( $u$ ),  $Q, Q'$ )

```

FIGURE 27.4 The basic range search algorithm.

would be discarded, and partially outside Q' , else it would be completely counted in the output size. A slightly more complex but similar argument applies for nearest and farthest neighbor algorithms. In the next section, we discuss a general theorem providing provable running time bounds for partition trees satisfying a fundamental packing argument.

27.4 Quasi-BAR Bounds

We are now ready to examine closely a sufficient condition for a data structure to guarantee efficient performance on the aforementioned searches. Before we can proceed, we must first discuss a few more basic definitions presented in Dickerson et al. [12].

Definition 27.3

For any region R , the *region annulus with radius r* , denoted $A_{R,r}$ is the set of all points $p \in \mathbb{R}^d$ such that $p \notin R$ and $\delta(p, R) < r$. A region R' *pierces* an annulus $A_{R,r}$ if and only if there exist two points $p, q \in R'$ such that $p \in R$ and $q \notin R \cup A_{R,r}$.

In other words, an annulus $A_{R,r}$ contains all points outside but near the region R . If R were a sphere of radius r' , this would be the standard definition of an annulus with inner radius r' and outer radius $r' + r$. For convenience, when the region and radius of an annulus are understood, we use A . Figure 27.5 illustrates the basic idea of a spherical annulus with multiple piercing regions.

The core of the performance analysis for the searches lies in a critical packing argument. The packing lemmas work by bounding the number of disjoint regions that can pierce an annulus and hence simultaneously fit inside the annulus, see Figure 27.5b. When this packing size is small, the searches are efficient. Rather than cover each structure's search analysis separately, we use the following more generalized notion from Dickerson et al. [12].

Definition 27.4

Given a BSP tree T and a region annulus A , let $\mathcal{P}(A)$ denote the largest set of disjoint nodes in T whose associated regions pierce A . A class of BSP trees is a $\rho(n)$ -quasi-BAR tree if, for any tree T in the class constructed on a set S of n points in \mathbb{R}^d and any region annulus $A_{R,r}$, $|\mathcal{P}(A_{R,r})| \leq \rho(n)V_A/r^d$, where V_A is the volume of $A_{R,r}$. The function $\rho(n)$ is called the *packing* function.

Basically, the packing function $\rho(n)$ represents the maximum number of regions that can pierce any query annulus. By proving that a class of BSP trees is a $\rho(n)$ -quasi-BAR tree, we can automatically inherit the following theorems proven in [4,7,10] and generalized in Reference 12:

Theorem 27.1

Suppose we are given a $\rho(n)$ -quasi-BAR tree T with depth $D_T = \Omega(\log n)$ constructed on a set S of n points in \mathbb{R}^d . For any query point q , the priority search algorithms in Figures 27.2 and 27.3 find respectively a $(1 + \epsilon)$ -nearest and a $(1 - \epsilon)$ -farthest neighbor to q in $O(\epsilon^{1-d}\rho(n)D_T)$ time.

Theorem 27.2

Suppose we are given a $\rho(n)$ -quasi-BAR tree T with depth D_T constructed on a set S of n points in \mathbb{R}^d . For any convex query region Q , the search algorithm in Figure 27.4 solves an ϵ -approximate range searching query in T in $O(\epsilon^{1-d}\rho(n)D_T)$ time (plus

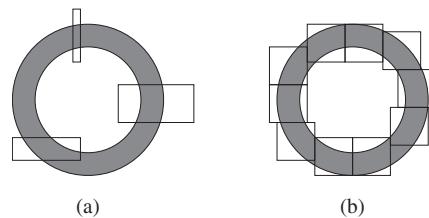

FIGURE 27.5 An example of a simple annulus region (a) with three other regions which pierce this annulus and (b) with several “fat” square regions. Observe that only a limited number of such “fat” squares can pierce the annulus.

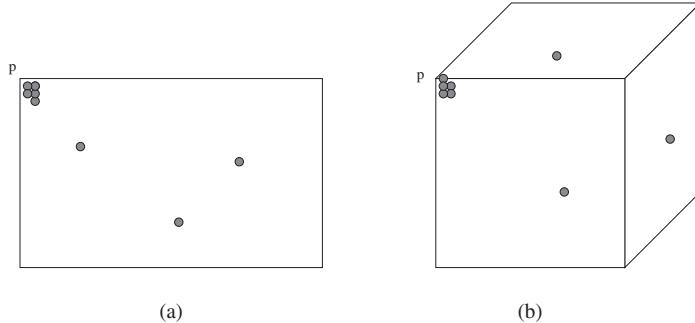

FIGURE 27.6 (a) A bad corner of a simple rectangular region with nearly all of the points clustered near a corner. Notice a cut in either the x or y direction dividing the points located inside p would cause a “skinny” region. (b) The same situation in \mathbb{R}^3 .

output size in the reporting case). For any general non-convex query region Q , the time required is $O(\epsilon^{-d}\rho(n)D_T)$ (plus output size).[†]

Trivially, $\rho(n)$ is always less than n but this accomplishes little in the means of getting good bounds. Having a class of trees with both a good packing function and low depth helps guarantee good asymptotic performance in answering geometric queries. One approach to finding such classes is to require that all regions produced by the tree be fat. The idea behind this is that there is a limit to the number of disjoint fat regions that pierce an annulus dependent upon the aspect ratio of the regions and the thickness of the annulus. Unfortunately, guaranteeing fat regions and good depth is not readily possible using the standard BSP trees like k -d trees and octrees. Imagine building a k -d tree using only axis-parallel partitioning cuts. Figure 27.6 illustrates such an example. Here the majority of the points are concentrated at a particular corner of a rectangular region. Now, any axis-parallel cut is either too close to the opposing face or does not partition the points in the region well, resulting in large tree depth.

Fortunately, there are structures that can provably be shown to be $\rho(n)$ -quasi-BAR trees with small values for $\rho(n)$ and D_T . The next few sections discuss some of these structures.

27.5 BBD Trees

Arya et al. [4] introduced the first BSP tree structure to guarantee both balanced aspect ratio and $O(\log n)$ depth. In addition, the aspect ratio achieved allowed them to prove a packing constraint. From this, one can verify that the BBD tree has a packing function of $\rho(n) = O(1)$ where the constant factor depends on the dimension d . In the following section, we describe the basic construction of the BBD tree using terminology from [7].

Every region R_u associated with a node u in a BBD tree is either an *outer* rectangular box or the set theoretic difference between an *outer* rectangular box and an *inner* rectangular box. The *size* of a box is the length of its longest side and the *size* of R_u is the size of the outer box. In order to guarantee balanced aspect ratio for these cells, Arya et al. [4] introduced a *stickiness* restriction on the inner box. Briefly described, an inner box is *sticky* if the distance between the inner box and every face on the outer box is either 0 or not less than the size of the inner box. Although not necessary to the structure, we shall assume that the aspect ratio of the outer box is no more than two.

The construction of the BBD tree is done by a sequence of alternating splitting and shrinking operations. In the (*midpoint*) *split* operation, a region is bisected by a hyperplane cut orthogonal to one of the longest sides. This is essentially the standard type of cut used in a quadtree or octree. Its simplicity, speed of computation, and effectiveness are major reasons for preferring these operations.

The *shrink* operation partitions a region by a box lying inside the region, creating an inner region. The shrink operation is actually part of a sequence of up to three operations called a *centroid shrink*. The centroid shrink attempts to partition the region into a small number of subregions R_i such that $|R_i| \leq 2|R_u|/3$.

When R_u is simply an outer box, with no inner box, a centroid operation is performed with one shrink operation. The inner partitioning box is found by conceptually applying midpoint split operations recursively on the subregion with the larger number of points. The process stops when the subregion contains no more than $2|R_u|/3$ points. The outer box of this subregion is the inner partitioning box for the shrink operation. The other merely conceptual midpoint splits are simply ignored. Choosing this inner box guarantees that both subregions produced by the split have no more than $2|R_u|/3$ points. This can be seen by observing

[†] Actually, BBD trees and BAR trees have a slightly better running time for these searches and we mention this in the respective sections.

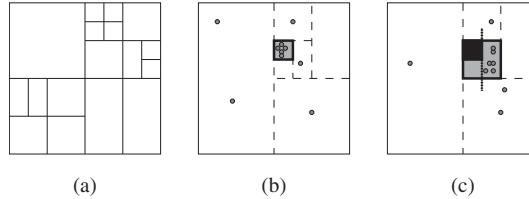

FIGURE 27.7 Examples of (a) multiple iterations of the midpoint split rule, (b) centroid shrinking, with dashed lines representing the conceptual midpoint splits and the highlighted inner box being the actual partition cut, (c) centroid shrinking with an inner box. In the final example, the original inner box is solid, the final midpoint split is shown with slightly extended dotted lines, and the new inner box partition cut is shown shaded in gray.

that the inner box has no more than $2|R_u|/3$ points and also must contain at least $|R_u|/3$ points. The technique as stated is not theoretically ideal because the number of midpoint split operations computed cannot be bounded. Each midpoint split may not partition even a single point. Arya et al. [4,7] describe a simple solution to this problem, which repeatedly computes the smallest bounding midpoint box using a technique due to Clarkson [17].

When R_u has an inner box associated with it, we cannot simply find another inner box as this would violate the restriction on having only one inner box. Let b_i represent the original inner box. The solution is to proceed as in the previous centroid shrink operation, repeatedly applying midpoint split operations on the subregion with the larger number of points. However, we now stop in one of two situations; when the size of the larger subregion either has no more than $2|R_u|/3$ points or no longer contains b_i . In the former case, let b be the outer box of this subregion. In the latter case, or in the event both cases happen, let b represent the outer box of the subregion prior to this final split. We perform a shrink operation using b as the partitioning box. Since b clearly contains b_i , the subregion associated with the original outer box continues to have one inner box, albeit a slightly larger one than its parent. The subregion R_1 , whose outer box is b , also has one inner box, b_i . If $|R_1| > 2|R_u|/3$, we perform a midpoint split on this subregion. Let R_2 be the larger subregion formed by this last split, which we know does not contain b_i . Since R_2 does not contain an inner box, if R_2 contains more than $2|R_u|/3$ points, we simply perform the basic shrink operation thus dividing R_2 into two smaller subregions as well. Clearly, all the subregions produced by this centroid shrink have no more than $2|R_u|/3$ points. Figure 27.7 shows the three main operations, splitting, shrinking, and the three-step shrinking process.

In addition to this simple version of the BBD tree, there are more flexible variations on this approach. The reader should refer to [4,7] for details on an efficient $O(dn \log n)$ construction algorithm and for discussions on some of the BBD variations. To highlight a few options, at any stage in the construction, rather than alternate between shrinking and splitting operations, it is preferable to perform split operations whenever possible, so long as the point set is divided evenly after every few levels, and to use the more costly shrinking operations only when necessary. Another approach is to use a more flexible split operation, a *fair split*, which attempts to partition the points in the region more evenly. In this case, more care has to be taken to avoid producing skinny regions and to avoid violating the stickiness property; however, as was shown experimentally, the flexibility provides for better experimental performance.

The following theorem summarizes the basic result [4,7]:

Theorem 27.3

Given a set S of n data points in \mathbb{R}^d , in $O(dn \log n)$ time it is possible to construct a BBD tree such that

1. The tree has $O(n)$ nodes and depth $O(\log n)$,
2. The regions have outer boxes with balanced aspect ratio and inner boxes that are sticky to the outer box,
3. The sizes of the regions are halved after every $2d$ levels in the tree.

The above conditions imply that the BBD tree is an $O(1)$ -quasi-BAR tree.

The size reduction constraint above helps guarantee a slightly better performance for geometric queries than given for general quasi-BAR trees. In particular, Arya and Mount [7] show that the size reduction allows range queries on BBD trees to be solved in $O(2^d \log n + d(3\sqrt{d}/\epsilon)^d)$ time, or $O(2^d \log n + d^3(3\sqrt{d}/\epsilon)^{d-1})$ for convex queries plus output size. Duncan [8] later extended the separation of the n and ϵ dependencies to nearest and farthest neighbor queries showing that the running time for both is $O(\log n + \epsilon^{1-d} \log(1/\epsilon))$ for fixed dimension d .

27.6 BAR Trees

The balanced aspect ratio tree introduced in Reference 9 for the basic two-dimensional case and subsequently revised to higher dimensions in References 8 and 10 can be shown to have a packing function of $\rho(n) = O(1)$ where the constant factor depends on the dimension d and a user-specified aspect ratio parameter α . In the following section, we borrow terminology from [8,10].

Unlike BBD trees, k -d trees, and octrees, BAR trees do not exclusively use axis-orthogonal hyperplane cuts. Instead, to achieve simultaneously the goals of good aspect ratio, balanced depth, and convex regions, cuts in several different directions are used. These directions are called canonical cuts, and the particular choice and size of canonical cuts is essential in creating good BAR trees.

Definition 27.5

The following terms relate to specific cutting directions:

- A *canonical cut set*, $\mathcal{C} = \{\vec{v}_1, \vec{v}_2, \dots, \vec{v}_\gamma\}$, is a collection of γ not necessarily independent vectors that span \mathbb{R}^d (thus, $\gamma \geq d$).
- A *canonical cut direction* is any vector $\vec{v}_i \in \mathcal{C}$.
- A *canonical cut* is any hyperplane, H , in \mathbb{R}^d with a normal in \mathcal{C} .
- A *canonical region* is any region formed by the intersection of a set of hyperspaces defined by canonical cuts, that is, a convex polyhedron in \mathbb{R}^d with every facet having a normal in \mathcal{C} .

Figure 27.8a shows a region composed of three cut directions $(1, 0), (0, 1)$, and $(1, -1)$, or simply cuts along the x, y , and $x - y$ directions. After cutting the region at the dashed line c , we have two regions R_1 and R_2 . In R_2 notice the left side is replaced by the new cut c , and more importantly the diagonal cut is no longer tangential to R_2 . The following definition describes this property more specifically.

Definition 27.6

A canonical cut c defines a canonical region R , written $c \in R$, if and only if c is tangential to R . In other words, c intersects the border of R . For a canonical region R , any two parallel canonical cuts $b, c \in R$ are *opposing canonical cuts*. For any canonical region R , we define the *canonical bounding cuts* with respect to a direction $\vec{v}_i \in \mathcal{C}$ to be the two unique opposing canonical cuts normal to \vec{v}_i and tangent to R . We often refer to these cuts as b_i and c_i or simply b and c when i is understood from the context. Intuitively, R is “sandwiched” between b_i and c_i . To avoid confusion, when referring to a canonical cut of a region R , we *always* mean a canonical bounding cut.

For any canonical bounding cut, c , the *facet* of $c \in R$, $\text{facet}_c(R)$, is defined as the region formed by the intersection of R with c .

The canonical set used to define a partition tree can vary from method to method. For example, the standard k -d tree algorithm [18] uses a canonical set composed of all axis-orthogonal directions.

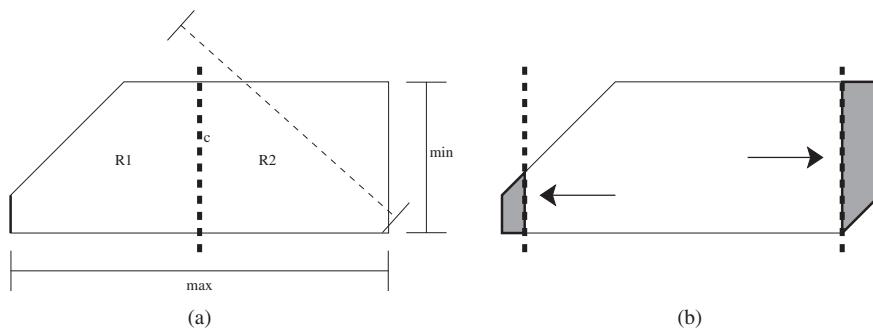

FIGURE 27.8 (a) An example of a canonical region of three cut directions, x, y , and $x - y$. Observe the three widths highlighted with lines and the min and max widths of the region. The left facet associated with the x direction is drawn in bold. The bold dashed line in the center represents a cut c and the respective subregions R_1 and R_2 . (b) An example of a similar region highlighting the two shield regions associated with the x -direction for $\alpha \approx 4$. Notice the size difference between the two shield regions corresponding to the associated facet sizes.

Definition 27.7

For a canonical set \mathcal{C} and a canonical region R , we define the following terms (see [Figure 27.8a](#)):

- For a canonical direction $\vec{v}_i \in \mathcal{C}$, the *width of R in the direction \vec{v}_i* , written $\text{width}_i(R)$, is the distance between b_i and c_i , that is, $\text{width}_i(R) = \delta(b_i, c_i)$.
- The *maximum side of R* is $\max(R) = \max_{i \in \mathcal{C}}(\text{width}_i(R))$.
- The *minimum side of R* is $\min(R) = \min_{i \in \mathcal{C}}(\text{width}_i(R))$.

For simplicity, we also refer to the facets of a region in the same manner. We define the following terms for a facet of a region R , $f = \text{facet}_c(R)$:

- The *width off in the direction \vec{v}_i* is $\text{width}_i(f) = \delta(b_i, c_i)$ where b_i and c_i are the opposing bounding cuts off in the direction \vec{v}_i .
- The *maximum side off* is $\max(f) = \max_{i \in \mathcal{C}}(\text{width}_i(R))$.
- In addition, for any canonical cut $c \in R$, the *length of c* , $\text{len}_c(R)$, is defined as $\max(\text{facet}_c(R))$.

When using a canonical cut c_i to partition a region R into two pieces R_1 and R_2 as the cut gets closer to a side of R , one of the two respective regions gets increasingly skinnier. At some point, the region is no longer α -balanced, see [Figure 27.8b](#). This threshold region is referred to as a shield region and is defined in References 8 as the following:

Definition 27.8

Given an α -balanced canonical region R and a canonical cut direction \vec{v}_i , sweep a cut c' from the opposing cut b_i toward c_i . Let P be the region of R between c' and c_i . Sweep c' until either region P is empty or just before $\text{asp}(P) > \alpha$. If P is not empty, then P has maximum aspect ratio. Call the region P the *shield region of c_i in R* , $\text{shield}_{c_i}(R)$. Let the *maximal outer shield*, $\text{mos}_i(R)$, be the shield region $\text{shield}_{b_i}(R)$ or $\text{shield}_{c_i}(R)$ such that $|\text{mos}_i(R)| = \max(|\text{shield}_{b_i}(R)|, |\text{shield}_{c_i}(R)|)$, that is, the maximal outer shield is the shield region with the greater number of points.

Definition 27.9

An α -balanced canonical region, R , is *one-cuttable* with reduction factor β , where $1/2 \leq \beta < 1$, if there exists a cut $c^1 \in \mathcal{C}$, called a *one-cut*, dividing R into two subregions R_1 and R_2 such that the following conditions hold:

1. R_1 and R_2 are α -balanced canonical regions,
2. $|R_1| \leq \beta|R|$ and $|R_2| \leq \beta|R|$.

Definition 27.10

An α -balanced canonical region, R , is *k-cuttable* with reduction factor β , for $k > 1$, if there exists a cut $c^k \in \mathcal{C}$, called a *k-cut*, dividing R into two subregions R_1 and R_2 such that the following conditions hold:

1. R_1 and R_2 are α -balanced canonical regions,
2. $|R_2| \leq \beta|R|$,
3. Either $|R_1| \leq \beta|R|$ or R_1 is $(k-1)$ -cuttable with reduction factor β .

In other words, the sequence of cuts, c^k, c^{k-1}, \dots, c^1 , results in $k+1$ α -balanced canonical regions each containing no more than $\beta|R|$ points. If the reduction factor β is understood, we simply say R is k -cuttable.

Definition 27.11

For a canonical cut set, \mathcal{C} , a binary space partition tree T constructed on a set S is a *BAR tree with maximum aspect ratio α* if every region $R \in T$ is α -balanced.

[Figure 27.9](#) illustrates an algorithm to construct a BAR tree from a sequence of k -cuttable regions.

Theorem 27.4

For a canonical cut set, \mathcal{C} , if every possible α -balanced canonical region is k -cuttable with reduction factor β , then a BAR tree with maximum aspect ratio α can be constructed with depth $O(k \log_{1/\beta} n)$, for any set S of n points in \mathbb{R}^d .

```

CREATEBARTREE( $u, S_u, R_u, \alpha, \beta$ )
  Arguments: Current node  $u$  to build (initially the root),
     $S_u$  is the current point set (initially  $S$ )
     $R_u$  is the  $\alpha$ -balanced region containing  $S_u$ 
      (initially a bounding hypercube of  $S$ )
    (Optional) node  $u$  can contain any of the following:
      region  $R_u$ , sample point  $p \in S_u$ , size  $|S_u|$ 
  if  $|S_u| \leq \text{leafSize}$  then
    (leaf) node  $u$  stores the set  $S_u$ 
    return
  find  $c^i$ , an  $i$ -cut for  $R_u$ , for smallest value of  $i$ 
  (internal) node  $u$  stores  $c^i$ 
  create two child nodes of  $u$ ,  $v$  and  $w$ 
  partition  $S_u$  into  $S_v$  and  $S_w$  by the cut  $s^i$ 
  partition  $R_u$  into  $R_v$  and  $R_w$  by the cut  $s^i$ 
  call CREATEBARTREE( $v, S_v, R_v, \alpha, \beta$ )
  call CREATEBARTREE( $w, S_w, R_w, \alpha, \beta$ )

```

FIGURE 27.9 General BAR tree construction algorithm.

The main challenge in creating a specific instance of a BAR tree is in defining a canonical set \mathcal{C} such that every possible α -balanced canonical region is k -cuttable with reduction factor β for reasonable choices of α , β , and k . The α -balanced regions produced help BAR trees have the following packing function.

Theorem 27.5

For a canonical cut set, \mathcal{C} , if every possible α -balanced canonical region is k -cuttable with reduction factor β , then the class of BAR trees with maximum aspect ratio α has a packing function $\rho(n) = O(\alpha^d)$ where the hidden constant factor depends on the angles between the various cut directions. For fixed α , this is constant.

Theorems 27.4 and 27.5 immediately show us that approximate geometric nearest-neighbor and farthest-neighbor queries can be solved in $O(\epsilon^{1-d} \log n)$ time and approximate geometric range searches for convex and non-convex regions take, respectively, $O(\epsilon^{1-d} \log n)$ and $O(\epsilon^{-d} \log n)$ plus the output size. As with the BBD tree, in fact, these structures can also be shown to have running times of $O(\log n + \epsilon^{1-d} \log \frac{1}{\epsilon})$ for nearest-neighbor and farthest-neighbor queries [8] and $O(\log n + \epsilon^{1-d})$ and $O(\log n + \epsilon^{-d})$ for convex and non-convex range queries [7].

Another examination of Figure 27.6 shows why simple axis-orthogonal cuts cannot guarantee k -cuttability. By concentrating a large number of points at an actual corner of the rectangular region, no sequence of axis-orthogonal cuts will divide the points and maintain balanced aspect ratio regions. We can further extend this notion of a bad corner to a general κ -corner associated with a canonical region R .

Definition 27.12

For a canonical cut set \mathcal{C} and a canonical region R , a κ -corner $B \in R$ is a ball with center ρ and radius κ such that, for every cut direction $\vec{v}_i \in \mathcal{C}$ with bounding cuts b_i and c_i , either b_i or c_i intersects B , that is, $\min(\delta(\rho, b_i), \delta(\rho, c_i)) \leq \kappa$.

When $\kappa = 0$, we are not only defining a vertex of a region but a vertex which is tangential to one of every cut direction's bounding planes. As described in References 8, these corners represent the worst-case placement of points in the region. These corners can always exist in regions. However, if one of the facets associated with this corner has size proportional to (or smaller than) the κ ball, then we can still get close enough to this facet and properly divide the point set without introducing unbalanced regions. The following property formalizes this notion more:

Property 27.13

A canonical cut set \mathcal{C} satisfies the κ -Corner Property if for any $\kappa \geq 0$ and any canonical region R containing a κ -corner $B \in R$, there exists a canonical cut $c \in R$ intersecting B such that $\text{len}_c(R) \leq \mathcal{F}_\kappa \kappa$ for some constant \mathcal{F}_κ .

In particular, notice that if $\kappa = 0$, one of the bounding cutting planes must intersect at a single point. The advantage to this can be seen in the two-dimensional case. Construct any canonical region using any three cutting directions, for simplicity use

```

COMPUTETWOCUT( $u$ )
  Arguments: An  $\alpha$ -balanced node  $u$  in a BAR tree
  Returns: A one or two-cut for  $u$ 
  for all  $c_i \in \mathcal{C}$ 
    if  $c_i$  is a one-cut, return  $c_i$ 
    let  $P$  be the smallest maximal outer shield of  $R$ 
    let  $c = c_i$  be the bounding cut associated with  $P$ 
    let  $c'$  be the cut parallel to  $c$  intersecting  $R$  such that
       $\delta(c, c') = \text{width}_i(P) + \text{len}_c(R)/\sigma$ 
    return  $c'$ 
  //  $c'$  partitions  $R$  into two  $\alpha$ -balanced regions  $R_1$  and  $R_2$ 
  //  $|R_2| \leq \beta|R|$ 
  //  $R_1$  incident to  $c_i$  is one-cuttable

```

FIGURE 27.10 An algorithm to find either a one or two cut in a region.

the two axis-orthogonal cuts and one cut with slope +1. It is impossible to find a κ -corner without having at least one of the three bounding sides be small with respect to the corner. This small side has a matching very small shield region. Unfortunately, having a small shield region does not mean that the initial region is one-cuttable. The points may all still be concentrated within this small shield region. However, it is possible that this small shield region is one-cuttable. In fact, in References 8, it is shown that there exist canonical cut sets that guarantee *two-cutability* for sufficient values of α , β , and σ , where the σ parameter is used in the construction. The sufficiency requirements depend only on certain constant properties associated with the angles of the canonical cut set labeled here as \mathcal{F}_{\min} , \mathcal{F}_{\max} , \mathcal{F}_{box} , and \mathcal{F}_{κ} . For specific values of these constants, see Reference 8. Figure 27.10 describes an algorithm to find an appropriate cut.

The general idea is to find the smallest (in physical size) shield region containing a majority of the points. If none exist, the region must be one-cuttable. Otherwise, we take this shield region and pull the partitioning cut back slightly,[†] increasing the size of this particular shield region. Given an appropriate cut set and various constant bounds, we can guarantee that this new region is one-cuttable. The following theorems summarize this result [8]:

Theorem 27.6: (Two-Cuttable Theorem)

Suppose we are given a canonical cut set, \mathcal{C} , which satisfies the κ -Corner Property 27.13. Any α -balanced canonical region R is two-cuttable if the following three conditions are met:

$$\beta \geq (d+1)/(d+2), \quad (27.1)$$

$$\alpha \mathcal{F}_{\min}/4(\mathcal{F}_{\text{box}} + 1) > \sigma > (2\mathcal{F}_{\max} + \mathcal{F}_{\kappa}), \text{ and} \quad (27.2)$$

$$\alpha > 4(\mathcal{F}_{\text{box}} + 1)(2\mathcal{F}_{\max} + \mathcal{F}_{\kappa})/\mathcal{F}_{\min} + \mathcal{F}_{\max}/\mathcal{F}_{\min}. \quad (27.3)$$

Theorems 27.6 and 27.4 can be combined to yield the following theorem:

Theorem 27.7

Suppose we are given a canonical cut set \mathcal{C} that satisfies the κ -Corner Property and an $\alpha > f(\mathcal{C})$. A BAR tree with depth $O(d \log n)$ and balancing factor α can be constructed in $O(g(\mathcal{C})dn \log n)$ time, where f and g are constant functions depending on properties of the canonical set. In particular, the running time of the algorithm is $O(n \log n)$ for fixed dimensions and fixed canonical sets.

Let us now present two cut sets that do satisfy the κ -Corner Property. The two cut sets we present below are composed of axis-orthogonal cuts and one other set of cuts. Let us give specific names to a few vector directions.

Definition 27.14

A vector $v = (x_0, x_1, x_2, \dots, x_d)$ is

- an *axis-orthogonal cut* if $x_i = 0$ for all values except one where $x_j = 1$, for example, $(0, 0, 1, 0)$,

[†] This is actually only necessary in dimensions greater than 2.

- a *corner cut* if $x_i = \pm 1$ for all values of i , for example, $(1, 1, -1, -1)$,
- a *wedge cut* if $x_i = 0$ for all values except two where $x_j, x_i = \pm 1$, for example, $(0, 1, -1, 0)$.

The *Corner Cut Canonical Set* \mathcal{C}_c is the set of all axis-orthogonal cuts and corner cuts. The *Wedge Cut Canonical Set* \mathcal{C}_w is the set of all axis-orthogonal cuts and wedge cuts.

Notice that $|\mathcal{C}_c|$ is $\Theta(2^d)$ and $|\mathcal{C}_w|$ is $\Theta(d^2)$. Although the corner cut canonical set does not necessarily have to be as large as this, the complexity of the corner cut itself means sidedness tests take longer than axis-orthogonal and wedge cuts, namely d computations instead of 1 or 2. The above two canonical sets satisfy the κ -Corner Property 27.13 and from Theorem 27.7, we get the following two corollaries [8]:

Corollary 27.1

For the Corner Cut Canonical set \mathcal{C}_c , a BAR tree with depth $O(d \log n)$ and balancing factor $\alpha = \Omega(d^2)$ can be constructed in $O(n \log n)$ time.

Corollary 27.2

For the Wedge Cut Canonical set \mathcal{C}_w , a BAR tree with depth $O(d \log n)$ and balancing factor $\alpha = \Omega(\sqrt{d})$ can be constructed in $O(n \log n)$ time.

To get the exact values needed, see [8]. However, it is important to note that the α bounds above are overestimates of the minimum value needed. In practice, one should try an initially small value of α , say 6, and when that fails to provide two-cutability double the value for the lower subtree levels. In this manner, one can arrive at the true minimum value in $O(\log \alpha)$ such iterations, if necessary, without having to calculate it. Since the minimum α needed in both cut sets is $O(d^2)$, this adds only an $O(\log(d))$ factor to the depth.

27.7 Maximum-Spread k -d Trees

One very popular class of BSP tree is the k -d tree, see Chapter 17. Although there are very few theoretical bounds known on these structures, there is a lot of empirical evidence that shows them to be extremely efficient for numerous geometric applications. In particular, one variant the maximum-spread k -d tree has long been considered an ideal k -d tree. Given a set of points S and a particular axis dimension x_d , define the *spread* of S in x_d to be the difference between the minimum and maximum coordinates of the points in that dimension. The maximum-spread k -d tree is formed by choosing at each internal node a cutting plane orthogonal to the axis of maximum spread placed at the median point in this direction, see for example [11]. Arya et al. [4] applied the maximum-spread k -d tree to their approximate nearest-neighbor searching algorithm and experimentally showed that they were comparable to the theoretically efficient BBD tree. Later Dickerson et al. [8,12] proved the following theorem regarding maximum-spread k -d trees, referred to there as longest-side k -d trees:

Theorem 27.8

Suppose we are given a maximum-spread k -d tree T constructed on a set S of n points in \mathbb{R}^d . Then the packing function $\rho(n)$ of T for a region annulus A is $O(\log^{d-1} n)$. That is, the class of maximum-spread k -d trees is an $O(\log^{d-1} n)$ -quasi-BAR tree.

Although the bound is not as good as for BBD trees and BAR trees, the simplicity of the structure yields low constant factors and explains why in practice these trees perform so well. Experimental comparisons to BBD trees and BAR trees verified this result and showed that only for very highly clustered data did the dependency on $\log^{d-1} n$ become prominent [4,8]. In practice, unless data is highly clustered and the dimension is moderately large, the maximal-spread k -d tree is an ideal structure to use. However, for such data sets both the BBD tree and the BAR tree revert to the same behavior as the maximal-spread tree, and they perform well even with highly clustered data. Because of its simpler structure, the BBD tree is potentially more practical than the BAR tree.

28.1 Introduction

Input/Output communication (or simply *I/O*) between the fast internal memory and the slow external memory (EM, such as disk) can be a bottleneck when processing massive amounts of data, as is the case in many spatial and geometric applications [1]. Problems involving massive amounts of geometric data are ubiquitous in spatial databases, geographic information systems (GIS), constraint logic programming, object-oriented databases, statistics, virtual reality systems, and computer graphics. E-Business and space applications produce petabytes (10^{15} bytes) of data per year. A major challenge is to develop mechanisms for processing the data, or else much of the data will be useless.

One promising approach for efficient I/O is to design algorithms and data structures that bypass the virtual memory system and explicitly manage their own I/O. We refer to such algorithms and data structures as *external memory* (or *EM*) *algorithms and data structures*. (The terms *out-of-core algorithms* and *I/O algorithms* are also sometimes used.)

We concentrate in this chapter on the design and analysis of EM memory data structures for batched and online problems involving geometric and spatial data. Luckily, many problems on geometric objects can be reduced to a small core of problems, such as computing intersections, convex hulls, multidimensional search, range search, stabbing queries, point location, and nearest-neighbor search. In this chapter, we discuss useful paradigms for solving these problems in EM.

28.1.1 Disk Model

The three primary measures of performance of an algorithm or data structure are *the number of I/O operations performed, the amount of disk space used, and the internal (parallel) computation time*. For reasons of brevity, we shall focus in this chapter on only the first two measures. Most of the algorithms we mention run in optimal CPU time, at least for the single processor case.

We can capture the main properties of magnetic disks and multiple disk systems by the commonly used *parallel disk model* (PDM) (Figure 28.1) introduced by Vitter and Shriver [2]. Data is transferred in large units of *blocks* of size B so as to amortize the latency of moving the read–write head and waiting for the disk to spin into position. Storage systems such as RAID use multiple

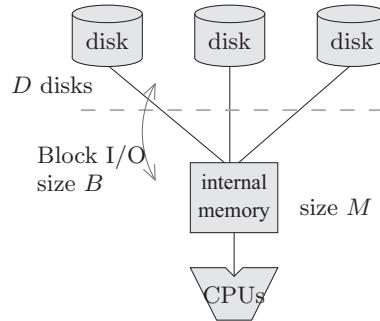

FIGURE 28.1 Parallel disk model.

disks to get more bandwidth [3,4]. The principal parameters of PDM are the following:

$$\begin{aligned} N &= \text{problem input data size (in terms of items)}, \\ M &= \text{size of internal memory (in terms of items)}, \\ B &= \text{size of disk block (in terms of items), and} \\ D &= \# \text{ independent disks}, \end{aligned}$$

where $M < N$ and $1 \leq DB \leq M$.

Queries are naturally associated with online computations, but they can also be done in batched mode. For example, in the batched orthogonal 2-D range searching problem discussed in Section 28.2, we are given a set of N points in the plane and a set of Q queries in the form of rectangles, and the problem is to report the points lying in each of the Q query rectangles. In both the batched and online settings, the number of items reported in response to each query may vary. We thus define two more performance parameters:

$$\begin{aligned} Q &= \text{number of input queries (for a batched problem) and} \\ Z &= \text{query output size (in terms of items).} \end{aligned}$$

If the problem does not involve queries, we set $Q = 0$.

It is convenient to refer to some of the above PDM parameters in units of disk blocks rather than in units of data items; the resulting formulas are often simplified. We define the lowercase notation

$$n = \frac{N}{B}, \quad m = \frac{M}{B}, \quad z = \frac{Z}{B}, \quad q = \frac{Q}{B},$$

to be the problem input size, internal memory size, query output size, and number of queries, respectively, in units of disk blocks.

For simplicity, we restrict our attention in this chapter to the single disk case $D = 1$. The batched algorithms we discuss can generally be sped up by using multiple disks in an optimal manner using the load balancing techniques discussed in Reference 1. Online data structures that use a single disk can generally be transformed automatically by the technique of disk striping to make optimal use of multiple disks [1].

Programs that perform well in terms of PDM will generally perform well when implemented on real systems [1]. More complex and precise models have been formulated [5–7]. Hierarchical (multilevel) memory models are discussed in [1] and its references. Cache-oblivious models are discussed in Chapter 35. Many of the algorithm design techniques we discuss in this chapter, which exploit data locality so as to minimize I/O communication steps, form the basis for algorithms in the other models.

28.1.2 Design Criteria for EM Data Structures

The data structures we examine in this chapter are used in batched algorithms and in online settings. In batched problems, no preprocessing is done, and the entire file of data items must be processed, often by streaming the data through the internal memory in one or more passes. Queries are done in a batched manner during the processing. The goal is generally twofold:

- To solve the problem in $O((n + q) \log_m n + z)$ I/Os
- To use only a linear number $O(n + q)$ of blocks of disk storage

Most nontrivial problems require the same number of I/Os as does sorting. In particular, criterion B1 is related to the I/O complexity of sorting N items in the PDM model, which is $O(n \log_m n)$ [1].

Online data structures support query operations in a continuous manner. When the data items do not change and the data structure can be preprocessed before any queries are made, the data structure is known as *static*. When the data structure supports insertions and deletions of items, intermixed with the queries, the data structure is called *dynamic*. The primary theoretical challenges in the design and analysis of online EM data structures are threefold:

- To answer queries in $O(\log_B N + z)$ I/Os
- To use only a linear number $O(n)$ of blocks of disk storage
- To do updates (in the case of dynamic data structures) in $O(\log_B N)$ I/Os

Criteria O1–O3 correspond to the natural lower bounds for online search in the comparison model. The three criteria are problem dependent, and for some problems they cannot be met. For dictionary queries, we can do better using hashing, achieving $O(1)$ I/Os per query on the average.

Criterion O1 combines together the $O(\log_B N)$ I/O cost for the search with the $O(\lceil z \rceil)$ I/O cost for reporting the output. When one cost is much larger than the other, the query algorithm has the extra freedom to follow a *filtering* paradigm [8], in which both the search component and the output reporting are allowed to use the larger number of I/Os. For example, when the output size Z is large, the search component can afford to be somewhat sloppy as long as it doesn't use more than $O(z)$ I/Os; when Z is small, the Z output items do not have to reside compactly in only $O(\lceil z \rceil)$ blocks. Filtering is an important design paradigm in online EM data structures.

For many of the batched and online problems we consider, there is a data structure (such as a scanline structure or binary search tree) for the internal memory version of the problem that can answer each query in $O(\log N + Z)$ CPU time, but if we use the same data structure naively in an EM setting (using virtual memory to handle page management), a query may require $\Omega(\log N + Z)$ I/Os, which is excessive.*

The goal for online algorithms is to build locality directly into the data structure and explicitly manage I/O so that the $\log N$ and Z terms in the I/O bounds of the naive approach are replaced by $\log_B N$ and z , respectively. The relative speedup in I/O performance, namely $(\log N + Z)/(\log_B N + z)$, is at least $(\log N)/\log_B N = \log B$, which is significant in practice, and it can be as much as $Z/z = B$ for large Z .

For batched problems, the I/O performance can be improved further, since the answers to the queries do not need to be provided immediately but can be reported as a group at the end of the computation. For the batched problems we consider in this chapter, the $Q = qB$ queries collectively use $O(q \log_m n + z)$ I/Os, which is about B times less than a naive approach.

28.1.3 Overview of Chapter

In the next section, we discuss batched versions of geometric search problems. One of the primary methods used for batched geometric problems is distribution sweeping, which uses a data structure reminiscent of the distribution paradigm in external sorting. Other useful batched techniques include persistent B-trees, batched filtering, external fractional cascading, external marriage-before-conquest, and batched incremental construction.

The most popular EM online data structure is the B-tree structure, which provides excellent performance for dictionary operations and one-dimensional range searching. We give several variants and applications of B-trees in Section 28.3. We look at several aspects of multidimensional range search in Section 28.4 and related problems such as stabbing queries and point location. Data structures for other variants and related problems such as nearest-neighbor search are discussed in Section 28.5. Dynamic and kinetic data structures are discussed in Section 28.6. The content of this chapter comes largely from portions of a survey article by Vitter [9]. A more comprehensive manuscript on EM data structures appears in Reference 1.

28.2 EM Algorithms for Batched Geometric Problems

Advances in recent years have allowed us to solve a variety of batched geometric problems optimally, meeting both optimality Criteria B1 and B2 of Section 28.1.2. These problems include

1. Computing the pairwise intersections of N segments in the plane and their trapezoidal decomposition
2. Finding all intersections between N nonintersecting red line segments and N nonintersecting blue line segments in the plane

* We use the notation $\log N$ to denote the binary (base 2) logarithm $\log_2 N$. For bases other than 2, the base will be specified explicitly, as in the base- B logarithm $\log_B N$.

3. Answering Q orthogonal 2-D range queries on N points in the plane (i.e., finding all the points within the Q query rectangles)
4. Constructing the 2-D and 3-D convex hull of N points
5. Voronoi diagram and Triangulation of N points in the plane
6. Performing Q point location queries in a planar subdivision of size N
7. Finding all nearest neighbors for a set of N points in the plane
8. Finding the pairwise intersections of N orthogonal rectangles in the plane
9. Computing the measure of the union of N orthogonal rectangles in the plane
10. Computing the visibility of N segments in the plane from a point
11. Performing Q ray-shooting queries in 2-D Constructive Solid Geometry (CSG) models of size N

Goodrich et al. [10], Zhu [11], Arge et al. [12,13], and Crauser et al. [14,15] developed EM algorithms for those problems using these EM paradigms for batched problems:

Distribution sweeping, a generalization of the sorting distribution paradigm [1] for “externalizing” plane sweep algorithms.

Persistent B-trees: An offline method for constructing an optimal space persistent version of the B-tree data structure (see Section 28.3.1), yielding a factor of B improvement over the generic persistence techniques of Driscoll et al. [16].

Batched filtering: A general method for performing simultaneous EM searches in data structures that can be modeled as planar layered directed acyclic graphs; it is useful for 3-D convex hulls and batched point location. Multisearch on parallel computers is considered in Reference 17.

External fractional cascading: An EM analogue to fractional cascading on a segment tree, in which the degree of the segment tree is $O(m^\alpha)$ for some constant $0 < \alpha \leq 1$. Batched queries can be performed efficiently using batched filtering; online queries can be supported efficiently by adapting the parallel algorithms of work of Tamassia and Vitter [18] to the I/O setting.

External marriage-before-conquest: An EM analogue to the technique of Kirkpatrick and Seidel [19] for performing output-sensitive convex hull constructions.

Batched incremental construction: A localized version of the randomized incremental construction paradigm of Clarkson and Shor [20], in which the updates to a simple dynamic data structure are done in a random order, with the goal of fast overall performance on the average. The data structure itself may have bad worst-case performance, but the randomization of the update order makes worst-case behavior unlikely. The key for the EM version so as to gain the factor of B I/O speedup is to batch together the incremental modifications.

For illustrative purposes, we focus in the remainder of this section primarily on the distribution sweep paradigm [10], which is a combination of the distribution paradigm for sorting [1] and the well-known sweeping paradigm from computational geometry [21,22]. As an example, let us consider how to achieve optimality Criteria B1 and B2 for computing the pairwise intersections of N orthogonal segments in the plane, making use of the following recursive distribution sweep. At each level of recursion, the region under consideration is partitioned into $\Theta(m)$ vertical slabs, each containing $\Theta(N/m)$ of the segments’ endpoints.

We sweep a horizontal line from top to bottom to process the N segments. When the sweep line encounters a vertical segment, we insert the segment into the appropriate slab. When the sweep line encounters a horizontal segment h , as pictured in Figure 28.2, we report h ’s intersections with all the “active” vertical segments in the slabs that are spanned *completely* by h . (A vertical segment is “active” if it intersects the current sweep line; vertical segments that are found to be no longer active are deleted from the slabs.) The remaining two end portions of h (which “stick out” past a slab boundary) are passed recursively to the next level, along with the vertical segments. The downward sweep then proceeds. After the initial sorting (to get the segments with respect to the y -dimension), the sweep at each of the $O(\log_m n)$ levels of recursion requires $O(n)$ I/Os, yielding the desired bound in B1 of $O((n + q) \log_m n + z)$. Some timing experiments on distribution sweeping appear in Reference 23. Arge et al. [13] develop a unified approach to distribution sweep in higher dimensions.

A central operation in spatial databases is spatial join. A common preprocessing step is to find the pairwise intersections of the bounding boxes of the objects involved in the spatial join. The problem of intersecting orthogonal rectangles can be solved by combining the previous sweep line algorithm for orthogonal segments with one for range searching. Arge et al. [13] take a more unified approach using distribution sweep, which is extendible to higher dimensions. The active objects that are stored in the data structure in this case are rectangles, not vertical segments. The authors choose the branching factor to be $\Theta(\sqrt{m})$. Each rectangle is associated with the largest contiguous range of vertical slabs that it spans. Each of the possible $\Theta\left(\binom{\sqrt{m}}{2}\right) = \Theta(m)$ contiguous ranges of slabs is called a *multislab*. The reason why the authors choose the branching factor to be $\Theta(\sqrt{m})$ rather than $\Theta(m)$ is so that the number of multislabs is $\Theta(m)$, and thus there is room in internal memory for a buffer for each multislab. The height of the tree remains $O(\log_m n)$.

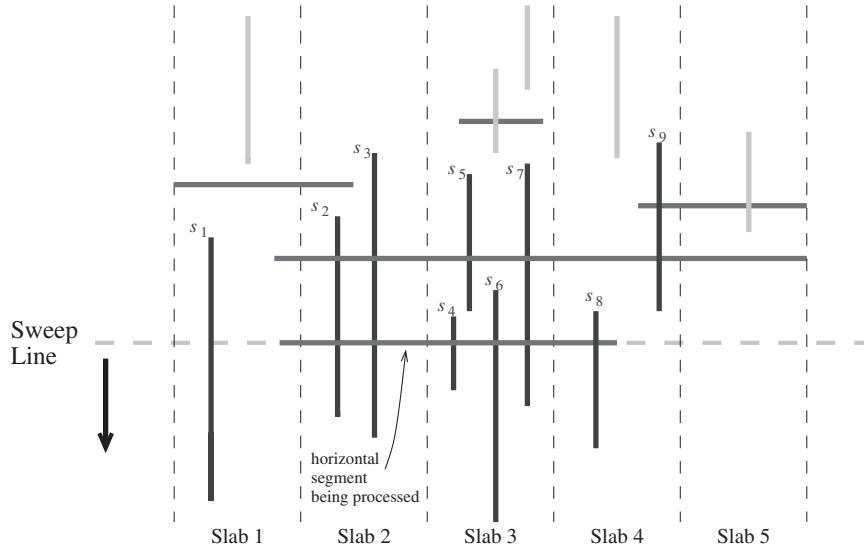

FIGURE 28.2 Distribution sweep used for finding intersections among N orthogonal segments. The vertical segments currently stored in the slabs are indicated in bold (namely, s_1, s_2, \dots, s_9). Segments s_5 and s_9 are not active but have not yet been deleted from the slabs. The sweep line has just advanced to a new horizontal segment that completely spans slabs 2 and 3, so slabs 2 and 3 are scanned and all the active vertical segments in slabs 2 and 3 (namely, s_2, s_3, s_4, s_6, s_7) are reported as intersecting the horizontal segment. In the process of scanning slab 3, segment s_5 is discovered to be no longer active and can be deleted from slab 3. The end portions of the horizontal segment that “stick out” into slabs 1 and 4 are handled by the lower levels of recursion, where the intersection with s_8 is eventually discovered.

The algorithm proceeds by sweeping a horizontal line from top to bottom to process the N rectangles. When the sweep line first encounters a rectangle R , we consider the multislab lists for all the multislabs that R intersects. We report all the active rectangles in those multislab lists, since they are guaranteed to intersect R . (Rectangles no longer active are discarded from the lists.) We then extract the left and right end portions of R that partially “stick out” past slab boundaries, and we pass them down to process in the next lower level of recursion. We insert the remaining portion of R , which spans complete slabs, into the list for the appropriate multislab. The downward sweep then continues. After the initial sorting preprocessing, each of the $O(\log_m n)$ sweeps (one per level of recursion) takes $O(n)$ I/Os, yielding the desired bound $O((n + q) \log_m n + z)$.

The resulting algorithm, called Scalable Sweeping-Based Spatial Join (SSSJ) [13,24], outperforms other techniques for rectangle intersection. It was tested against two other sweep line algorithms: the Partition-Based Spatial Merge (QPBSM) used in Paradise [25] and a faster version called MPBSM that uses an improved dynamic data structure for intervals [24]. The TPIE (Transparent Parallel I/O Environment) system [26–28] served as the common implementation platform. The algorithms were tested on several data sets. The timing results for the two data sets in Figure 28.3a and b are given in Figure 28.3c and d, respectively. The first data set is the worst case for sweep line algorithms; a large fraction of the line segments in the file are active (i.e., they intersect the current sweep line). The second data set is a best case for sweep line algorithms, but the two PBSM algorithms have the disadvantage of making extra copies of the rectangles. In both cases, SSSJ shows considerable improvement over the PBSM-based methods. In other experiments done on more typical data, such as TIGER/line road data sets [29], SSSJ and MPBSM perform about 30% faster than does QPBSM. The conclusion we draw is that SSSJ is as fast as other known methods on typical data, but unlike other methods, it scales well even for worst-case data. If the rectangles are already stored in an index structure, such as the R-tree index structure we consider in Section 28.4.2, hybrid methods that combine distribution sweep with inorder traversal often perform best [30].

For the problem of finding all intersections among N line segments, Arge et al. [12] give an efficient algorithm based upon distribution sort, but the output component of the I/O bound is slightly nonoptimal: $z \log_m n$ rather than z . Crauser et al. [14,15] attain the optimal I/O bound of criterion B1, namely $O((n + q) \log_m n + z)$, by constructing the trapezoidal decomposition for the intersecting segments using an incremental randomized construction. For I/O efficiency, they do the incremental updates in a series of batches, in which the batch size is geometrically increasing by a factor of m .

Online issues also arise in the analysis of batched EM algorithms. In practice, batched algorithms must adapt in a robust and online way when the memory allocation changes, and online techniques can play an important role. Some initial work has been done on memory-adaptive EM algorithms in a competitive framework [31].

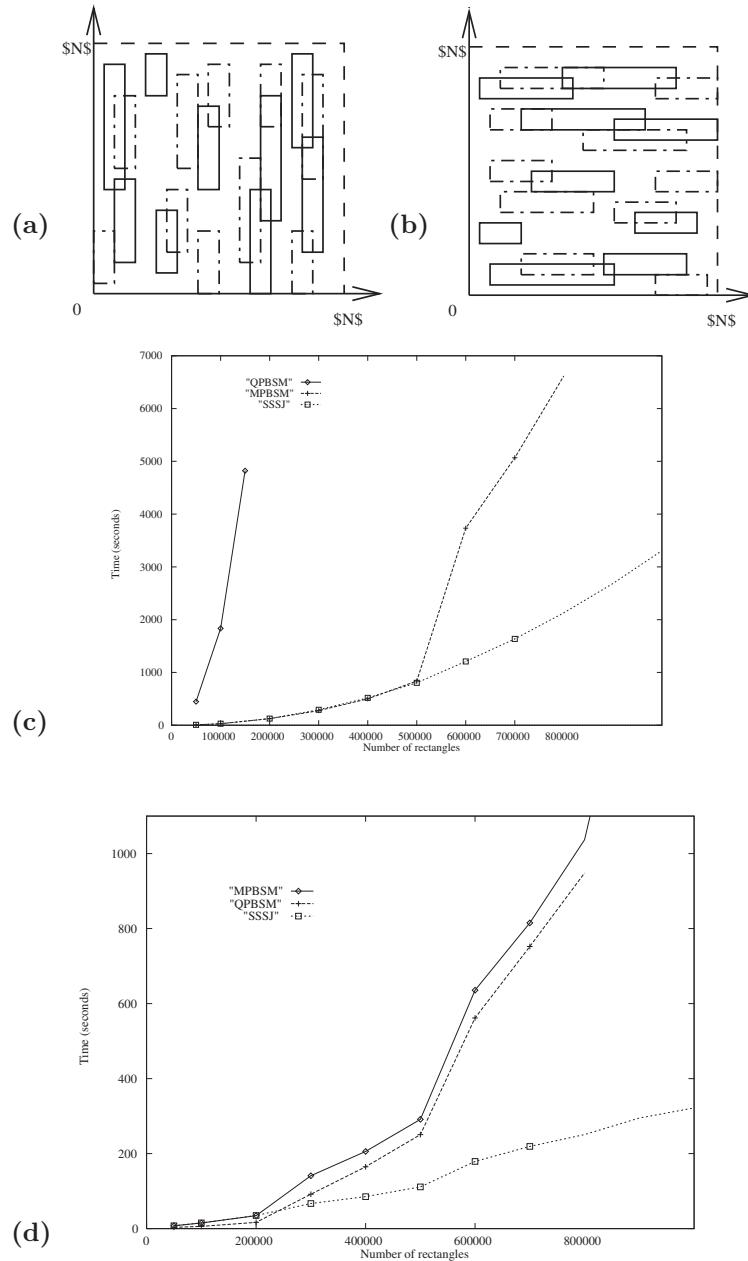

FIGURE 28.3 Comparison of SSSJ with the original PBSM (QPBSM) and a new variant (MPBSM). Each data set contains $N/2$ red rectangles (designated by solid sides) and $N/2$ blue rectangles (designated by dashed sides), and the goal is to find all intersections between red rectangles and blue rectangles. In each data set shown, the number of intersections is $O(N)$: (a) data set 1 consists of tall, skinny (vertically aligned) rectangles; (b) data set 2 consists of short, wide (horizontally aligned) rectangles; (c) running times on data set 1; and (d) running times on data set 2.

28.3 EM Tree Data Structures

In this section, we consider the basic online EM data structures for storing and querying spatial data in one dimension. The dictionary problem is an important special case, which can be solved efficiently in the average case by use of hashing. However, hashing does not support sequential search in a natural way, such as retrieving all the items with key value in a specified range. Some clever work has been done on order-preserving hash functions, in which items with sequential keys are stored in the same block or in adjacent blocks, but the search performance is less robust and tends to deteriorate because of unwanted collisions (see References 1 and 32 for surveys).

A more effective EM approach for geometric queries is to use multiway trees, which we explore in this section. For illustration, we use orthogonal range search as our canonical problem. It is a fundamental database primitive in spatial databases and GIS, and it includes dictionary lookup as a special case. A range query, for a given d -dimensional rectangle, returns all the points in the interior of the rectangle. Other types of spatial queries include point location queries, ray shooting queries, nearest-neighbor queries, and intersection queries, but for brevity we restrict our attention primarily to range searching.

Spatial data structures tend to be of two types: space-driven or data-driven. Quad trees and grid files are space-driven since they are based upon a partitioning of the embedding space, somewhat akin to using order-preserving hash functions, whereas methods like R-trees and kd-trees are organized by partitioning the data items themselves. We shall discuss primarily the latter type in this chapter.

28.3.1 B-trees and Variants

Tree-based data structures arise naturally in the online setting, in which the data can be updated and queries must be processed immediately. Binary trees have a host of applications in the (internal memory) RAM model. In order to exploit block transfer, trees in EM generally use a block for each node, which can store $\Theta(B)$ pointers and data values.

The well-known balanced multiway *B-tree* due to Bayer and McCreight [33–35] is the most widely used nontrivial EM data structure. The degree of each node in the B-tree (with the exception of the root) is required to be $\Theta(B)$, which guarantees that the height of a B-tree storing N items is roughly $\log_B N$. B-trees support dynamic dictionary operations and one-dimensional range search optimally in linear space, $O(\log_B N)$ I/Os per insert or delete, and $O(\log_B N + z)$ I/Os per query, where $Z = zB$ is the number of items output. When a node overflows during an insertion, it splits into two half-full nodes, and if the splitting causes the parent node to overflow, the parent node splits, and so on. Splittings can thus propagate up to the root, which is how the tree grows in height. Deletions are handled in a symmetric way by merging nodes.

In the *B⁺-tree* variant, pictured in Figure 28.4, all the items are stored in the leaves, and the leaves are linked together in symmetric order to facilitate range queries and sequential access.

The internal nodes store only key values and pointers and thus can have a higher branching factor. In the most popular variant of B⁺-trees, called *B^{*}-trees*, splitting can usually be postponed when a node overflows by “sharing” the node’s data with one of its adjacent siblings. The node needs to be split only if the sibling is also full; when that happens, the node splits into two, and its data and those of its full sibling are evenly redistributed, making each of the three nodes about two-thirds full. This local optimization reduces the number of times new nodes must be created and thus increases the storage utilization. And since there are fewer nodes in the tree, search I/O costs are lower. When no sharing is done (as in B⁺-trees), Yao [36] shows that nodes are roughly $\ln 2 \approx 69\%$ full on the average, assuming random insertions. With sharing (as in B^{*}-trees), the average storage utilization increases to about $2\ln(3/2) \approx 81\%$ [37,38]. Storage utilization can be increased further by sharing among several siblings, at the cost of more complicated insertions and deletions. Some helpful space-saving techniques borrowed from hashing are partial expansions [39] and use of overflow nodes [40].

A cross between B-trees and hashing, where each subtree rooted at a certain level of the B-tree is instead organized as an external hash table, was developed by Litwin and Lomet [41] and further studied in References 42 and 43. O’Neil [44] proposed a B-tree variant called the SB-tree that clusters together on the disk symmetrically ordered nodes from the same level so as to optimize range queries and sequential access. Rao and Ross [45,46] use similar ideas to exploit locality and optimize search tree performance in internal memory. Reducing the number of pointers allows a higher branching factor and thus faster search.

Partially persistent versions of B-trees have been developed by Becker et al. [47] and Varman and Verma [48]. By persistent data structure, we mean that searches can be done with respect to any timestamp y [16,49]. In a partially persistent data structure,

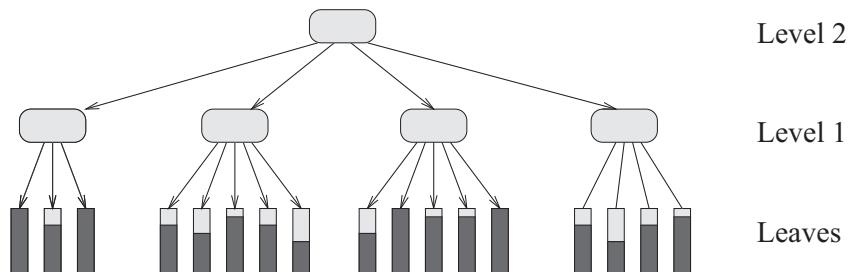

FIGURE 28.4 B⁺-tree multiway search tree. Each internal and leaf node corresponds to a disk block. All the items are stored in the leaves; the darker portion of each leaf block indicates its relative fullness. The internal nodes store only key values and pointers, $\Theta(B)$ of them per node. Although not indicated here, the leaf blocks are linked sequentially.

only the most recent version of the data structure can be updated. In a fully persistent data structure, any update done with timestamp y affects all future queries for any time after y . An interesting open problem is whether B-trees can be made fully persistent. Salzberg and Tsotras [50] survey work done on persistent access methods and other techniques for time-evolving data. Lehman and Yao [51], Mohan [52], and Lomet and Salzberg [53] explore mechanisms to add concurrency and recovery to B-trees. Other variants are discussed in Chapter 16.

28.3.2 Weight-Balanced B-trees

Arge and Vitter [54] introduce a powerful variant of B-trees called *weight-balanced B-trees*, with the property that the weight of any subtree at level h (i.e., the number of nodes in the subtree rooted at a node of height h) is $\Theta(a^h)$, for some fixed parameter a of order B . By contrast, the sizes of subtrees at level h in a regular B-tree can differ by a multiplicative factor that is exponential in h . When a node on level h of a weight-balanced B-tree gets rebalanced, no further rebalancing is needed until its subtree is updated $\Omega(a^h)$ times. Weight-balanced B-trees support a wide array of applications in which the I/O cost to rebalance a node of weight w is $O(w)$; the rebalancings can be scheduled in an amortized (and often worst-case) way with only $O(1)$ I/Os. Such applications are very common when the nodes have secondary structures, as in multidimensional search trees, or when rebuilding is expensive. Agarwal et al. [55] apply weight-balanced B-trees to convert partition trees such as kd-trees, BBD trees, and BAR trees, which were designed for internal memory, into efficient EM data structures.

Weight-balanced trees called BB[α]-trees [56,57] have been designed for internal memory; they maintain balance via rotations, which is appropriate for binary trees, but not for the multiway trees needed for EM. In contrast, weight-balanced B-trees maintain balance via splits and merges.

Weight-balanced B-trees were originally conceived as part of an optimal dynamic EM interval tree structure for stabbing queries and a related EM segment tree structure. We discuss their use for stabbing queries and other types of range queries in Sections 28.4.3 through 28.4.5. They also have applications in the (internal memory) RAM model [54,58], where they offer a simpler alternative to BB[α]-trees. For example, by setting a to a constant in the EM interval tree based upon weight-balanced B-trees, we get a simple worst-case implementation of interval trees [59,60] in internal memory. Weight-balanced B-trees are also preferable to BB[α]-trees for purposes of augmenting one-dimensional data structures with range restriction capabilities [61].

28.3.3 Parent Pointers and Level-Balanced B-trees

It is sometimes useful to augment B-trees with parent pointers. For example, if we represent a total order via the leaves in a B-tree, we can answer order queries such as “Is $x < y$ in the total order?” by walking upwards in the B-tree from the leaves for x and y until we reach their common ancestor. Order queries arise in online algorithms for planar point location and for determining reachability in monotone subdivisions [62]. If we augment a conventional B-tree with parent pointers, then each split operation costs $\Theta(B)$ I/Os to update parent pointers, although the I/O cost is only $O(1)$ when amortized over the updates to the node. However, this amortized bound does not apply if the B-tree needs to support cut and concatenate operations, in which case the B-tree is cut into contiguous pieces and the pieces are rearranged arbitrarily. For example, reachability queries in a monotone subdivision are processed by maintaining two total orders, called the leftist and rightist orders, each of which is represented by a B-tree. When an edge is inserted or deleted, the tree representing each order is cut into four consecutive pieces, and the four pieces are rearranged via concatenate operations into a new total order. Doing cuts and concatenation via conventional B-trees augmented with parent pointers will require $\Theta(B)$ I/Os per level in the worst case. Node splits can occur with each operation (unlike the case where there are only inserts and deletes), and thus there is no convenient amortization argument that can be applied.

Agarwal et al. [62] describe an interesting variant of B-trees called *level-balanced B-trees* for handling parent pointers and operations such as cut and concatenate. The balancing condition is “global.” The data structure represents a forest of B-trees in which the number of nodes on level h in the forest is allowed to be at most $N_h = 2N/(b/3)^h$, where b is some fixed parameter in the range $4 < b < B/2$. It immediately follows that the total height of the forest is roughly $\log_b N$.

Unlike previous variants of B-trees, the degrees of individual nodes of level-balanced B-trees can be arbitrarily small, and for storage purposes, nodes are packed together into disk blocks. Each node in the forest is stored as a node record (which points to the parent’s node record) and a doubly linked list of child records (which point to the node records of the children). There are also pointers between the node record and the list of child records. Every disk block stores only node records or only child records, but all the child records for a given node must be stored in the same block (possibly with child records for other nodes). The advantage of this extra level of indirection is that cuts and concatenates can usually be done in only $O(1)$ I/Os per level of the forest. For example, during a cut, a node record gets split into two, and its list of child nodes is chopped into two separate lists. The parent node must therefore get a new child record to point to the new node. These updates require $O(1)$ I/Os except when there is not enough space in the disk block of the parent’s child records, in which case the block must be split into two, and extra

I/Os are needed to update the pointers to the moved child records. The amortized I/O cost, however, is only $O(1)$ per level, since each update creates at most one node record and child record at each level. The other dynamic update operations can be handled similarly.

All that remains is to reestablish the global level invariant when a level gets too many nodes as a result of an update. If level h is the lowest such level out of balance, then level h and all the levels above it are reconstructed via a postorder traversal in $O(N_h)$ I/Os so that the new nodes get degree $\Theta(b)$ and the invariant is restored. The final trick is to construct the new parent pointers that point from the $\Theta(N_{h-1}) = \Theta(bN_h)$ node records on level $h-1$ to the $\Theta(N_h)$ level- h nodes. The parent pointers can be accessed in a blocked manner with respect to the new ordering of the nodes on level h . By sorting, the pointers can be rearranged to correspond to the ordering of the nodes on level $h-1$, after which the parent pointer values can be written via a linear scan. The resulting I/O cost is $O((bN_h/B) \log_m(bN_h/B))$, which can be amortized against the $\Theta(N_h)$ updates that occurred since the last time the level- h invariant was violated, yielding an amortized update cost of $O(1 + (b/B) \log_m n)$ I/Os per level.

Order queries such as “Does leaf x precede leaf y in the total order represented by the tree?” can be answered using $O(\log_B N)$ I/Os by following parent pointers starting at x and y . The update operations insert, delete, cut, and concatenate can be done in $O((1 + (b/B) \log_m n) \log_b N)$ I/Os amortized, for any $2 \leq b \leq B/2$, which is never worse than $O((\log_B N)^2)$ by appropriate choice of b .

Using the multislab decomposition we discuss in Section 28.4.3, Agarwal et al. [62] apply level-balanced B-trees in a data structure for point location in monotone subdivisions, which supports queries and (amortized) updates in $O((\log_B N)^2)$ I/Os. They also use it to dynamically maintain planar *st*-graphs using $O((1 + (b/B) \log_m n) \log_b N)$ I/Os (amortized) per update, so that reachability queries can be answered in $O(\log_B N)$ I/Os (worst-case). (Planar *st*-graphs are planar directed acyclic graphs with a single source and a single sink.) An interesting open question is whether level-balanced B-trees can be implemented in $O(\log_B N)$ I/Os per update. Such an improvement would immediately give an optimal dynamic structure for reachability queries in planar *st*-graphs.

28.3.4 Buffer Trees

An important paradigm for constructing algorithms for batched problems in an internal memory setting is to use a dynamic data structure to process a sequence of updates. For example, we can sort N items by inserting them one by one into a priority queue, followed by a sequence of N *delete_min* operations. Similarly, many batched problems in computational geometry can be solved by dynamic plane sweep techniques. For example, in Section 28.2 we showed how to compute orthogonal segment intersections by dynamically keeping track of the active vertical segments (i.e., those hit by the horizontal sweep line); we mentioned a similar algorithm for orthogonal rectangle intersections.

However, if we use this paradigm naively in an EM setting, with a B-tree as the dynamic data structure, the resulting I/O performance will be highly nonoptimal. For example, if we use a B-tree as the priority queue in sorting or to store the active vertical segments hit by the sweep line, each update and query operation will take $O(\log_B N)$ I/Os, resulting in a total of $O(N \log_B N)$ I/Os, which is larger than the optimal bound $O(n \log_m n)$ by a substantial factor of roughly B . One solution suggested in Reference 63 is to use a binary tree data structure in which items are pushed lazily down the tree in blocks of B items at a time. The binary nature of the tree results in a data structure of height $O(\log n)$, yielding a total I/O bound of $O(n \log n)$, which is still nonoptimal by a significant $\log m$ factor.

Arge [64] developed the elegant *buffer tree* data structure to support *batched dynamic* operations, as in the sweep line example, where the queries do not have to be answered right away or in any particular order. The buffer tree is a balanced multiway tree, but with degree $\Theta(m)$ rather than degree $\Theta(B)$, except possibly for the root. Its key distinguishing feature is that each node has a buffer that can store $\Theta(M)$ items (i.e., $\Theta(m)$ blocks of items). Items in a node are pushed down to the children when the buffer fills. Emptying a full buffer requires $\Theta(m)$ I/Os, which amortizes the cost of distributing the M items to the $\Theta(m)$ children. Each item thus incurs an amortized cost of $O(m/M) = O(1/B)$ I/Os per level, and the resulting cost for queries and updates is $O((1/B) \log_m n)$ I/Os amortized.

Buffer trees have an ever-expanding list of applications. They can be used as a subroutine in the standard sweep line algorithm in order to get an optimal EM algorithm for orthogonal segment intersection. Arge showed how to extend buffer trees to implement segment trees [65] in EM in a batched dynamic setting by reducing the node degrees to $\Theta(\sqrt{m})$ and by introducing *multislabs* in each node, which were explained in Section 28.2 for the related batched problem of intersecting rectangles. Buffer trees provide a natural amortized implementation of priority queues for *time-forward processing* applications such as discrete event simulation, sweeping, and list ranking [66]. Govindarajan et al. [67] use time-forward processing to construct a well-separated pair decomposition of N points in d dimensions in $O(n \log_m n)$ I/Os, and they apply it to the problems of finding the K nearest neighbors for each point and the K closest pairs. Brodal and Katajainen [68] provide a worst-case optimal priority queue, in the sense that every sequence of B *insert* and *delete_min* operations requires only $O(\log_m n)$ I/Os. Practical implementations of priority queues

based upon these ideas are examined in References 69 and 70. In Section 28.4.2, we report on some timing experiments involving buffer trees for use in bulk loading of R-trees. Further experiments on buffer trees appear in Reference 71.

28.4 Spatial Data Structures and Range Search

In this section, we consider online EM data structures for storing and querying spatial data. A fundamental database primitive in spatial databases and GIS is range search, which includes dictionary lookup as a special case. An orthogonal range query, for a given d -dimensional rectangle, returns all the points in the interior of the rectangle. In this section, we use range searching (especially for the orthogonal 2-D case when $d = 2$) as the canonical query operation on spatial data. Other types of spatial queries include point location, ray shooting, nearest neighbor, and intersection queries, but for brevity we restrict our attention primarily to range searching.

There are two types of spatial data structures: data-driven and space-driven. R-trees and kd-trees are data-driven since they are based upon a partitioning of the data items themselves, whereas space-driven methods such as quad trees and grid files are organized by a partitioning of the embedding space, akin to order-preserving hash functions. In this section, we discuss primarily data-driven data structures.

Multidimensional range search is a fundamental primitive in several online geometric applications, and it provides indexing support for constraint and object-oriented data models (see Reference 72 for background). We have already discussed multidimensional range searching in a batched setting in Section 28.2. In this section, we concentrate on data structures for the online case.

For many types of range searching problems, it is very difficult to develop theoretically optimal algorithms and data structures. Many open problems remain. The goal for online data structures is typically to achieve the three optimality Criteria O1–O3 of Section 28.1.2.

We explain in Section 28.4.6 that under a fairly general computational model for general 2-D orthogonal queries, as pictured in Figure 28.5d, it is impossible to satisfy Criteria O1 and O2 simultaneously. At least $\Omega(n(\log n)/\log(\log_B N + 1))$ blocks of disk space must be used to achieve a query bound of $O((\log_B N)^c + z)$ I/Os per query, for any constant c [73]. Three natural questions arise:

- What sort of performance can be achieved when using only a linear amount of disk space? In Sections 28.4.1 and 28.4.2, we discuss some of the linear-space data structures used extensively in practice. None of them come close to satisfying Criteria O1 and O3 for range search in the worst case, but in typical case scenarios they often perform well. We devote Section 28.4.2 to R-trees and their variants, which are the most popular general-purpose spatial structures developed to date.
- Since the lower bound applies only to general 2-D rectangular queries, are there any data structures that meet Criteria O1–O3 for the important special cases of 2-D range searching pictured in Figure 28.5a–c? Fortunately the answer is yes. We show in Sections 28.4.3 and 28.4.4 how to use a “bootstrapping” paradigm to achieve optimal search and update performance.
- Can we meet Criteria O1 and O2 for general four-sided range searching if the disk space allowance is increased to $O(n(\log n)/\log(\log_B N + 1))$ blocks? Yes again! In Section 28.4.5, we show how to adapt the optimal structure for three-sided searching in order to handle general four-sided searching in optimal search cost. The update cost, however, is not known to be optimal.

In Section 28.5, we discuss other scenarios of range search dealing with three dimensions and nonorthogonal queries. We discuss the lower bounds for 2-D range searching in Section 28.4.6.

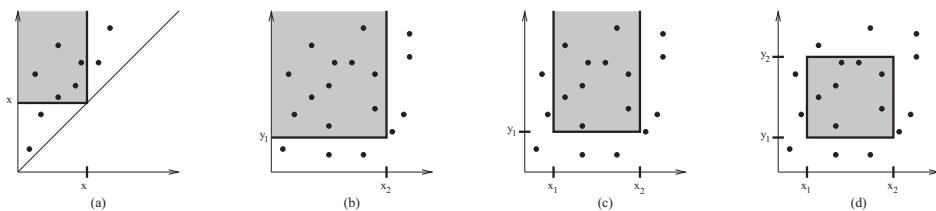

FIGURE 28.5 Different types of 2-D orthogonal range queries: (a) diagonal corner two-sided 2-D query (equivalent to a stabbing query, cf. Section 28.4.3), (b) two-sided 2-D query, (c) three-sided 2-D query, and (d) general four-sided 2-D query.

28.4.1 Linear-Space Spatial Structures

Grossi and Italiano [74] construct an elegant multidimensional version of the B-tree called the *cross tree*. Using linear space, it combines the data-driven partitioning of weight-balanced B-trees (cf. Section 28.3.2) at the upper levels of the tree with the space-driven partitioning of methods such as quad trees at the lower levels of the tree. For $d > 1$, d -dimensional orthogonal range queries can be done in $O(n^{1-1/d} + z)$ I/Os, and inserts and deletes take $O(\log_B N)$ I/Os. The O-tree of Kanth and Singh [75] provides similar bounds. Cross trees also support the dynamic operations of cut and concatenate in $O(n^{1-1/d})$ I/Os. In some restricted models for linear-space data structures, the 2-D range search query performance of cross trees and O-trees can be considered to be optimal, although it is much larger than the logarithmic bound of Criterion O1.

One way to get multidimensional EM data structures is to augment known internal memory structures, such as quad trees and kd-trees, with block-access capabilities. Examples include *kd-B-trees* [76], *buddy trees* [77], and *hb-trees* [78,79]. *Grid files* [80–82] are a flattened data structure for storing the cells of a two-dimensional grid in disk blocks. Another technique is to “linearize” the multidimensional space by imposing a total ordering on it (a so-called space-filling curve), and then the total order is used to organize the points into a B-tree [83–85]. Linearization can also be used to represent nonpoint data, in which the data items are partitioned into one or more multidimensional rectangular regions [86,87]. All the methods described in this paragraph use linear space, and they work well in certain situations; however, their worst-case range query performance is no better than that of cross trees, and for some methods, such as grid files, queries can require $\Theta(n)$ I/Os, even if there are no points satisfying the query. We refer the reader to References 32, 88, and 89 for a broad survey of these and other interesting methods. Space-filling curves arise again in connection with R-trees, which we describe next.

28.4.2 R-trees

The *R-tree* of Guttman [90] and its many variants are a practical multidimensional generalization of the B-tree for storing a variety of geometric objects, such as points, segments, polygons, and polyhedra, using linear disk space. Internal nodes have degree $\Theta(B)$ (except possibly the root), and leaves store $\Theta(B)$ items. Each node in the tree has associated with it a bounding box (or bounding polygon) of all the items in its subtree. A big difference between R-trees and B-trees is that in R-trees the bounding boxes of sibling nodes are allowed to overlap. If an R-tree is being used for point location, for example, a point may lie within the bounding box of several children of the current node in the search. In that case the search must proceed to all such children.

In the dynamic setting, there are several popular heuristics for where to insert new items into an R-tree and how to rebalance it (see Chapter 22 and References 32, 88, and 91 for a survey). The *R*-tree* variant of Beckmann et al. [92] seems to give best overall query performance. To insert an item, we start at the root and recursively insert the item into the subtree whose bounding box would expand the least in order to accommodate the item. In case of a tie (e.g., if the item already fits inside the bounding boxes of two or more subtrees), we choose the subtree with the smallest resulting bounding box. In the normal R-tree algorithm, if a leaf node gets too many items or if an internal node gets too many children, we split it, as in B-trees. Instead, in the *R*-tree* algorithm, we remove a certain percentage of the items from the overflowing node and reinsert them into the tree. The items we choose to reinsert are the ones whose centroids are furthest from the center of the node’s bounding box. This *forced reinsertion* tends to improve global organization and reduce query time. If the node still overflows after the forced reinsertion, we split it. The splitting heuristics try to partition the items into nodes so as to minimize intuitive measures such as coverage, overlap, or perimeter. During deletion, in both the normal R-tree and *R*-tree* algorithms, if a leaf node has too few items or if an internal node has too few children, we delete the node and reinsert all its items back into the tree by forced reinsertion.

The rebalancing heuristics perform well in many practical scenarios, especially in low dimensions, but they result in poor worst-case query bounds. An interesting open problem is whether nontrivial query bounds can be proven for the “typical case” behavior of R-trees for problems such as range searching and point location. Similar questions apply to the methods discussed in Section 28.4.1. New R-tree partitioning methods by de Berg et al. [93] and Agarwal et al. [94] provide some provable bounds on overlap and query performance.

In the static setting, in which there are no updates, constructing the *R*-tree* by repeated insertions, one by one, is extremely slow. A faster alternative to the dynamic R-tree construction algorithms mentioned above is to bulk-load the R-tree in a bottom-up fashion [86,87,95]. Such methods use some heuristic for grouping the items into leaf nodes of the R-tree, and then recursively build the nonleaf nodes from bottom to top. As an example, in the so-called Hilbert R-tree of Kamel and Faloutsos [95], each item is labeled with the position of its centroid on the Peano–Hilbert space-filling curve, and a B^+ -tree is built upon the totally ordered labels in a bottom-up manner. Bulk loading a Hilbert R-tree is therefore easy to do once the centroid points are presorted. These static construction methods algorithms are very different in spirit from the dynamic insertion methods. The dynamic methods explicitly try to reduce the coverage, overlap, or perimeter of the bounding boxes of the R-tree nodes, and as a result, they usually achieve good query performance. The static construction methods do not consider the bounding box information at all. Instead, the hope is that the improved storage utilization (up to 100%) of these packing methods compensates for a higher degree of node

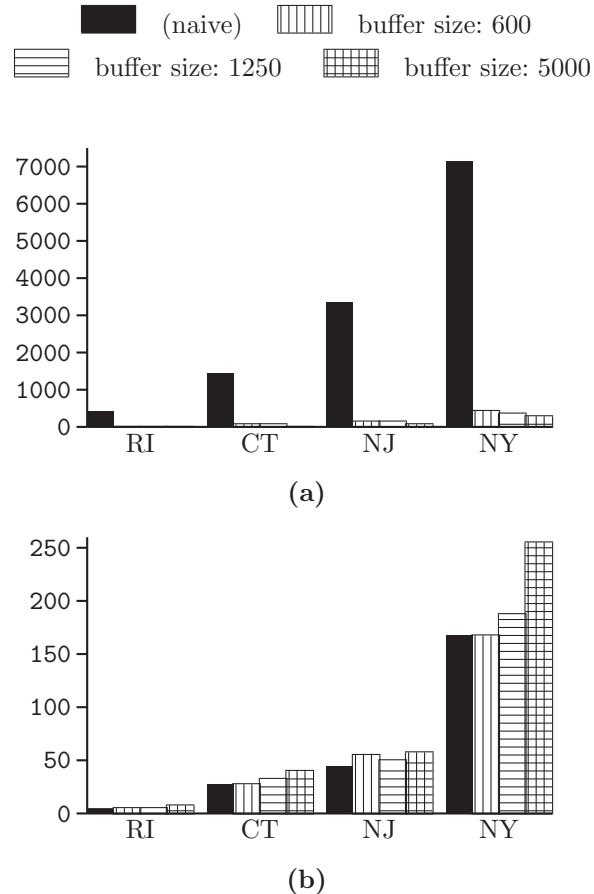

FIGURE 28.6 Costs for R-tree processing (in units of 1000 I/Os) using the naive repeated insertion method and the buffer R-tree for various buffer sizes: (a) cost for bulk-loading the R-tree, (b) query cost.

overlap. A dynamic insertion method related to Reference 95 was presented in Reference 84. The quality of the Hilbert R-tree in terms of query performance is generally not as good as that of an R*-tree, especially for higher dimensional data [96,97].

In order to get the best of both worlds—the query performance of R*-trees and the bulk construction efficiency of Hilbert R-trees—Arge et al. [26] and van den Bercken et al. [98] independently devised fast bulk loading methods based upon buffer trees that do top-down construction in $O(n \log_m n)$ I/Os, which matches the performance of the bottom-up methods within a constant factor. The former method is especially efficient and supports dynamic batched updates and queries. In Figure 28.6 and Table 28.1, we report on some experiments that test the construction, update, and query performance of various R-tree methods. The experimental data came from TIGER/line data sets from four U.S. states [29]; the implementations were done using the TPIE system.

Figure 28.6 compares the construction cost for building R-trees and the resulting query performance in terms of I/Os for the naive sequential method for construction into R*-trees (labeled “naive”) and the newly developed buffer R*-tree method [26] (labeled “buffer”). An R-tree was constructed on the TIGER road data for each state and for each of four possible buffer sizes. The four buffer sizes were capable of storing 0, 600, 1250, and 5000 rectangles, respectively; buffer size 0 corresponds to the naive method, and the larger buffers correspond to the buffer method. The query performance of each resulting R-tree was measured by posing rectangle intersection queries using rectangles taken from TIGER hydrographic data. The results, depicted in Figure 28.6, show that buffer R*-trees, even with relatively small buffers, achieve a tremendous speedup in number of I/Os for construction without any worsening in query performance, compared with the naive method. The CPU costs of the two methods are comparable. The storage utilization of buffer R*-trees tends to be in the 90% range, as opposed to roughly 70% for the naive method.

Bottom-up methods can build R-trees even more quickly and more compactly, but they generally do not support bulk dynamic operations, which are a big advantage of the buffer tree approach. Kamel et al. [97] develop a way to do bulk updates with Hilbert R-trees, but at a cost in terms of query performance. Table 28.1 compares dynamic update methods for the naive method, for

TABLE 28.1 Summary of the Costs (in Number of I/Os) for R-tree Updates and Queries

Data Set	Update Method	Update with 50% of the Data		
		Building	Querying	Packing
RI	Naive	259,263	6670	64
	Hilbert	15,865	7262	92
	Buffer	13,484	5485	90
CT	Naive	805,749	40,910	66
	Hilbert	51,086	40,593	92
	Buffer	42,774	37,798	90
NJ	Naive	1,777,570	70,830	66
	Hilbert	120,034	69,798	92
	Buffer	101,017	65,898	91
NY	Naive	3,736,601	224,039	66
	Hilbert	246,466	230,990	92
	Buffer	206,921	227,559	90

Note: Packing refers to the percentage storage utilization.

buffer R-trees, and for Hilbert R-trees [97] (labeled “Hilbert”). A single R-tree was built for each of the four U.S. states, containing 50% of the road data objects for that state. Using each of the three algorithms, the remaining 50% of the objects were inserted into the R-tree, and the construction time was measured. Query performance was then tested as before. The results in Table 28.1 indicate that the buffer R*-tree and the Hilbert R-tree achieve a similar degree of packing, but the buffer R*-tree provides better update and query performance.

Arge et al. [99] introduce the priority R-tree, which provides guaranteed query performance of $O(n^{1-1/d} + z)$ I/Os, similarly to the search structures in Section 28.4.1. This query performance is optimal in the worst case for linear-sized data structures. The priority R-tree uses a bulk loading to construct the tree, and it supports updates efficiently in the amortized sense.

28.4.3 Bootstrapping for 2-D Diagonal Corner and Stabbing Queries

An obvious paradigm for developing an efficient dynamic EM data structure, given an existing data structure that works well when the problem fits into internal memory, is to “externalize” the internal memory data structure. If the internal memory data structure uses a binary tree, then a multiway tree such as a B-tree must be used instead. However, when searching a B-tree, it can be difficult to report the outputs in an output-sensitive manner. For example, in certain searching applications, each of the $\Theta(B)$ subtrees of a given node in a B-tree may contribute one item to the query output, and as a result each subtree may need to be explored (costing several I/Os) just to report a single output item.

Fortunately, we can sometimes achieve output-sensitive reporting by augmenting the data structure with a set of filtering substructures, each of which is a data structure for a smaller version of the same problem. We refer to this approach, which we explain shortly in more detail, as the *bootstrapping* paradigm. Each substructure typically needs to store only $O(B^2)$ items and to answer queries in $O(\log_B B^2 + Z'/B) = O(\lceil Z'/B \rceil)$ I/Os, where Z' is the number of items reported. A substructure can even be static if it can be constructed in $O(B)$ I/Os, since we can keep updates in a separate buffer and do a global rebuilding in $O(B)$ I/Os whenever there are $\Theta(B)$ updates. Such a rebuilding costs $O(1)$ I/Os (amortized) per update. We can often remove the amortization and make it worst case using the weight-balanced B-trees of Section 28.3.2 as the underlying B-tree structure.

Arge and Vitter [54] first uncovered the bootstrapping paradigm while designing an optimal dynamic EM data structure for diagonal corner two-sided 2-D queries (see Figure 28.5a) that meets all three design criteria for online data structures listed in Section 28.1.2. Diagonal corner two-sided queries are equivalent to stabbing queries, which have the following form: “Given a set of one-dimensional intervals, report all the intervals ‘stabbed’ by the query value x ” (i.e., report all intervals that contain x). A diagonal corner query x on a set of 2-D points $\{(a_1, b_1), (a_2, b_2), \dots\}$ is equivalent to a stabbing query x on the set of closed intervals $\{[a_1, b_1], [a_2, b_2], \dots\}$.

The EM data structure for stabbing queries is a multiway version of the well-known interval tree data structure [59,60] for internal memory, which supports stabbing queries in $O(\log N + Z)$ CPU time and updates in $O(\log N)$ CPU time and uses $O(N)$ space. We can externalize it by using a weight-balanced B-tree as the underlying base tree, where the nodes have degree $\Theta(\sqrt{B})$. Each node in the base tree corresponds in a natural way to a one-dimensional range of x -values; its $\Theta(\sqrt{B})$ children correspond to subranges called slabs, and the $\Theta(\sqrt{B^2}) = \Theta(B)$ contiguous sets of slabs are called *multislabs*, as in Section 28.2 for a similar batched problem. Each input interval is stored in the lowest node v in the base tree whose range completely contains the interval.

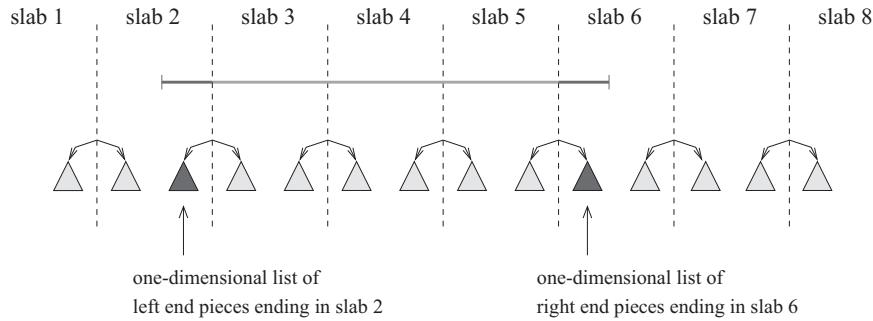

FIGURE 28.7 Internal node v of the EM priority search tree, for $B = 64$ with $\sqrt{B} = 8$ slabs. Node v is the lowest node in the tree completely containing the indicated interval. The middle piece of the interval is stored in the multislab list corresponding to slabs 3–5. (The multislab lists are not pictured.) The left and right end pieces of the interval are stored in the left-ordered list of slab 2 and the right-ordered list of slab 6, respectively.

The interval is decomposed by v 's $\Theta(\sqrt{B})$ slabs into at most three pieces: the middle piece that completely spans one or more slabs of v , the left end piece that partially protrudes into a slab of v , and the right end piece that partially protrudes into another slab of v , as shown in Figure 28.7. The three pieces are stored in substructures of v . In the example in Figure 28.7, the middle piece is stored in a list associated with the multislab it spans (corresponding to the contiguous range of slabs 3–5), the left end piece is stored in a one-dimensional list for slab 2 ordered by left endpoint, and the right end piece is stored in a one-dimensional list for slab 6 ordered by right endpoint.

Given a query value x , the intervals stabbed by x reside in the substructures of the nodes of the base tree along the search path from the root to the leaf for x . For each such node v , we consider each of v 's multislab lists that contains x and report all the intervals in the multislab list. We also walk sequentially through the right-ordered list and left-ordered list for the slab of v that contains x , reporting intervals in an output-sensitive way.

The big problem with this approach is that we have to spend at least one I/O per multislab containing x , regardless of how many intervals are in the multislab lists. For example, there may be $\Theta(B)$ such multislab lists, with each list containing only a few stabbed intervals (or worse yet, none at all). The resulting query performance will be highly nonoptimal. The solution, according to the bootstrapping paradigm, is to use a substructure in each node consisting of an optimal static data structure for a smaller version of the same problem; a good choice is the corner data structure developed by Kanellakis et al. [72]. The corner substructure in this case is used to store all the intervals from the “sparse” multislab lists, namely those that contain fewer than B intervals, and thus the substructure contains only $O(B^2)$ intervals. When visiting node v , we access only v 's nonsparse multislab lists, each of which contributes $Z' \geq B$ intervals to the output, at an output-sensitive cost of $O(Z'/B)$ I/Os, for some Z' . The remaining Z'' stabbed intervals stored in v can be found by a single query to v 's corner substructure, at a cost of $O(\log_B B^2 + Z''/B) = O(\lceil Z''/B \rceil)$ I/Os. Since there are $O(\log_B N)$ nodes along the search path in the base tree, the total collection of Z stabbed intervals is reported in $O(\log_B N + z)$ I/Os, which is optimal. Using a weight-balanced B-tree as the underlying base tree allows the static substructures to be rebuilt in worst-case optimal I/O bounds.

Stabbing queries are important because, when combined with one-dimensional range queries, they provide a solution to *dynamic interval management*, in which one-dimensional intervals can be inserted and deleted, and intersection queries can be performed. These operations support indexing of one-dimensional constraints in constraint databases. Other applications of stabbing queries arise in graphics and GIS. For example, Chiang and Silva [100] apply the EM interval tree structure to extract at query time the boundary components of the isosurface (or contour) of a surface. A data structure for a related problem, which in addition has optimal output complexity, appears in Reference 101. The above bootstrapping approach also yields dynamic EM segment trees with optimal query and update bound and $O(n \log_B N)$ -block space usage.

28.4.4 Bootstrapping for Three-Sided Orthogonal 2-D Range Search

Arge et al. [102] provide another example of the bootstrapping paradigm by developing an optimal dynamic EM data structure for three-sided orthogonal 2-D range searching (see Figure 28.5c) that meets all three design Criteria O1–O3. In internal memory, the optimal structure is the priority search tree [103], which answers three-sided range queries in $O(\log N + Z)$ CPU time, does updates in $O(\log N)$ CPU time, and uses $O(N)$ space. The EM structure of Arge et al. [102] is an externalization of the priority search tree, using a weight-balanced B-tree as the underlying base tree. Each node in the base tree corresponds to a one-dimensional range of x -values, and its $\Theta(B)$ children correspond to subranges consisting of vertical slabs. Each node v contains a small substructure called a *child cache* that supports three-sided queries. Its child cache stores the “Y-set” $Y(w)$ for

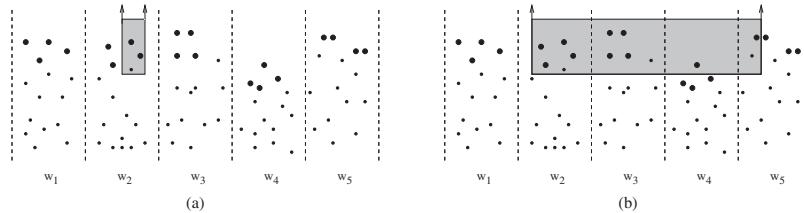

FIGURE 28.8 Internal node v of the EM priority search tree, with slabs (children) w_1, w_2, \dots, w_5 . The Y-sets of each child, which are stored collectively in v 's child cache, are indicated by the bold points. (a) The three-sided query is completely contained in the x -range of w_2 . The relevant (bold) points are reported from v 's child cache, and the query is recursively answered in w_2 . (b) The three-sided query spans several slabs. The relevant (bold) points are reported from v 's child cache, and the query is recursively answered in w_2, w_3 , and w_5 . The query is *not* extended to w_4 in this case because not all of its Y-set $Y(w_4)$ (stored in v 's child cache) satisfies the query, and as a result, none of the points stored in w_4 's subtree can satisfy the query.

each of the $\Theta(B)$ children w of v . The Y-set $Y(w)$ for child w consists of the highest $\Theta(B)$ points in w 's slab that are not already stored in the child cache of some ancestor of v . There are thus a total of $\Theta(B^2)$ points stored in v 's child cache.

We can answer a three-sided query of the form $[x_1, x_2] \times [y_1, +\infty)$ by visiting a set of nodes in the base tree, starting with the root. For each visited node v , we pose the query $[x_1, x_2] \times [y_1, +\infty)$ to v 's child cache and output the results. The following rules are used to determine which of v 's children to visit. We visit v 's child w (see Figure 28.8) if either

1. w is along the leftmost search path for x_1 or the rightmost search path for x_2 in the base tree, or
2. the entire Y-set $Y(w)$ is reported when v 's child cache is queried.

There are $O(\log_B N)$ nodes w that are visited because of rule 1. When rule 1 is not satisfied, rule 2 provides an effective filtering mechanism to guarantee output-sensitive reporting. The I/O cost for initially accessing a child node w can be charged to the $\Theta(B)$ points of $Y(w)$ reported from v 's child cache; conversely, if not all of $Y(w)$ is reported, then the points stored in w 's subtree will be too low to satisfy the query, and there is no need to visit w (see Figure 28.8b). Provided that each child cache can be queried in $O(1)$ I/Os plus the output-sensitive cost to output the points satisfying the query, the resulting overall query time is $O(\log_B N + z)$, as desired.

All that remains is to show how to query a child cache in a constant number of I/Os, plus the output-sensitive cost. Arge et al. [102] provide an elegant and optimal static data structure for three-sided range search, which can be used in the EM priority search tree described earlier to implement the child caches of size $O(B^2)$. The static structure is a persistent B-tree optimized for batched construction. When used for $O(B^2)$ points, it occupies $O(B)$ blocks, can be built in $O(B)$ I/Os, and supports three-sided queries in $O(\lceil Z'/B \rceil)$ I/Os per query, where Z' is the number of points reported. The static structure is so simple that it may be useful in practice on its own.

Both the three-sided structure developed by Arge et al. [102] and the structure for two-sided diagonal queries discussed in Section 28.4.3 satisfy Criteria O1–O3 of Section 28.1.2. So in a sense, the three-sided query structure subsumes the diagonal two-sided structure, since three-sided queries are more general. However, diagonal two-sided structure may prove to be faster in practice, because in each of its corner substructures, the data accessed during a query are always in contiguous blocks, whereas the static substructures used for three-sided search do not guarantee block contiguity. Empirical work is ongoing to evaluate the performance of these data structures.

On a historical note, earlier work on two-sided and three-sided queries was done by Ramaswamy and Subramanian [104] using the notion of *path caching*; their structure met Criterion O1 but had higher storage overheads and amortized and/or nonoptimal update bounds. Subramanian and Ramaswamy [73] subsequently developed the *p-range tree* data structure for three-sided queries, with optimal linear disk space and nearly optimal query and amortized update bounds.

28.4.5 General Orthogonal 2-D Range Search

The dynamic data structure for three-sided range searching can be generalized using the filtering technique of Chazelle [8] to handle general four-sided queries with optimal I/O query bound $O(\log_B N + z)$ and optimal disk space usage $O(n(\log n)/\log(\log_B N + 1))$ [102]. The update bound becomes $O((\log_B N)(\log n)/\log(\log_B N + 1))$, which may not be optimal.

The outer level of the structure is a balanced $(\log_B N + 1)$ -way 1-D search tree with $\Theta(n)$ leaves, oriented, say, along the x -dimension. It therefore has about $(\log n)/\log(\log_B N + 1)$ levels. At each level of the tree, each input point is stored in four substructures (described later) that are associated with the particular tree node at that level that spans the x -value of the point. The space and update bounds quoted above follow from the fact that the substructures use linear space and can be updated in $O(\log_B N)$ I/Os.

To search for the points in a four-sided query rectangle $[x_1, x_2] \times [y_1, y_2]$, we decompose the four-sided query in the following natural way into two three-sided queries, a stabbing query, and $\log_B N - 1$ list traversals. We find the lowest node v in the tree whose x -range contains $[x_1, x_2]$. If v is a leaf, we can answer the query in a single I/O. Otherwise we query the substructures stored in those children of v whose x -ranges intersect $[x_1, x_2]$. Let $2 \leq k \leq \log_B N + 1$ be the number of such children. The range query when restricted to the leftmost such child of v is a three-sided query of the form $[x_1, +\infty] \times [y_1, y_2]$, and when restricted to the rightmost such child of v , the range query is a three-sided query of the form $[-\infty, x_2] \times [y_1, y_2]$. Two of the substructures at each node are devoted for three-sided queries of these types; using the linear-sized data structures of Arge et al. [102] in Section 28.4.4, each such query can be done in $O(\log_B N + z)$ I/Os.

For the $k - 2$ intermediate children of v , their x -ranges are completely contained inside the x -range of the query rectangle, and thus we need only do $k - 2$ list traversals in y -order and retrieve the points whose y -values are in the range $[y_1, y_2]$. If we store the points in each node in y -order (in the third type of substructure), the Z' output points from a node can be found in $O(\lceil Z'/B \rceil)$ I/Os, once a starting point in the linear list is found. We can find all $k - 2$ starting points via a single query to a stabbing query substructure S associated with v . (This structure is the fourth type of substructure.) For each two y -consecutive points (a_i, b_i) and (a_{i+1}, b_{i+1}) associated with a child of v , we store the y -interval $[b_i, b_{i+1}]$ in S . Note that S contains intervals contributed by each of the $\log_B N + 1$ children of v . By a single stabbing query with query value y_1 , we can thus identify the $k - 2$ starting points in only $O(\log_B N)$ I/Os [54], as described in Section 28.4.3. (We actually get starting points for all the children of v , not just the $k - 2$ ones of interest, but we can discard the starting points we don't need.) The total number of I/Os to answer the range query is thus $O(\log_B N + z)$, which is optimal.

28.4.6 Lower Bounds for Orthogonal Range Search

We mentioned in Section 28.4 that Subramanian and Ramaswamy [73] prove that no EM data structure for 2-D range searching can achieve design Criterion O1 of Section 28.1.2 using less than $O(n(\log n)/\log(\log_B N + 1))$ disk blocks, even if we relax the criterion and allow $O((\log_B N)^c + z)$ I/Os per query, for any constant c . The result holds for an EM version of the pointer machine model, based upon the approach of Chazelle [105] for the internal memory model.

Hellerstein et al. [106] consider a generalization of the layout-based lower bound argument of Kanellakis et al. [72] for studying the trade-off between disk space usage and query performance. They develop a model for *indexability*, in which an “efficient” data structure is expected to contain the Z output points to a query compactly within $O(\lceil Z/B \rceil) = O(\lceil z \rceil)$ blocks. One shortcoming of the model is that it considers only data layout and ignores the search component of queries, and thus it rules out the important filtering paradigm discussed earlier in Section 28.4. For example, it is reasonable for any query to perform at least $\log_B N$ I/Os, so if the output size Z is at most B , a data structure may still be able to satisfy Criterion O1 even if the output is contained within $O(\log_B N)$ blocks rather than $O(z) = O(1)$ blocks. Arge et al. [102] modify the model to rederive the same nonlinear space lower bound $O(n(\log n)/\log(\log_B N + 1))$ of Subramanian and Ramaswamy [73] for 2-D range searching by considering only output sizes Z larger than $(\log_B N)^c B$, for which the number of blocks allowed to hold the outputs is $Z/B = O((\log_B N)^c + z)$. This approach ignores the complexity of how to find the relevant blocks, but as mentioned in Section 28.4.5, the authors separately provide an optimal 2-D range search data structure that uses the same amount of disk space and does queries in the optimal $O(\log_B N + z)$ I/Os. Thus, despite its shortcomings, the indexability model is elegant and can provide much insight into the complexity of blocking data in EM. Further results in this model appear in References 107 and 108.

One intuition from the indexability model is that less disk space is needed to efficiently answer 2-D queries when the queries have bounded aspect ratio (i.e., when the ratio of the longest side length to the shortest side length of the query rectangle is bounded). An interesting question is whether R-trees and the linear-space structures of Sections 28.4.1 and 28.4.2 can be shown to perform provably well for such queries. Another interesting scenario is where the queries correspond to snapshots of the continuous movement of a sliding rectangle.

When the data structure is restricted to contain only a single copy of each point, Kanth and Singh [75] show for a restricted class of index-based trees that d -dimensional range queries in the worst case require $\Omega(n^{1-1/d} + z)$ I/Os, and they provide a data structure with a matching bound. Another approach to achieve the same bound is the cross tree data structure [74] mentioned in Section 28.4.1, which in addition supports the operations of cut and concatenate.

28.5 Related Problems

For other types of range searching, such as in higher dimensions and for nonorthogonal queries, different filtering techniques are needed. So far, relatively little work has been done, and many open problems remain.

Vengroff and Vitter [109] developed the first theoretically near-optimal EM data structure for static three-dimensional orthogonal range searching. They create a hierarchical partitioning in which all the points that dominate a query point are densely contained in a set of blocks. Compression techniques are needed to minimize disk storage. If we use $(B \log n)$ -approximate

boundaries rather than B -approximate boundaries, queries can be done in $O(\log_B N + z)$ I/Os, which is optimal, and the space usage is $O(n(\log n)^{k+1}/(\log(\log_B N + 1))^k)$ disk blocks to support $(3 + k)$ -sided 3-D range queries, in which k of the dimensions ($0 \leq k \leq 3$) have finite ranges. The result also provides optimal $O(\log N + Z)$ -time query performance for three-sided 3-D queries in the (internal memory) RAM model, but using $O(N \log N)$ space.

Afshani [110] introduced the first optimal 3-D structure for dominance queries, and Afshani et al. [111] developed structures for range queries in higher dimensions.

By the reduction in Reference 112, a data structure for three-sided 3-D queries also applies to 2-D *homothetic range search*, in which the queries correspond to scaled and translated (but not rotated) transformations of an arbitrary fixed polygon. An interesting special case is “fat” orthogonal 2-D range search, where the query rectangles are required to have bounded aspect ratio. For example, every rectangle with bounded aspect ratio can be covered by two overlapping squares. An interesting open problem is to develop linear-sized optimal data structures for fat orthogonal 2-D range search. By the reduction, one possible approach would be to develop optimal linear-sized data structures for three-sided 3-D range search.

Agarwal et al. [113] consider halfspace range searching, in which a query is specified by a hyperplane and a bit indicating one of its two sides, and the output of the query consists of all the points on that side of the hyperplane. They give various data structures for half-space range searching in two, three, and higher dimensions, including one that works for simplex (polygon) queries in two dimensions, but with a higher query I/O cost. They have subsequently improved the storage bounds for half-space range queries in two dimensions to obtain an optimal static data structure satisfying Criteria O1 and O2 of Section 28.1.2.

The number of I/Os needed to build the data structures for 3-D orthogonal range search and half-space range search is rather large (more than $\Omega(N)$). Still, the structures shed useful light on the complexity of range searching and may open the way to improved solutions. An open problem is to design efficient construction and update algorithms and to improve upon the constant factors.

Cheng et al. [114,115] look at a model of uncertainty, in which the location of each data point is given by a probability distribution, and give efficient indexes for range queries and join queries.

An interesting model related to range searching involves pattern matching in string data, and there has been great interest recently in EM algorithms for string processing. Chien et al. [116] derive a duality relation that links the number of I/O steps and the space bound for range searching to the corresponding measures for text indexing. Hon et al. [117] provide a formal framework for efficiently retrieving the most relevant occurrences satisfying a query pattern. Their index takes linear space and can be reduced to sublinear space by exploiting the compressibility of the data. Their work is an example of a compressed data structure, in which the goal is to construct a search structure whose size is roughly comparable to the size of the input in compressed format, but which can still be queried directly in an efficient manner. Other work on compressed data structures appears in Vitter [1].

Callahan et al. [118] develop dynamic EM data structures for several online problems in d dimensions. For any fixed $\epsilon > 0$, they can find an approximate nearest neighbor of a query point (within a $1 + \epsilon$ factor of optimal) in $O(\log_B N)$ I/Os; insertions and deletions can also be done in $O(\log_B N)$ I/Os. They use a related approach to maintain the closest pair of points; each update costs $O(\log_B N)$ I/Os. Govindarajan et al. [67] achieve the same bounds for closest pair by maintaining a well-separated pair decomposition. For finding nearest neighbors and approximate nearest neighbors, two other approaches are partition trees [113,119] and locality-sensitive hashing [120]. Numerous other data structures have been developed for range queries and related problems on spatial data. We refer to References 32, 88, and 89 for a broad survey.

28.6 Dynamic and Kinetic Data Structures

In this section, we consider two scenarios where data items change: *dynamic* (in which items are inserted and deleted) and *kinetic* (in which the data items move continuously along specified trajectories). In both cases, queries can be done at any time. It is often useful for kinetic data structures to allow insertions and deletions; for example, if the trajectory of an item changes, we must delete the old trajectory and insert the new one.

28.6.1 Logarithmic Method for Decomposable Search Problems

In previous sections, we've already encountered several dynamic data structures for the problems of dictionary lookup and range search. In Section 28.4, we saw how to develop optimal EM range search data structures by externalizing some known internal memory data structures. The key idea was to use the bootstrapping paradigm, together with weight-balanced B-trees as the underlying data structure, in order to consolidate several static data structures for small instances of range searching into one dynamic data structure for the full problem. The bootstrapping technique is specific to the particular data structures involved. In this section, we look at another technique that is based upon the properties of the problem itself rather than upon that of the data structure.

We call a problem *decomposable* if we can answer a query by querying individual subsets of the problem data and then computing the final result from the solutions to each subset. Dictionary search and range searching are obvious examples of decomposable problems. Bentley developed the *logarithmic method* [121,122] to convert efficient static data structures for decomposable problems into general dynamic ones. In the internal memory setting, the logarithmic method consists of maintaining a series of static substructures, at most one each of size 1, 2, 4, 8, . . . When a new item is inserted, it is initialized in a substructure of size 1. If a substructure of size 1 already exists, the two substructures are combined into a single substructure of size 2. If there is already a substructure of size 2, they in turn are combined into a single substructure of size 4, and so on. For the current value of N , it is easy to see that the k th substructure (i.e., of size 2^k) is present exactly when the k th bit in the binary representation of N is 1. Since there are at most $\log N$ substructures, the search time bound is $\log N$ times the search time per substructure. As the number of items increases from 1 to N , the k th structure is built a total of $N/2^k$ times (assuming N is a power of 2). If it can be built in $O(2^k)$ time, the total time for all insertions and all substructures is thus $O(N \log N)$, making the amortized insertion time $O(\log N)$. If we use up to three substructures of size 2^k at a time, we can do the reconstructions in advance and convert the amortized update bounds to worst case [122].

In the EM setting, in order to eliminate the dependence upon the binary logarithm in the I/O bounds, the number of substructures must be reduced from $\log N$ to $\log_B N$, and thus the maximum size of the k th substructure must be increased from 2^k to B^k . As the number of items increases from 1 to N , the k th substructure has to be built NB/B^k times (when N is a power of B), each time taking $O(B^k(\log_B N)/B)$ I/Os. The key point is that the extra factor of B in the numerator of the first term is cancelled by the factor of B in the denominator of the second term, and thus the resulting total insertion time over all N insertions and all $\log_B N$ structures is $O(N(\log_B N)^2)$ I/Os, which is $O((\log_B N)^2)$ I/Os amortized per insertion. By global rebuilding, we can do deletions in $O(\log_B N)$ I/Os amortized. As in the internal memory case, the amortized updates can typically be made worst case.

Arge and Vahrenhold [123] obtain I/O bounds for dynamic point location in general planar subdivisions similar to those of Reference 62, but without use of level-balanced trees. Their method uses a weight-balanced base structure at the outer level and a multislab structure for storing segments similar to that of Arge and Vitter [54] described in Section 28.4.3. They use the logarithmic method to construct a data structure to answer vertical rayshooting queries in the multislab structures. The method relies upon a total ordering of the segments, but such an ordering can be changed drastically by a single insertion. However, each substructure in the logarithmic method is static (until it is combined with another substructure), and thus a static total ordering can be used for each substructure. The authors show by a type of fractional cascading that the queries in the $\log_B N$ substructures do not have to be done independently, which saves a factor of $\log_B N$ in the I/O cost, but at the cost of making the data structures amortized instead of worst case.

Agarwal et al. [55] apply the logarithmic method (in both the binary form and B -way variant) to get EM versions of kd-trees, BBD trees, and BAR trees.

28.6.2 Continuously Moving Items

Early work on temporal data generally concentrated on time-series or multiversion data [50]. A question of growing interest in this mobile age is how to store and index continuously moving items, such as mobile telephones, cars, and airplanes, using kinetic data structures [124–126]. There are two main approaches to storing moving items. The first technique is to use the same sort of data structure as for nonmoving data, but to update it whenever items move sufficiently far so as to trigger important combinatorial *events* that are relevant to the application at hand [127]. For example, an event relevant for range search might be triggered when two items move to the same horizontal displacement (which happens when the x -ordering of the two items is about to switch). A different approach is to store each item's location and speed trajectory, so that no updating is needed as long as the item's trajectory plan does not change. Such an approach requires fewer updates, but the representation for each item generally has higher dimension, and the search strategies are therefore less efficient.

Kollios et al. [128] developed a linear-space indexing scheme for moving points along an 1-D line, based upon the notion of partition trees. Their structure supports a variety of range search and approximate nearest-neighbor queries. For example, given a range and time, the points in that range at the indicated time can be retrieved in $O(n^{1/2+\epsilon} + k)$ I/Os, for arbitrarily small $\epsilon > 0$. Updates require $O((\log n)^2)$ I/Os. Agarwal et al. [119] extend the approach to handle range searches in two dimensions, and they improve the update bound to $O((\log_B n)^2)$ I/Os. They also propose an event-driven data structure with the same query times as the range search data structure of Arge and Vitter [102] discussed in Section 28.4.5, but with the potential need to do many updates. A hybrid data structure combining the two approaches permits a trade-off between query performance and update frequency.

R-trees offer a practical generic mechanism for storing multidimensional points and are thus a natural alternative for storing mobile items. One approach is to represent time as a separate dimension and to cluster trajectories using the R-tree heuristics. However, the orthogonal nature of the R-tree does not lend itself well to diagonal trajectories. For the case of points moving along linear trajectories, Šaltenis et al. [125] build the R-tree upon only the spatial dimensions, but parameterize the bounding

box coordinates to account for the movement of the items stored within. They maintain an outer approximation of the true bounding box, which they periodically update to refine the approximation. Agarwal and Har-Peled [129] show how to maintain a provably good approximation of the minimum bounding box with need for only a constant number of refinement events. Further discussion of kinetic data structures, primarily for internal memory, appears in [Chapter 24](#).

28.7 Conclusion

In this chapter, we have surveyed several useful paradigms and techniques for the design and implementation of efficient data structures for EM. A variety of interesting challenges remain in geometric search applications, such as methods for high-dimensional and nonorthogonal range searches as well as the analysis of R-trees and linear-space methods for typical case scenarios. A continuing goal is to translate theoretical gains into observable improvements in practice. For some of the problems that can be solved optimally up to a constant factor, the constant overhead is too large for the algorithm to be of practical use, and simpler approaches are needed.

Acknowledgments

The author thanks the members of the Center for Geometric Computing at Duke University for helpful comments and suggestions. 29.1 What Is a Trie?

A *trie* (pronounced “try” and derived from the word *retrieval*) is a data structure that uses the digits in the keys to organize and search the dictionary. Although, in practice, we can use any radix to decompose the keys into digits, in our examples, we shall choose our radices so that the digits are natural entities such as decimal digits (0, 1, 2, 3, 4, 5, 6, 7, 8, 9) and letters of the English alphabet (*a*–*z*, *A*–*Z*).

Suppose that the elements in our dictionary are student records that contain fields such as student name, major, date of birth, and social security number (SS#). The key field is the social security number, which is a nine digit decimal number. To keep the example manageable, assume that the dictionary has only five elements. [Table 29.1](#) shows the name and SS# fields for each of the five elements in our dictionary.

To obtain a trie representation for these five elements, we first select a radix that will be used to decompose each key into digits. If we use the radix 10, the decomposed digits are just the decimal digits shown in [Table 29.1](#). We shall examine the digits of the key field (i.e., SS#) from left to right. Using the first digit of the SS#, we partition the elements into three groups—elements whose SS# begins with 2 (i.e., Bill and Kathy), those that begin with 5 (i.e., Jill), and those that begin with 9 (i.e., April and Jack). Groups with more than one element are partitioned using the next digit in the key. This partitioning process is continued until every group has exactly one element in it.

The partitioning process described above naturally results in a tree structure that has 10-way branching as is shown in [Figure 29.1](#). The tree employs two types of nodes—*branch nodes* and *element nodes*. Each branch node has 10 children (or pointer/reference) fields. These fields, *child[0:9]*, have been labeled 0, 1, . . . , 9 for the root node of [Figure 29.1](#). *root.child[i]* points to the root of a subtree that contains all elements whose first digit is *i*. In [Figure 29.1](#), nodes A, B, D, E, F, and I are branch nodes. The remaining nodes, nodes C, G, H, J, and K are element nodes. Each element node contains exactly one element of the dictionary. In [Figure 29.1](#), only the key field of each element is shown in the element nodes.

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

TABLE 29.1 Five Elements
(Student Records) in a Dictionary

Name	Social Security Number (SS#)
Jack	951-94-1654
Jill	562-44-2169
Bill	271-16-3624
Kathy	278-49-1515
April	951-23-7625

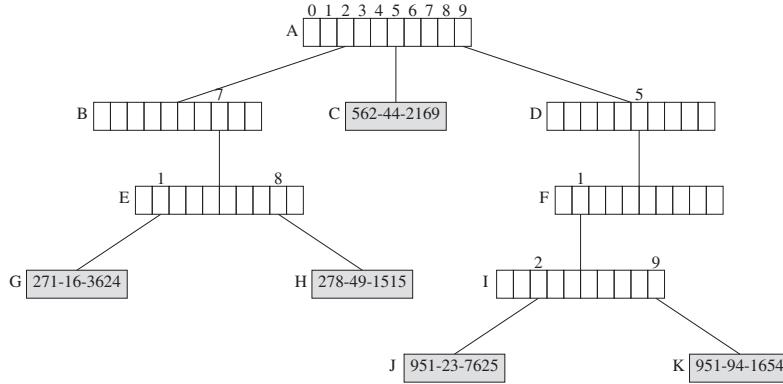

FIGURE 29.1 Trie for the elements of Table 29.1.

29.2 Searching a Trie

To search a trie for an element with a given key, we start at the root and follow a path down the trie until we either fall off the trie (i.e., we follow a *null* pointer in a branch node) or we reach an element node. The path we follow is determined by the digits of the search key. Consider the trie of Figure 29.1. Suppose we are to search for an element with key 951-23-7625. We use the first digit, 9, in the key to move from the root node A to the node $A.child[9] = D$. Since D is a branch node, we use the next digit, 5, of the key to move further down the trie. The node we reach is $D.child[5] = F$. To move to the next level of the trie, we use the next digit, 1, of the key. This move gets us to the node $F.child[1] = I$. Once again, we are at a branch node and must move further down the trie. For this move, we use the next digit, 2, of the key, and we reach the element node $I.child[2] = J$. When an element node is reached, we compare the search key and the key of the element in the reached element node. Performing this comparison at node J , we get a match. The element in node J , is to be returned as the result of the search.

When searching the trie of Figure 29.1 for an element with key 951-23-1669, we follow the same path as for the key 951-23-7625. The key comparison made at node J tells us that the trie has no element with key 951-23-1669, and the search returns the value *null*.

To search for the element with key 562-44-2169, we begin at the root A and use the first digit, 5, of the search key to reach the element node $A.child[5] = C$. The key of the element in node C is compared with the search key. Since the two keys agree, the element in node C is returned.

When searching for an element with key 273-11-1341, we follow the path $A, A.child[2] = B, B.child[7] = E, E.child[3] = \text{null}$. Since we fall off the trie, we know that the trie contains no element whose key is 273-11-1341.

When analyzing the complexity of trie operations, we make the assumption that we can obtain the next digit of a key in $O(1)$ time. Under this assumption, we can search a trie for an element with a d digit key in $O(d)$ time.

29.3 Keys with Different Length

In the example of Figure 29.1, all keys have the same number of digits (i.e., 9). In many applications, however, different keys have different length. This does not pose a problem unless one key is a prefix of another (e.g., 27 is a prefix of 276). For applications in which one key may be a prefix of another, we normally add a special digit (say #) at the end of each key. Doing this ensures that no key is a prefix of another.

To see why we cannot permit a key that is a prefix of another key, consider the example of [Figure 29.1](#). Suppose we are to search for an element with the key 27. Using the search strategy just described, we reach the branch node E . What do we do now? There is no next digit in the search key that can be used to reach the terminating condition (i.e., you either fall off the trie or reach an element node) for downward moves. To resolve this problem, we add the special digit $\#$ at the end of each key and also increase the number of children fields in an element node by one. The additional child field is used when the next digit equals $\#$.

An alternative to adding a special digit at the end of each key is to give each node a *data* field that is used to store the element (if any) whose key exhausts at that node. So, for example, the element whose key is 27 can be stored in node E of [Figure 29.1](#). When this alternative is used, the search strategy is modified so that when the digits of the search key are exhausted, we examine the *data* field of the reached node. If this *data* field is empty, we have no element whose key equals the search key. Otherwise, the desired element is in this *data* field.

It is important to note that in applications that have different length keys with the property that no key is a prefix of another, neither of just mentioned strategies is needed; the scheme described in Section 29.2 works as is.

29.4 Height of a Trie

In the worst case, a root-node to element-node path has a branch node for every digit in a key. Therefore, the height^{*} of a trie is at most *number of digits* + 1.

A trie for social security numbers has a height that is at most 10. If we assume that it takes the same time to move down one level of a trie as it does to move down one level of a binary search tree, then with at most 10 moves we can search a social-security trie. With this many moves, we can search a binary search tree that has at most $2^{10} - 1 = 1023$ elements. This means that, we expect searches in the social security trie to be faster than searches in a binary search tree (for student records) whenever the number of student records is more than 1023. The breakeven point will actually be less than 1023 because we will normally not be able to construct full or complete binary search trees for our element collection.

Since a SS# is nine digits, a social security trie can have up to 10^9 elements in it. An AVL tree with 10^9 elements can have a height that is as much as (approximately) $1.44 \log_2(10^9 + 2) = 44$. Therefore, it could take us four times as much time to search for elements when we organize our student-record dictionary as an AVL tree than when this dictionary is organized as a trie!

29.5 Space Required and Alternative Node Structures

The use of branch nodes that have as many child fields as the radix of the digits (or one more than this radix when different keys may have different length) results in a fast search algorithm. However, this node structure is often wasteful of space because many of the child fields are *null*. A radix r trie for d digit keys requires $O(rdn)$ child fields, where n is the number of elements in the trie. To see this, notice that in a d digit trie with n information nodes, each information node may have at most d ancestors, each of which is a branch node. Therefore, the number of branch nodes is at most dn . (Actually, we cannot have this many branch nodes, because the information nodes have common ancestors like the root node.)

We can reduce the space requirements, at the expense of increased search time, by changing the node structure. For example, each branch node of a trie could be replaced by any of the following:

1. A chain of nodes, each node having the three fields *digit Value*, *child*, *next*. Node A of [Figure 29.1](#), for example, would be replaced by the chain shown in [Figure 29.2](#).

The space required by a branch node changes from that required for r children/pointer/reference fields to that required for $2p$ pointer fields and p digit value fields, where p is the number of children fields in the branch node that are not *null*. Under the assumption that pointer fields and digit value fields are of the same size, a reduction in space is realized when more than two-thirds of the children fields in branch nodes are *null*. In the worst case, almost all the branch nodes have only 1 field that is not *null* and the space savings become almost $(1 - 3/r) * 100\%$.

2. A (balanced) binary search tree in which each node has a digit value and a pointer to the subtrie for that digit value. [Figure 29.3](#) shows the binary search tree for node A of [Figure 29.1](#).

Under the assumption that digit values and pointers take the same amount of space, the binary search tree representation requires space for $4p$ fields per branch node, because each search tree node has fields for a digit value, a subtrie pointer, a left child pointer, and a right child pointer. The binary search tree representation of a branch node saves us space when more than three-fourths of the children fields in branch nodes are *null*. Note that for large r , the binary search tree is faster to search than the chain described above.

^{*} The definition of height used in this chapter is: the height of a trie equals the number of levels in that trie.

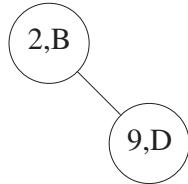

FIGURE 29.3 Binary search tree for node A of Figure 29.1.

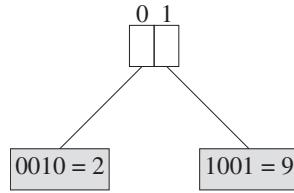

FIGURE 29.4 Binary trie for node A of Figure 29.1.

3. A binary trie (i.e., a trie with radix 2). Figure 29.4 shows the binary trie for node A of Figure 29.1. The space required by a branch node represented as a binary trie is at most $(2 * \lceil \log_2 r \rceil + 1)p$.
4. A hash table. When a hash table with a sufficiently small loading density is used, the expected time performance is about the same as when the node structure of Figure 29.1 is used. Since we expect the fraction of *null* child fields in a branch node to vary from node to node and also to increase as we go down the trie, maximum space efficiency is obtained by consolidating all of the branch nodes into a single hash table. To accomplish this, each node in the trie is assigned a number, and each parent to child pointer is replaced by a triple of the form $(currentNode, digitValue, childNode)$. The numbering scheme for nodes is chosen so as to easily distinguish between branch and information nodes. For example, if we expect to have at most 100 elements in the trie at any time, the numbers 0 through 99 are reserved for information nodes and the numbers 100 on up are used for branch nodes. The information nodes are themselves represented as an array *information* [100]. (An alternative scheme is to represent pointers as tuples of the form $(currentNode, digitValue, childNode, childNodeIsBranchNode)$, where *childNodeIsBranchNode* = *true* iff the child node is a branch node.)

Suppose that the nodes of the trie of Figure 29.1 are assigned numbers as given in Figure 29.5. This number assignment assumes that the trie will have no more than 10 elements.

The pointers in node A are represented by the tuples $(10, 2, 11)$, $(10, 5, 0)$, and $(10, 9, 12)$. The pointers in node E are represented by the tuples $(13, 1, 1)$ and $(13, 8, 2)$.

The pointer triples are stored in a hash table using the first two fields (i.e., the *currentNode* and *digitValue*) as the key. For this purpose, we may transform the two field key into an integer using the formula $currentNode * r + digitValue$, where *r* is the trie radix, and use the division method to hash the transformed key into a home bucket. The data presently in information node *i* is stored in *information[i]*.

To see how all this works, suppose we have set up the trie of Figure 29.1 using the hash table scheme just described. Consider searching for an element with key 278-49-1515. We begin with the knowledge that the root node is assigned the number 10. Since the first digit of the search key is 2, we query our hash table for a pointer triple with key $(10, 2)$. The hash table search is successful and the triple $(10, 2, 11)$ is retrieved. The *childNode* component of this triple is 11, and since all information nodes have a number 9 or less, the child node is determined to be a branch node. We make a move to the branch node 11. To move to the next level of the trie, we use the second digit 7 of the search key. For the move,

Node Number	A	B	C	D	E	F	G	H	I	J	K
10	11	0	12	13	14	1	2	15	3	4	

FIGURE 29.5 Number assignment to nodes of trie of Figure 29.1.

we query the hash table for a pointer with key (11, 7). Once again, the search is successful and the triple (11, 7, 13) is retrieved. The next query to the hash table is for a triple with key (13, 8). This time, we obtain the triple (13, 8, 2). Since $childNode = 2 < 10$, we know that the pointer gets us to an information node. So, we compare the search key with the key of the element *information* [2]. The keys match, and we have found the element we were looking for.

When searching for an element with key 322-167-8976, the first query is for a triple with key (10, 3). The hash table has no triple with this key, and we conclude that the trie has no element whose key equals the search key.

The space needed for each pointer triple is about the same as that needed for each node in the chain of nodes representation of a trie node. Therefore, if we use a linear open addressed hash table with a loading density of α , the hash table scheme will take approximately $(1/\alpha - 1) * 100\%$ more space than required by the chain of nodes scheme. However, when the hash table scheme is used, we can retrieve a pointer in $O(1)$ expected time, whereas the time to retrieve a pointer using the chain of nodes scheme is $O(r)$. When the (balanced) binary search tree or binary trie schemes are used, it takes $O(\log r)$ time to retrieve a pointer. For large radices, the hash table scheme provides significant space saving over the scheme of [Figure 29.1](#) and results in a small constant factor degradation in the expected time required to perform a search.

The hash table scheme actually reduces the expected time to insert elements into a trie, because when the node structure of [Figure 29.1](#) is used, we must spend $O(r)$ time to initialize each new branch node (see the description of the insert operation below). However, when a hash table is used, the insertion time is independent of the trie radix.

To support the removal of elements from a trie represented as a hash table, we must be able to reuse information nodes. This reuse is accomplished by setting up an available space list of information nodes that are currently not in use.

Andersson and Nilsson [1] propose a trie representation in which nodes have a variable degree. Their data structure, called LC-tries (level-compressed tries), is obtained from a binary trie by replacing full subtrees of the binary trie by single node whose degree is 2^i , where i is the number of levels in the replaced full subtree. This replacement is done by examining the binary trie from top to bottom (i.e., from root to leaves).

29.6 Inserting into a Trie

To insert an element *theElement* whose key is *theKey*, we first search the trie for an existing element with this key. If the trie contains such an element, then we replace the existing element with *theElement*. When the trie contains no element whose key equals *theKey*, *theElement* is inserted into the trie using the following procedure.

Case 1 For Insert Procedure

If the search for *theKey* ended at an element node *X*, then the key of the element in *X* and *theKey* are used to construct a subtree to replace *X*.

Suppose we are to insert an element with key 271-10-2529 into the trie of [Figure 29.1](#). The search for the key 271-10-2529 terminates at node *G* and we determine that the key, 271-16-3624, of the element in node *G* is not equal to the key of the element to be inserted. Since the first three digits of the keys are used to get as far as node *E* of the trie, we set up branch nodes for the fourth digit (from the left) onwards until we reach the first digit at which the two keys differ. This results in branch nodes for the fourth and fifth digits followed by element nodes for each of the two elements. [Figure 29.6](#) shows the resulting trie.

Case 2 For Insert Procedure

If the search for *theKey* ends by falling off the trie from the branch node *X*, then we simply add a child (which is an element node) to the node *X*. The added element node contains *theElement*.

Suppose we are to insert an element with key 987-33-1122 to the trie of [Figure 29.1](#). The search for an element with key equal to 987-33-1122 ends when we fall off the trie while following the pointer *D.child[8]*. We replace the *null* pointer *D.child[8]* with a pointer to a new element node that contains *theElement*, as is shown in [Figure 29.7](#).

The time required to insert an element with a d digit key into a radix r trie is $O(dr)$ because the insertion may require us to create $O(d)$ branch nodes and it takes $O(r)$ time to initialize the children pointers in a branch node.

29.7 Removing an Element

To remove the element whose key is *theKey*, we first search for the element with this key. If there is no matching element in the trie, nothing is to be done. So, assume that the trie contains an element *theElement* whose key is *theKey*. The element node *X* that contains *theElement* is discarded, and we retrace the path from *X* to the root discarding branch nodes that are roots of subtrees that have only 1 element in them. This path retracing stops when we either reach a branch node that is not discarded or we discard the root.

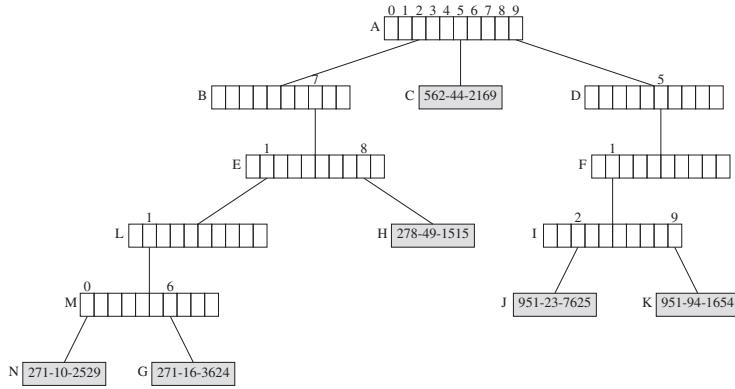

FIGURE 29.6 Trie of Figure 29.1 with 271-10-2529 inserted.

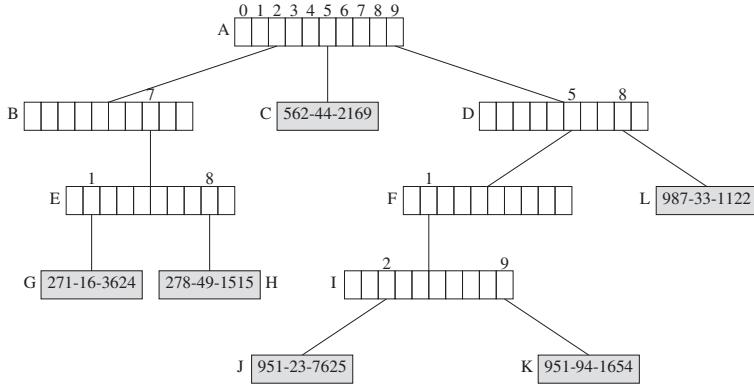

FIGURE 29.7 Trie of Figure 29.1 with 987-33-1122 inserted.

Consider the trie of Figure 29.7. When the element with key 951-23-7625 is removed, the element node *J* is discarded and we follow the path from node *J* to the root node *A*. The branch node *I* is discarded because the subtrie with root *I* contains the single element node *K*. We next reach the branch node *F*. This node is also discarded, and we proceed to the branch node *D*. Since the subtrie rooted at *D* has 2 element nodes (*K* and *L*), this branch node is not discarded. Instead, node *K* is made a child of this branch node, as is shown in Figure 29.8.

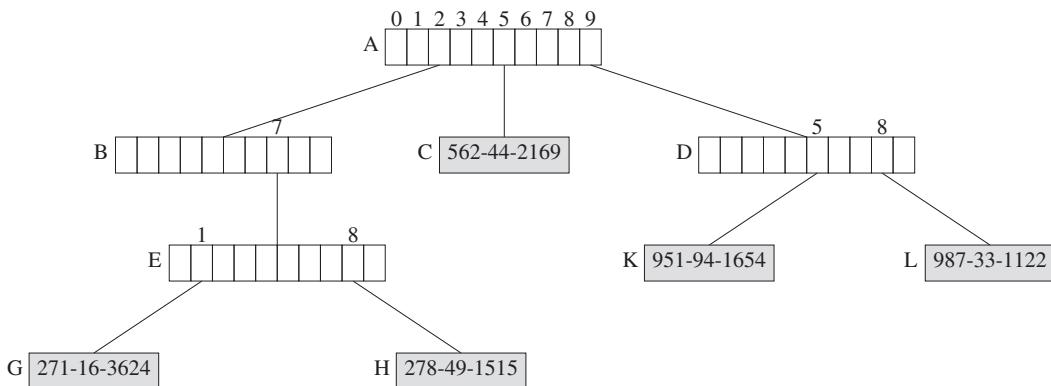

FIGURE 29.8 Trie of Figure 29.7 with 951-23-7635 removed.

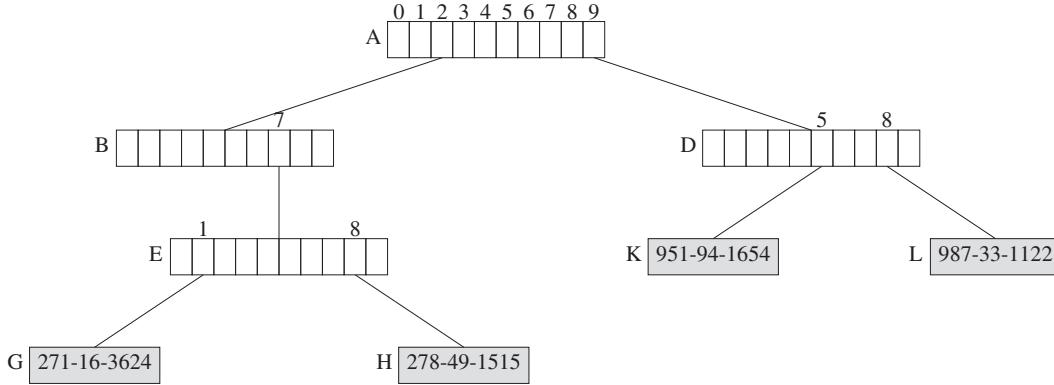

FIGURE 29.9 Trie of Figure 29.8 with 562-44-2169 removed.

To remove the element with key 562-44-2169 from the trie of Figure 29.8, we discard the element node C. Since its parent node remains the root of a subtree that has more than one element, the parent node is not discarded and the removal operation is complete. Figure 29.9 show the resulting trie.

The time required to remove an element with a d digit key from a radix r trie is $O(dr)$ because the removal may require us to discard $O(d)$ branch nodes and it takes $O(r)$ time to determine whether a branch node is to be discarded. The complexity of the remove operation can be reduced to $O(r + d)$ by adding a *numberOfElementsInSubtrie* field to each branch node.

29.8 Prefix Search and Applications

You have probably realized that to search a trie we do not need the entire key. Most of the time, only the first few digits (i.e., a prefix) of the key is needed. For example, our search of the trie of Figure 29.1 for an element with key 951-23-7625 used only the first four digits of the key. The ability to search a trie using only the prefix of a key enables us to use tries in applications where only the prefix might be known or where we might desire the user to provide only a prefix. Some of these applications are described below.

Criminology

Suppose that you are at the scene of a crime and observe the first few characters CRX on the registration plate of the getaway car. If we have a trie of registration numbers, we can use the characters CRX to reach a subtree that contains all registration numbers that begin with CRX. The elements in this subtree can then be examined to see which cars satisfy other properties that might have been observed.

Automatic Command Completion

When using an operating system such as Unix or DOS, we type in system commands to accomplish certain tasks. For example, the Unix and DOS command *cd* may be used to change the current directory. Table 29.2 gives a list of commands that have the prefix *ps* (this list was obtained by executing the command *ls/usr/local/bin/ps** on a Unix system).

We can simplify the task of typing in commands by providing a command completion facility which automatically types in the command suffix once the user has typed in a long enough prefix to uniquely identify the command. For instance, once the letters *psi* have been entered, we know that the command must be *psidtopgm* because there is only one command that has the prefix *psi*. In this case, we replace the need to type in a 9 character command name by the need to type in just the first 3 characters of the command!

A command completion system is easily implemented when the commands are stored in a trie using ASCII characters as the digits. As the user types the command digits from left to right, we move down the trie. The command may be completed as soon

TABLE 29.2 Commands that Begin with “ps”

ps2ascii	ps2pdf	psbook	psmandup	psselect
ps2epsi	ps2pk	pscal	psmerge	pstopnm
ps2frag	ps2ps	psidtopgm	psnup	pstops
ps2gif	psbb	pslatex	psresize	pstruct

as we reach an element node. If we fall off the trie in the process, the user can be informed that no command with the typed prefix exists.

Although we have described command completion in the context of operating system commands, the facility is useful in other environments:

1. A network browser keeps a history of the URLs of sites that you have visited. By organizing this history as a trie, the user need only type the prefix of a previously used URL and the browser can complete the URL.
2. A word processor can maintain a dictionary of words and can complete words as you type the text. Words can be completed as soon as you have typed a long enough prefix to identify the word uniquely.
3. An automatic phone dialer can maintain a list of frequently called telephone numbers as a trie. Once you have punched in a long enough prefix to uniquely identify the phone number, the dialer can complete the call for you.

29.9 Compressed Tries

Take a close look at the trie of [Figure 29.1](#). This trie has a few branch nodes (nodes *B*, *D*, and *F*) that do not partition the elements in their subtrie into two or more nonempty groups. We often can improve both the time and space performance metrics of a trie by eliminating all branch nodes that have only one child. The resulting trie is called a *compressed trie*.

When branch nodes with a single child are removed from a trie, we need to keep additional information so that dictionary operations may be performed correctly. The additional information stored in three compressed trie structures is described below.

29.9.1 Compressed Tries with Digit Numbers

In a *compressed trie with digit numbers*, each branch node has an additional field *digitNumber* that tells us which digit of the key is used to branch at this node. [Figure 29.11](#) shows the compressed trie with digit numbers that corresponds to the trie of [Figure 29.1](#). The leftmost field of each branch node of [Figure 29.10](#) is the *digitNumber* field.

29.9.1.1 Searching a Compressed Trie with Digit Numbers

A compressed trie with digit numbers may be searched by following a path from the root. At each branch node, the digit, of the search key, given in the branch node's *digitNumber* field is used to determine which subtrie to move to. For example, when searching the trie of [Figure 29.10](#) for an element with key 951-23-7625, we start at the root of the trie. Since the root node is a branch node with *digitNumber* = 1, we use the first digit 9 of the search key to determine which subtrie to move to. A move to node *A.child[9]* = *I* is made. Since *I.digitNumber* = 2, the fourth digit, 2, of the search key tells us which subtrie to move to. A move is now made to node *I.child[2]* = *J*. We are now at an element node, and the search key is compared with the key of the element in node *J*. Since the keys match, we have found the desired element.

Notice that a search for an element with key 913-23-7625 also terminates at node *J*. However, the search key and the element key at node *J* do not match and we conclude that the trie contains no element with key 913-23-7625.

29.9.1.2 Inserting into a Compressed Trie with Digit Numbers

To insert an element with key 987-26-1615 into the trie of [Figure 29.10](#), we first search for an element with this key. The search ends at node *J*. Since the search key and the key, 951-23-7625, of the element in this node do not match, we conclude that the trie has no element whose key matches the search key. To insert the new element, we find the first digit where the search key differs from the key in node *J* and create a branch node for this digit. Since the first digit where the search key 987-26-1615 and the

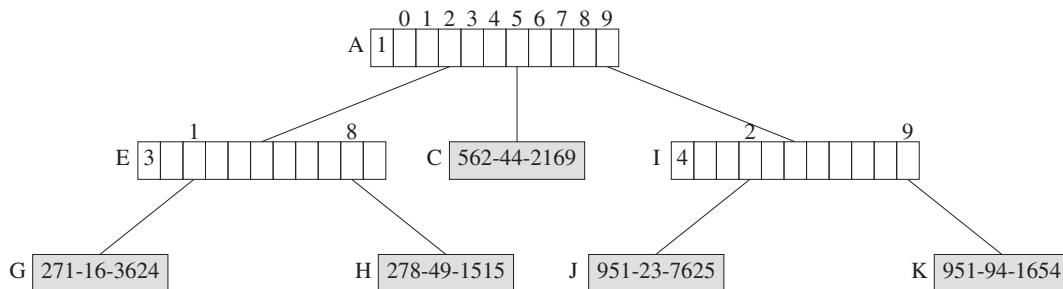

FIGURE 29.10 Compressed trie with digit numbers.

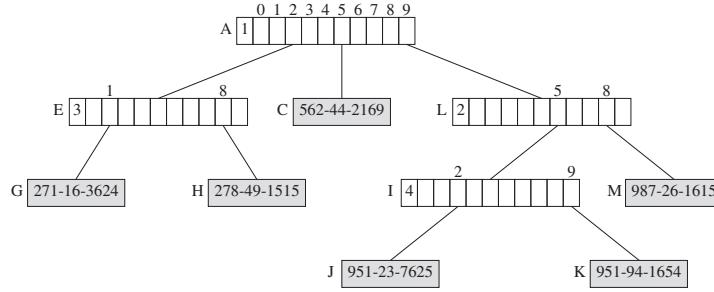

FIGURE 29.11 Compressed trie following the insertion of 987-26-1615 into the compressed trie of [Figure 29.10](#).

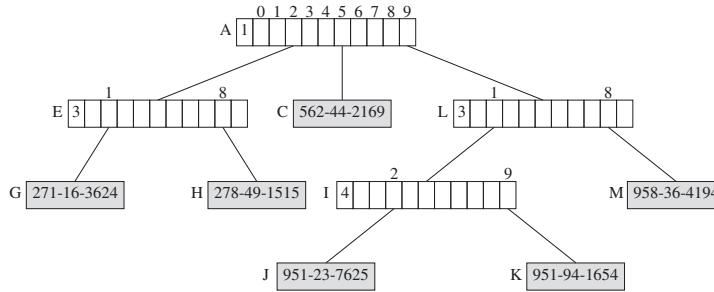

FIGURE 29.12 Compressed trie following the insertion of 958-36-4194 into the compressed trie of [Figure 29.10](#).

element key 951-23-7625 differ is the second digit, we create a branch node with $digitNumber = 2$. Since digit values increase as we go down the trie, the proper place to insert the new branch node can be determined by retracing the path from the root to node J and stopping as soon as either a node with digit value greater than 2 or the node J is reached. In the trie of [Figure 29.10](#), this path retracing stops at node I . The new branch node is made the parent of node I , and we get the trie of [Figure 29.11](#).

Consider inserting an element with key 958-36-4194 into the compressed trie of [Figure 29.10](#). The search for an element with this key terminates when we fall off the trie by following the pointer $I.child[3] = null$. To complete the insertion, we must first find an element in the subtrie rooted at node I . This element is found by following a downward path from node I using (say) the first non *null* link in each branch node encountered. Doing this on the compressed trie of [Figure 29.10](#), leads us to node J . Having reached an element node, we find the first digit where the element key and the search key differ and complete the insertion as in the previous example. [Figure 29.12](#) shows the resulting compressed trie.

Because of the possible need to search for the first non *null* child pointer in each branch node, the time required to insert an element into a compressed tries with digit numbers is $O(rd)$, where r is the trie radix and d is the maximum number of digits in any key.

29.9.1.3 Removing an Element from a Compressed Trie with Digit Numbers

To remove an element whose key is *theKey*, we do the following:

1. Find the element node X that contains the element whose key is *theKey*.
2. Discard node X .
3. If the parent of X is left with only one child, discard the parent node also. When the parent of X is discarded, the sole remaining child of the parent of X becomes a child of the grandparent (if any) of X .

To remove the element with key 951-94-1654 from the compressed trie of [Figure 29.12](#), we first locate the node K that contains the element that is to be removed. When this node is discarded, the parent I of K is left with only one child. Consequently, node I is also discarded, and the only remaining child J of node I is the made a child of the grandparent of K . [Figure 29.13](#) shows the resulting compressed trie.

Because of the need to determine whether a branch node is left with two or more children, removing a d digit element from a radix r trie takes $O(d + r)$ time.

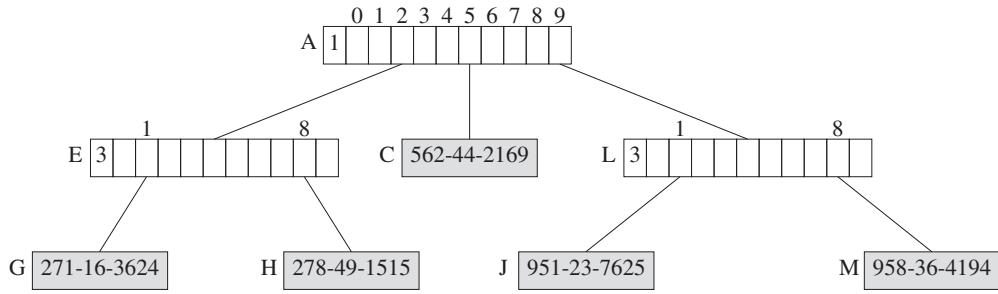

FIGURE 29.13 Compressed trie following the removal of 951-94-1654 from the compressed trie of Figure 29.12.

29.9.2 Compressed Tries with Skip Fields

In a *compressed trie with skip fields*, each branch node has an additional field *skip* which tells us the number of branch nodes that were originally between the current branch node and its parent. Figure 29.15 shows the compressed trie with skip fields that corresponds to the trie of Figure 29.1. The leftmost field of each branch node of Figure 29.14 is the *skip* field.

The algorithms to search, insert, and remove are very similar to those used for a compressed trie with digit numbers.

29.9.3 Compressed Tries with Edge Information

In a *compressed trie with edge information*, each branch node has the following additional information associated with it: a pointer/reference *element* to an element (or element node) in the subtrie, and an integer *skip* which equals the number of branch nodes eliminated between this branch node and its parent. Figure 29.15 shows the compressed trie with edge information that corresponds to the trie of Figure 29.1. The first field of each branch node is its *element* field, and the second field is the *skip* field.

Even though we store the “edge information” with branch nodes, it is convenient to think of this information as being associated with the edge that comes into the branch node from its parent (when the branch node is not the root). When moving down a trie, we follow edges, and when an edge is followed, we skip over the number of digits given by the *skip* field of the edge information. The value of the digits that are skipped over may be determined by using the *element* field.

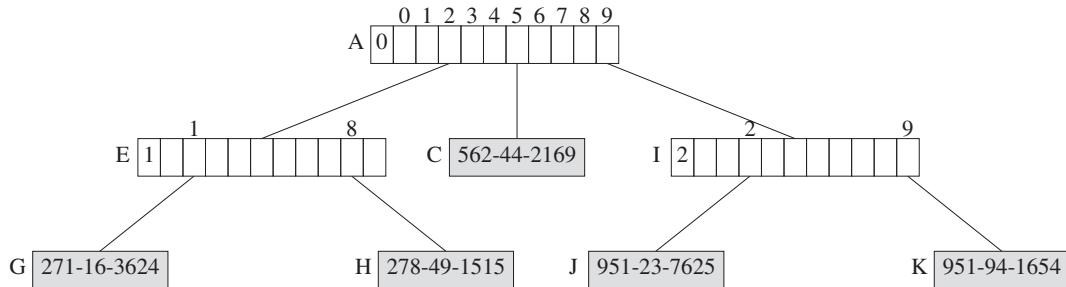

FIGURE 29.14 Compressed trie with skip fields.

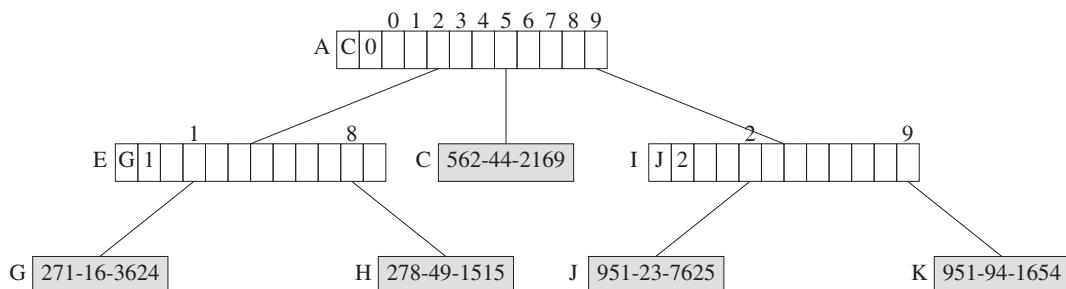

FIGURE 29.15 Compressed trie with edge information.

When moving from node A to node I of the compressed trie of Figure 29.15, we use digit 1 of the key to determine which child field of A is to be used. Also, we skip over the next 2 digits, that is, digits 2 and 3, of the keys of the elements in the subtrie rooted at I . Since all elements in the subtrie I have the same value for the digits that are skipped over, we can determine the value of these skipped over digits from any of the elements in the subtrie. Using the *element* field of the edge information, we access the element node J , and determine that the digits that are skipped over are 5 and 1.

29.9.3.1 Searching a Compressed Trie with Edge Information

When searching a compressed trie with edge information, we can use the edge information to terminate unsuccessful searches (possibly) before we reach an element node or fall off the trie. As in the other compressed trie variants, the search is done by following a path from the root. Suppose we are searching the compressed trie of Figure 29.15 for an element with key 921-23-1234. Since the *skip* value for the root node is 0, we use the first digit 9 of the search key to determine which subtrie to move to. A move to node $A.\text{child}[9] = I$ is made. By examining the edge information (stored in node I), we determine that, in making the move from node A to node I , the digits 5 and 1 are skipped. Since these digits do not agree with the next two digits of the search key, the search terminates with the conclusion that the trie contains no element whose key equals the search key.

29.9.3.2 Inserting into a Compressed Trie with Edge Information

To insert an element with key 987-26-1615 into the compressed trie of Figure 29.15, we first search for an element with this key. The search terminates unsuccessfully when we move from node A to node I because of a mismatch between the skipped over digits and the corresponding digits of the search key. The first mismatch is at the first skipped over digit. Therefore, we insert a branch node L between nodes A and I . The *skip* value for this branch node is 0, and its *element* field is set to reference the element node for the newly inserted element. We must also change the *skip* value of I to 1. Figure 29.16 shows the resulting compressed trie.

Suppose we are to insert an element with key 958-36-4194 into the compressed trie of Figure 16. The search for an element with this key terminates when we move to node I because of a mismatch between the digits that are skipped over and the corresponding digits of the search key. A new branch node is inserted between nodes A and I and we get the compressed trie that is shown in Figure 29.17.

The time required to insert a d digit element into a radix r compressed trie with edge information is $O(r + d)$.

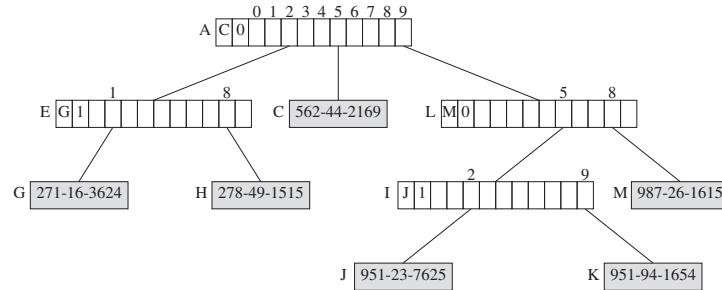

FIGURE 29.16 Compressed trie following the insertion of 987-26-1615 into the compressed trie of Figure 29.15.

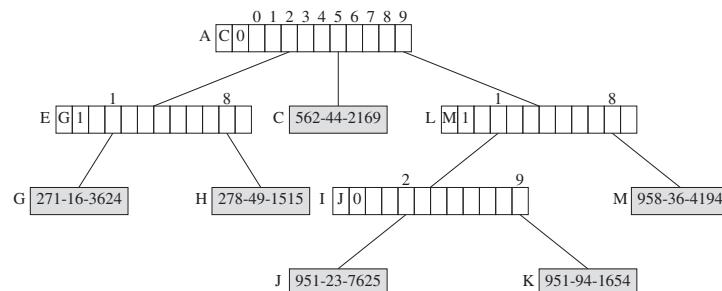

FIGURE 29.17 Compressed trie following the insertion of 958-36-4194 into the compressed trie of Figure 29.15.

29.9.3.3 Removing an Element from a Compressed Trie with Edge Information

This is similar to removal from a compressed trie with digit numbers except for the need to update the *element* fields of branch nodes whose *element* field references the removed element.

29.9.4 Space Required by a Compressed Trie

Since each branch node partitions the elements in its subtree into two or more nonempty groups, an n element compressed trie has at most $n - 1$ branch nodes. Therefore, the space required by each of the compressed trie variants described by us is $O(nr)$, where r is the trie radix.

When compressed tries are represented as hash tables, we need an additional data structure to store the nonpointer fields of branch nodes. We may use an array (much like we use the array *information*) for this purpose.

29.10 Patricia

The data structure Patricia (Practical Algorithm To Retrieve Information Coded In Alphanumeric) is a compressed binary trie in which the branch and element nodes have been melded into a single node type. Consider the compressed binary trie of Figure 29.18. Circular nodes are branch nodes and rectangular nodes are element nodes. The number inside a branch node is its bit number field; the left child of a branch node corresponds to the case when the appropriate key bit is 0 and the right child to the case when this bit is 1. The melding of branch and element nodes is done by moving each element from its element node to an ancestor branch node. Since the number of branch nodes is one less than the number of element nodes, we introduce a header node and make the compressed binary trie the left subtree of the header. Pointers that originally went from a branch node to an element node now go from that branch node to the branch node into which the corresponding element has been melded. Figure 29.19 shows a possible result of melding the nodes of Figure 29.18. The number outside a node is its bit number values. The thick pointers are *backward* pointers that replace branch-node to element-node pointers in Figure 29.18. A backward pointer has the property that the bit number value at the start of the pointer is \geq the bit number value at its end. For original branch-node to branch-node pointers (also called *downward* pointers), the bit number value at the pointer end is always greater than the bit number value at the pointer start.

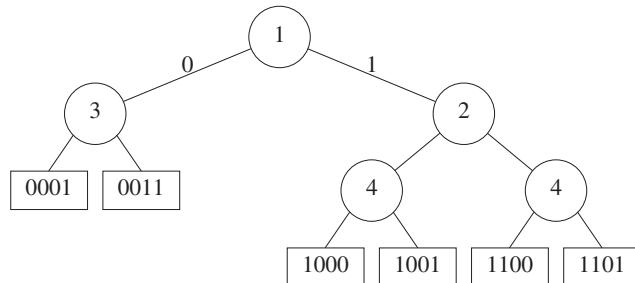

FIGURE 29.18 A compressed binary trie.

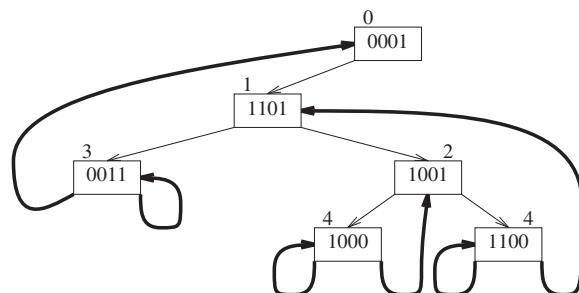

FIGURE 29.19 A Patricia instance that corresponds to Figure 29.18.

29.10.1 Searching

To search for an element with key *theKey*, we use the bits of *theKey* from left to right to move down the Patricia instance just as we would search a compressed binary trie. When a backward pointer is followed, we compare *theKey* with the key in the reached Patricia node. For example, to search for *theKey* = 1101, we start by moving into the left subtree of the header node. The pointer that is followed is a downward pointer (start bit number is 0 and end bit number is 1). We branch using bit 1 of *theKey*. Since this bit is 1, we follow the right child pointer. The start bit number for this pointer is 1 and the end bit number is 2. So, again, a downward pointer has been followed. The bit number for the reached node is 2. So, we use bit 2 of *theKey* to move further. Bit 2 is a 1. So, we use the right child pointer to get to the node that contains 1100. Again, a downward pointer was used. From this node, a move is made using bit 4 of *theKey*. This gets us to the node that contains 1101. This time, a backward pointer was followed (start bit of pointer is 4 and end bit is 1). When a backward pointer is followed, we compare *theKey* with the key in the reached node. In this case, the keys match and we have found the desired element. Notice that the same search path is taken when *theKey* = 1111. In this case, the final compare fails and we conclude that we have no element whose key is 1111.

29.10.2 Inserting an Element

We use an example to illustrate the insert algorithm. We start with an empty instance. Such an instance has no node; not even the header. For our example, we will consider keys that have 7 bits. For the first insert, we use the key 0000101. When inserting into an empty instance, we create a header node whose left child pointer points to the header node; the new element is inserted into the header; and the bit number field of the header set to 0. The configuration of [Figure 29.20a](#) results. Note that the right child field of the header node is not used.

The key for the next insert is 0000000. The search for this key terminates at the header. We compare the insert key and the header key and determine that the first bit at which they differ is bit 5. So, we create a new node with bit number field 5 and insert the new element into this node. Since bit 5 of the insert key is 0, the left child pointer of the new node points to the new node and the right child pointer to the header node ([Figure 29.20b](#)).

For the next insertion, assume that the key is 0000010. The search for this key terminates at the node with 0000000. Comparing the two keys, we determine that the first bit at which the two keys differ is bit 6. So, we create a new node with bit number field 6 and put the new element into this new node. The new node is inserted into the search path in such a way that bit number fields increase along this path. For our example, the new node is inserted as the left child of the node with 0000000. Since bit 6 of the insert key is 1, the right child pointer of the new node is a self pointer and the left child pointer points to the node with 0000000. [Figure 29.20c](#) shows the result.

The general strategy to insert an element other than the first one is given below. The key of the element to be inserted is *theKey*.

1. Search for *theKey*. Let *reachedKey* be the key in the node *endNode* where the search terminates.
2. Determine the leftmost bit position *lBitPos* at which *theKey* and *reachedKey* differ. *lBitPos* is well defined so long as one of the two keys isn't a prefix of the other.
3. Create a new node with bit number field *lBitPos*. Insert this node into the search path from the header to *endNode* so that bit numbers increase along this path. This insertion breaks a pointer from node *p* to node *q*. The pointer now goes from *p* to the new node.
4. If bit *lBitPos* of *theKey* is 1, the right child pointer of the new node becomes a self pointer (i.e., it points to the new node); otherwise, the left child pointer of the new node becomes a self pointer. The remaining child pointer of the new node points to *q*.

For our next insert, the insert key is 0001000. The search for this key terminates at the node with 0000000. We determine that the first bit at which the insert key and *reachedKey* = 0000000 differ is bit 4. We create a new node with bit number 4 and put the new element into this node. The new node is inserted on the search path so as to ensure that bit number fields increase along this path. So, the new node is inserted as the left child of the header node ([Figure 29.18d](#)). This breaks the pointer from the header to the node *q* with 0000000. Since bit 4 of the insert key is 1, the right child pointer of the new node is a self pointer and the left child pointer goes to node *q*.

We consider two more inserts. Consider inserting an element whose key is 0000100. The reached key is 0000101 (in the header). We see that the first bit at which the insert and reached keys differ is bit 7. So, we create a new node with bit number 7; the new element is put into the new node; the new node is inserted into the search path so as to ensure that bit numbers increase along this path (this requires the new node to be made a right child of the node with 0000000, breaking the child pointer from 0000000 to the header); for the broken pointer, *p* is the node with 0000000 and *q* is the header; the left child pointer of the new node is a self pointer (because bit 7 of the insert key is 0); and remaining child pointer (in this case the right child) of the new node points to *q* (see [Figure 29.21a](#)).

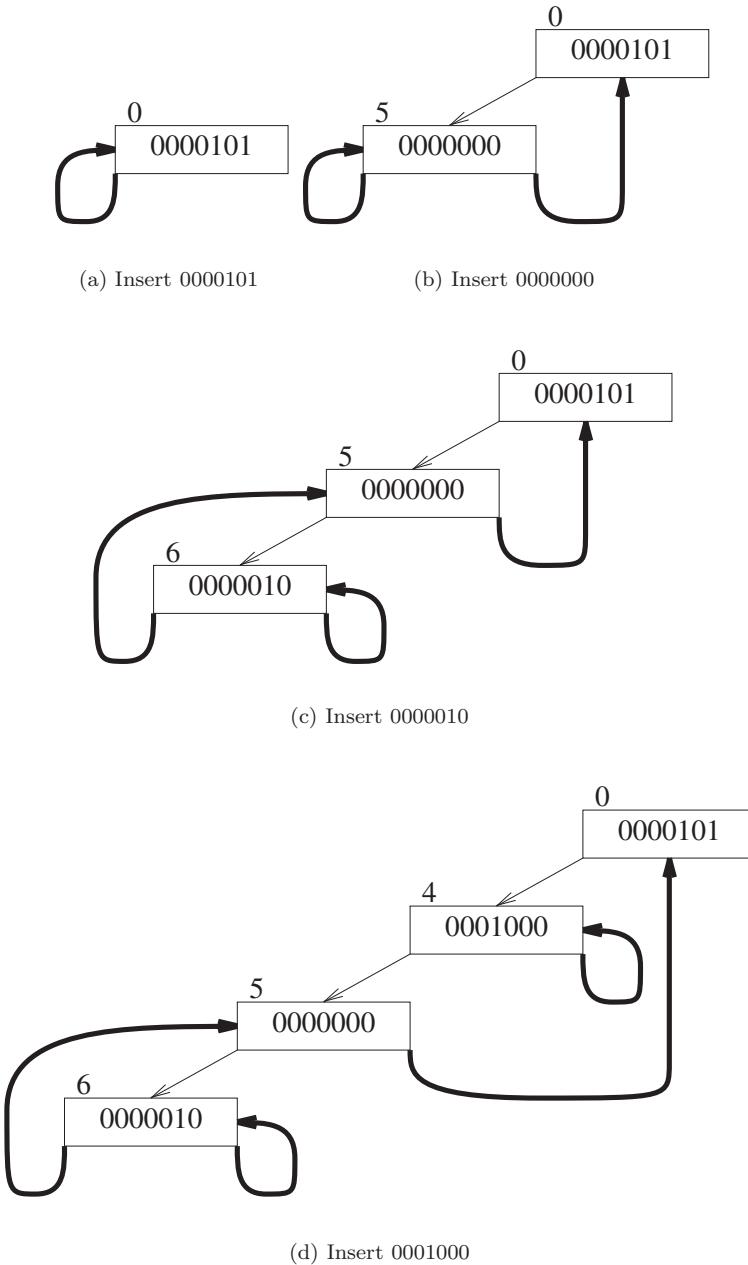

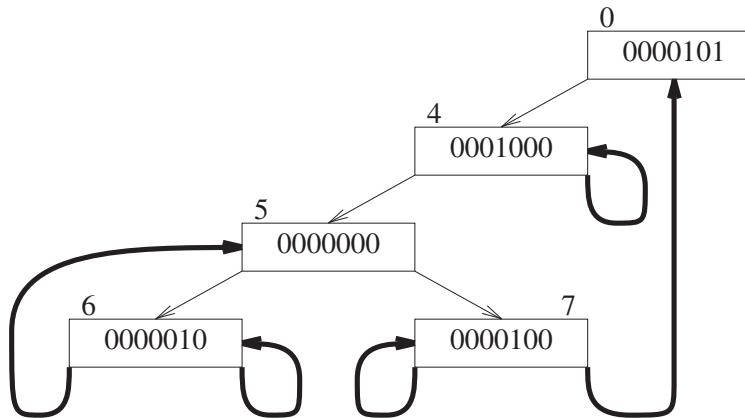

FIGURE 29.20 Insertion example.

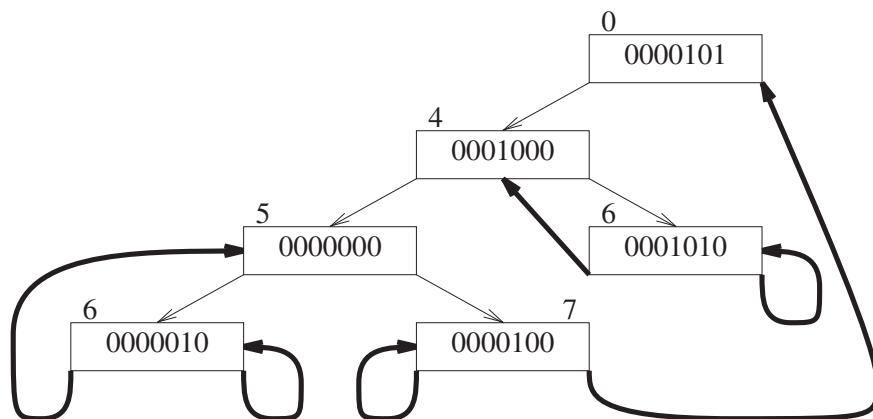

For our final insert, the insert key is 0001010. A search for this key terminates at the node with 0000100. The first bit at which the insert and reached keys differ is bit 6. So, we create a new node with bit number 6; the new element is put into the new node; the new node is inserted into the search path so as to ensure that bit numbers increase along this path (this requires the new node to be made a right child of the node with 0001000; so, $p = q = \text{node with } 0001000$); the right child pointer of the new node is a self pointer (because bit 6 of the insert key is 1); and the remaining child (in this case the left child) of the new node is q (see Figure 29.21b).

29.10.3 Removing an Element

Let p be the node that contains the element that is to be removed. We consider two cases for p —(a) p has a self pointer and (b) p has no self pointer. When p has a self pointer and p is the header, the Patricia instance becomes empty following the element removal (Figure 29.20a). In this case, we simply dispose of the header. When p has a self pointer and p is not the header, we set

(a) Insert 0000100

(b) Insert 0001010

FIGURE 29.21 Insertion example.

the pointer from the parent of p to the value of p 's non-self pointer. Following this pointer change, the node p is disposed. For example, to remove the element with key 0000010 from Figure 29.21a, we change the left child pointer in the node with 0000000 to point to the node pointed at by p 's non-self pointer (i.e., the node with 0000000). This causes the left child pointer of 0000000 to become a self pointer. The node with 0000010 is then disposed.

For the second case, we first find the node q that has a backward pointer to node p . For example, when we are to remove 0001000 from Figure 29.21b, the node q is the node with 0001010. The element $qElement$ in q (in our example, 0001010) is moved to node p and we proceed to delete node q instead of node p . Notice that node q is the node from which we reached node p in the search for the element that is to be removed. To delete node q , we first find the node r that has a back pointer to q (for our example $r = q$). The node r is found by using the key of $qElement$. Once r is found, the back pointer to q that is in r is changed from q to p to properly account for the fact that we have moved $qElement$ to p . Finally, the downward pointer from the parent of q to q is changed to q 's child pointer that was used to locate r . In our example p is the parent of q and the right child pointer of p is changed from q to the right child of q , which itself was just changed to p .

We see that the time for each of the Patricia operations search, insert, and delete is $O(h)$, where h is the height of the Patricia instance. For more information on Patricia and general tries, see [2,3].

30.1 Basic Definitions and Properties

Suffix trees and suffix arrays are versatile data structures fundamental to string processing applications. Let s' denote a string over the alphabet Σ . Let $\$ \notin \Sigma$ be a unique termination character, and $s = s'\$$ be the string resulting from appending $\$$ to s' . We use the following notation: $|s|$ denotes the size of s , $s[i]$ denotes the i th character of s , and $s[i..j]$ denotes the substring $s[i]s[i+1]\dots s[j]$. Let $suff_i = s[i]s[i+1]\dots s[|s|]$ be the suffix of s starting at i th position.

The suffix tree of s , denoted $ST(s)$ or simply ST , is a compacted trie (See [Chapter 28](#)) of all suffixes of string s . Let $|s| = n$. It has the following properties:

1. The tree has n leaves, labeled $1\dots n$, one corresponding to each suffix of s .
2. Each internal node has at least 2 children.
3. Each edge in the tree is labeled with a substring of s .
4. The concatenation of edge labels from the root to the leaf labeled i is $suff_i$.
5. The labels of the edges connecting a node with its children start with different characters.

The paths from root to the suffixes labeled i and j coincide up to their longest common prefix, at which point they bifurcate. If a suffix of the string is a prefix of another longer suffix, the shorter suffix must end in an internal node instead of a leaf, as desired. It is to avoid this possibility that the unique termination character is added to the end of the string. Keeping this in mind, we use the notation $ST(s')$ to denote the suffix tree of the string obtained by appending $\$$ to s' .

As each internal node has at least 2 children, an n -leaf suffix tree has at most $n - 1$ internal nodes. Because of property (5), the maximum number of children per node is bounded by $|\Sigma| + 1$. Except for the edge labels, the size of the tree is $O(n)$. In order to allow a linear space representation of the tree, each edge label is represented by a pair of integers denoting the starting and ending positions, respectively, of the substring describing the edge label. If the edge label corresponds to a repeat substring, the indices corresponding to any occurrence of the substring may be used. The suffix tree of the string *mississippi* is shown in [Figure 30.1](#). For convenience of understanding, we show the actual edge labels.

The suffix array of $s = s'\$$, denoted $SA(s)$ or simply SA , is a lexicographically sorted array of all suffixes of s . Each suffix is represented by its starting position in s . $SA[i] = j$ iff $Suff_j$ is the i th lexicographically smallest suffix of s . The suffix array is often used in conjunction with an array termed *Lcp* array, containing the lengths of the longest common prefixes between every consecutive

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

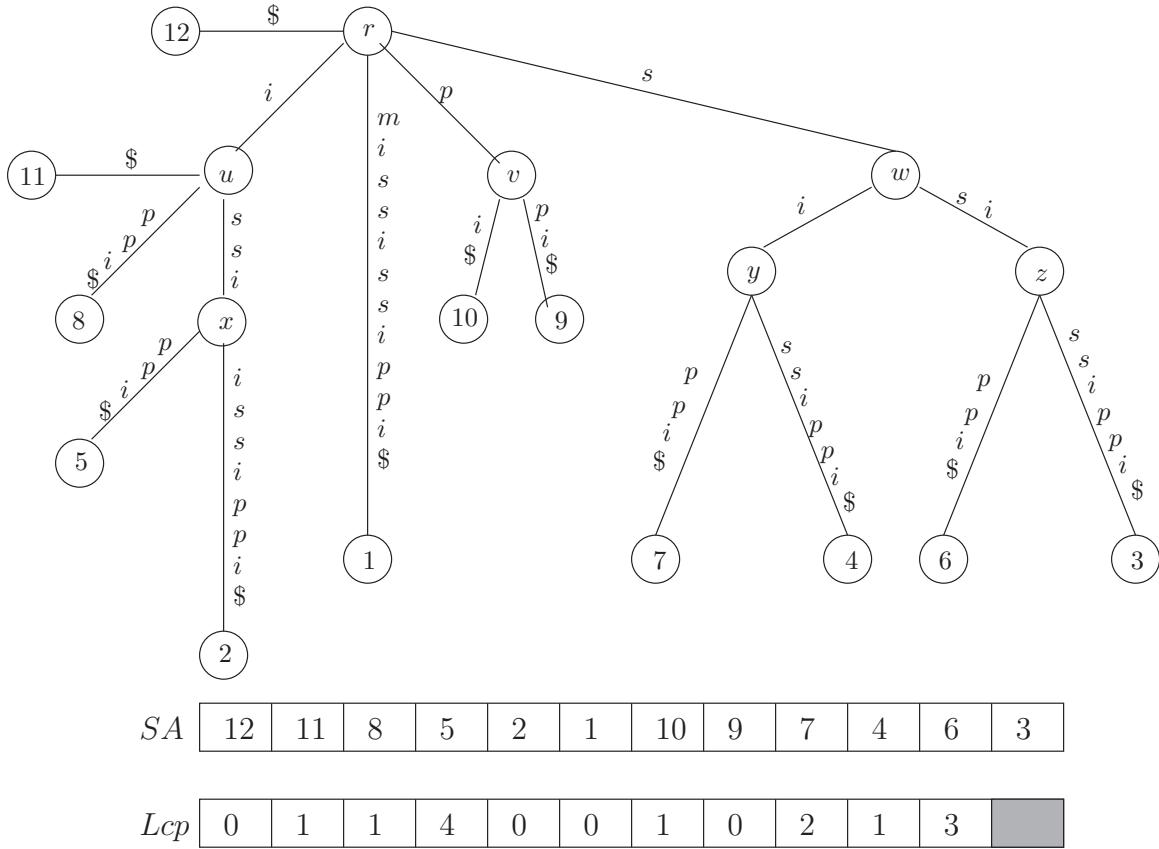

FIGURE 30.1 Suffix tree, suffix array and *Lcp* array of the string *mississippi*. The suffix links in the tree are given by $x \rightarrow z \rightarrow y \rightarrow u \rightarrow r$, $v \rightarrow r$, and $w \rightarrow r$.

pair of suffixes in SA. We use $\text{lcp}(\alpha, \beta)$ to denote the longest common prefix between strings α and β . We also use the term *lcp* as an abbreviation for the term *longest common prefix*. $\text{Lcp}[i]$ contains the length of the *lcp* between $\text{suff}_{\text{SA}[i]}$ and $\text{suff}_{\text{SA}[i+1]}$, that is, $\text{Lcp}[i] = \text{lcp}(\text{suff}_{\text{SA}[i]}, \text{suff}_{\text{SA}[i+1]})$. As with suffix trees, we use the notation $\text{SA}(s')$ to denote the suffix array of the string obtained by appending $\$\text{}$ to s' . The suffix and *Lcp* arrays of the string *mississippi* are shown in Figure 30.1.

Let v be a node in the suffix tree. Let $\text{path-label}(v)$ denote the concatenation of edge labels along the path from root to node v . Let $\text{string-depth}(v)$ denote the length of $\text{path-label}(v)$. To differentiate this with the usual notion of depth, we use the term *tree-depth* of a node to denote the number of edges on the path from root to the node. Note that the length of the longest common prefix between two suffixes is the string depth of the lowest common ancestor of the leaf nodes corresponding to the suffixes. A repeat substring of string S is *right-maximal* if there are two occurrences of the substring that are succeeded by different characters in the string. The path label of each internal node in the suffix tree corresponds to a right-maximal repeat substring and vice versa.

Let v be an internal node in the suffix tree with path-label $c\alpha$ where c is a character and α is a (possibly empty) string. Therefore, $c\alpha$ is a right-maximal repeat, which also implies that α is also a right maximal repeat. Let u be the internal node with path label α . A pointer from node v to node u is called a *suffix link*; we denote this by $\text{SL}(v) = u$. Each suffix suff_i in the subtree of v shares the common prefix $c\alpha$. The corresponding suffix suff_{i+1} with prefix α will be present in the subtree of u . The concatenation of edge labels along the path from v to leaf labeled i , and along the path from u to leaf labeled $i+1$ will be the same. Similarly, each internal node in the subtree of v will have a corresponding internal node in the subtree of u . In this sense, the entire subtree under v is contained in the subtree under u .

Every internal node in the suffix tree other than the root has a suffix link from it. Let v be an internal node with $\text{SL}(v) = u$. Let v' be an ancestor of v other than the root and let $u' = \text{SL}(v')$. As $\text{path-label}(v')$ is a prefix of $\text{path-label}(v)$, $\text{path-label}(u')$ is also a prefix of $\text{path-label}(u)$. Thus, u' is an ancestor of u . Each proper ancestor of v except the root will have a suffix link to a distinct proper ancestor of u . It follows that $\text{tree-depth}(u) \geq \text{tree-depth}(v) - 1$.

Suffix trees and suffix arrays can be generalized to multiple strings. The generalized suffix tree of a set of strings $S = \{s_1, s_2, \dots, s_k\}$, denoted $\text{GST}(S)$ or simply GST , is a compacted trie of all suffixes of each string in S . We assume that the unique termination character $\$$ is appended to the end of each string. A leaf label now consists of a pair of integers (i, j) , where

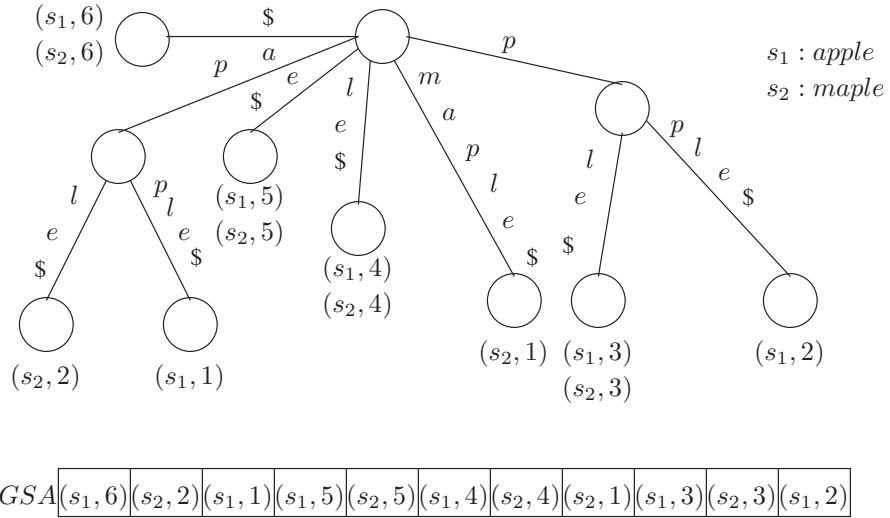

FIGURE 30.2 Generalized suffix tree and generalized suffix array of strings *apple* and *maple*.

i denotes the suffix is from string s_i and j denotes the starting position of the suffix in s_i . Similarly, an edge label in a GST is a substring of one of the strings. An edge label is represented by a triplet of integers (i, j, l) , where i denotes the string number, and j and l denote the starting and ending positions of the substring in s_i . For convenience of understanding, we will continue to show the actual edge labels. Note that two strings may have identical suffixes. This is compensated by allowing leaves in the tree to have multiple labels. If a leaf is multiply labeled, each suffix should come from a different string. If N is the total number of characters (including the \$ in each string) of all strings in \mathcal{S} , the GST has at most N leaf nodes and takes up $O(N)$ space. The generalized suffix array of \mathcal{S} , denoted $GSA(\mathcal{S})$ or simply GSA , is a lexicographically sorted array of all suffixes of each string in \mathcal{S} . Each suffix is represented by an integer pair (i, j) denoting suffix starting from position j in s_i . If suffixes from different strings are identical, they occupy consecutive positions in the GSA. For convenience, we make an exception for the suffix \$ by listing it only once, though it occurs in each string. The GST and GSA of strings *apple* and *maple* are shown in Figure 30.2.

Suffix trees and suffix arrays can be constructed in time linear to the size of the input. Suffix trees are very useful in solving a plethora of string problems in optimal run - time bounds. Moreover, in many cases, the algorithms are very simple to design and understand. For example, consider the classic pattern matching problem of determining if a pattern P occurs in text T over a constant sized alphabet. Note that P occurs starting from position i in T iff P is a prefix of suff_i in T . Thus, whether P occurs in T or not can be determined by checking if P matches an initial part of a path from root to a leaf in $ST(T)$. Traversing from the root matching characters in P , this can be determined in $O(|P|)$ time, independent of the size of T . As another application, consider the problem of finding a longest common substring of a pair of strings. Once the GST of the two strings is constructed, all that is needed is to identify an internal node with the largest string depth that contains at least one leaf from each string. These and many other applications are explored in great detail in subsequent sections. Suffix arrays are of interest because they require much less space than suffix trees, and can be used to solve many of the same problems. We first concentrate on linear time construction algorithms for suffix trees and suffix arrays. The reader interested in applications can safely skip to Section 30.3.

30.2 Linear Time Construction Algorithms

In this section, we explore linear time construction algorithms for suffix trees and suffix arrays. We also show how suffix trees and suffix arrays can be derived from each other in linear time. In suffix tree and suffix array construction algorithms, three different types of alphabets are considered: a constant or fixed size alphabet ($|\Sigma| = O(1)$), integer alphabet ($\Sigma = \{1, 2, \dots, n\}$), and arbitrary alphabet. Suffix trees and suffix arrays can be constructed in linear time for both constant size and integer alphabets. The constant alphabet size case covers many interesting application areas, such as English text, or DNA or protein sequences in molecular biology. The integer alphabet case is interesting because a string of length n can have at most n distinct characters. Furthermore, some algorithms use a recursive technique that would generate and require operating on strings over integer alphabet, even when applied to strings over a fixed alphabet.

30.2.1 Suffix Trees vs. Suffix Arrays

We first show that the suffix array and Lcp array of a string can be obtained from its suffix tree in linear time. Define lexicographic ordering of the children of a node to be the order based on the first character of the edge labels connecting the node to its children. Define lexicographic depth first search to be a depth first search of the tree where the children of each node are visited in lexicographic order. The order in which the leaves of a suffix tree are visited in a lexicographic depth first search gives the suffix array of the corresponding string. In order to obtain lcp information, the string - depth of the current node during the search is remembered. This can be easily updated in $O(1)$ time per edge as the search progresses. The length of the lcp between two consecutive suffixes is given by the smallest string - depth of a node visited between the two suffixes.

Given the suffix array and the Lcp array of a string s ($|s\$| = n$), its suffix tree can be constructed in $O(n)$ time. This is done by starting with a partial suffix tree for the lexicographically smallest suffix, and repeatedly inserting subsequent suffixes in the suffix array into the tree until the suffix tree is complete. Let T_i denote the compacted trie of the first i suffixes in lexicographic order. The first tree T_1 consists of a single leaf labeled $SA[1]$ connected to the root with an edge labeled $suff_{SA[1]} = \$$.

To insert $SA[i+1]$ into T_i , start with the most recently inserted leaf $SA[i]$ and walk up ($|suff_{SA[i]}| - |lcp(suff_{SA[i]})|$) = $((n - SA[i] + 1) - Lcp[i])$ characters along the path to the root. This walk can be done in $O(1)$ time per edge by calculating the lengths of the respective edge labels. If the walk does not end at an internal node, create an internal node. Create a new leaf labeled $SA[i+1]$ and connect it to this internal node with an edge. Set the label on this edge to $s[SA[i+1] + Lcp[i]..n]$. This creates the tree T_{i+1} . The procedure works because $suff_{SA[i+1]}$ shares a longer prefix with $suff_{SA[i]}$ than any other suffix inserted so far. To see that the entire algorithm runs in $O(n)$ time, note that inserting a new suffix into T_i requires walking up the rightmost path in T_i . Each edge that is traversed ceases to be on the rightmost path in T_{i+1} , and thus is never traversed again. An edge in an intermediate tree T_i corresponds to a path in the suffix tree ST . When a new internal node is created along an edge in an intermediate tree, the edge is split into two edges, and the edge below the newly created internal node corresponds to an edge in the suffix tree. Once again, this edge ceases to be on the rightmost path and is never traversed again. The cost of creating an edge in an intermediate tree can be charged to the lowest edge on the corresponding path in the suffix tree. As each edge is charged once for creating and once for traversing, the total run - time of this procedure is $O(n)$.

Finally, the Lcp array itself can be constructed from the suffix array and the string in linear time [1]. Let R be an array of size n such that $R[i]$ contains the position in SA of $suff_i$. R can be constructed by a linear scan of SA in $O(n)$ time. The Lcp array is computed in n iterations. In iteration i of the algorithm, the longest common prefix between $suff_i$ and its respective right neighbor in the suffix array is computed. The array R facilitates locating an arbitrary suffix $suff_i$ and finding its right neighbor in the suffix array in constant time. Initially, the length of the longest common prefix between $suff_1$ and its suffix array neighbor is computed directly and recorded. Let $suff_j$ be the right neighbor of $suff_i$ in SA . Let l be the length of the longest common prefix between them. Suppose $l \geq 1$. As $suff_j$ is lexicographically greater than $suff_i$ and $s[i] = s[j]$, $suff_{j+1}$ is lexicographically greater than $suff_{i+1}$. The length of the longest common prefix between them is $l - 1$. It follows that the length of the longest common prefix between $suff_{i+1}$ and its right neighbor in the suffix array is $\geq l - 1$. To determine its correct length, the comparisons need only start from the l th characters of the suffixes.

To prove that the run time of the above algorithm is linear, charge a comparison between the r th character in suffix $suff_i$ and the corresponding character in its right neighbor suffix in SA to the position in the string of the r th character of $suff_i$, that is, $i + r - 1$. A comparison made in an iteration is termed successful if the characters compared are identical, contributing to the longest common prefix being computed. Because there is one failed comparison in each iteration, the total number of failed comparisons is $O(n)$. As for successful comparisons, each position in the string is charged only once for a successful comparison. Thus, the total number of comparisons over all iterations is linear in n .

In light of the above discussion, a suffix tree and a suffix array can be constructed from each other in linear time. Thus, a linear time construction algorithm for one can be used to construct the other in linear time. In the following subsections, we explore such algorithms. Each algorithm is interesting in its own right, and exploits interesting properties that could be useful in designing algorithms using suffix trees and suffix arrays.

30.2.2 Linear Time Construction of Suffix Trees

Let s be a string of length n including the termination character $\$$. Suffix tree construction algorithms start with an empty tree and iteratively insert suffixes while maintaining the property that each intermediate tree represents a compacted trie of the suffixes inserted so far. When all the suffixes are inserted, the resulting tree will be the suffix tree. Suffix links are typically used to speedup the insertion of suffixes. While the algorithms are identified by the names of their respective inventors, the exposition presented does not necessarily follow the original algorithms and we take the liberty to comprehensively present the material in a way we feel contributes to ease of understanding.

30.2.2.1 McCreight's Algorithm

McCreight's algorithm inserts suffixes in the order $\text{suff}_1, \text{suff}_2, \dots, \text{suff}_n$. Let T_i denote the compacted trie after suff_i is inserted. T_1 is the tree consisting of a single leaf labeled 1 that is connected to the root by an edge with label $s[1..n]$. In iteration i of the algorithm, suff_i is inserted into tree T_{i-1} to form tree T_i . An easy way to do this is by starting from the root and following the unique path matching characters in suff_i one by one until no more matches are possible. If the traversal does not end at an internal node, create an internal node there. Then, attach a leaf labeled i to this internal node and use the unmatched portion of suff_i for the edge label. The run-time for inserting suff_i is proportional to $|\text{suff}_i| = n - i + 1$. The total run-time of the algorithm is $\sum_{i=1}^n (n - i + 1) = O(n^2)$.

In order to achieve an $O(n)$ run-time, suffix links are used to significantly speedup the insertion of a new suffix. Suffix links are useful in the following way—Suppose we are inserting suff_i in T_{i-1} and let v be an internal node in T_{i-1} on the path from root to leaf labeled $(i-1)$. Then, $\text{path-label}(v) = c\alpha$ is a prefix of suff_{i-1} . Since v is an internal node, there must be another suffix suff_j ($j < i-1$) that also has $c\alpha$ as prefix. Because suff_{j+1} is previously inserted, there is already a path from the root in T_{i-1} labeled α . To insert suff_i faster, if the end of path labeled α is quickly found, comparison of characters in suff_i can start beyond the prefix α . This is where suffix links will be useful. The algorithm must also construct suffix links prior to using them.

Lemma 30.1

Let v be an internal node in $ST(s)$ that is created in iteration $i-1$. Let $\text{path-label}(v) = c\alpha$, where c is a character and α is a (possibly empty) string. Then, either there exists an internal node u with $\text{path-label}(u) = \alpha$ or it will be created in iteration i .

Proof. As v is created when inserting suff_{i-1} in T_{i-2} , there exists another suffix suff_j ($j < i-1$) such that $\text{lcp}(\text{suff}_{i-1}, \text{suff}_j) = c\alpha$. It follows that $\text{lcp}(\text{suff}_i, \text{suff}_{j+1}) = \alpha$. The tree T_i already contains suff_{j+1} . When suff_i is inserted during iteration i , internal node u with path-label α is created if it does not already exist. ■

The above lemma establishes that the suffix link of a newly created internal node can be established in the next iteration.

The following procedure is used when inserting suff_i in T_{i-1} . Let v be the internal node to which suff_{i-1} is attached as a leaf. If v is the root, insert suff_i using character comparisons starting with the first character of suff_i . Otherwise, let $\text{path-label}(v) = c\alpha$. If v has a suffix link from it, follow it to internal node u with path-label α . This allows skipping the comparison of the first $|\alpha|$ characters of suff_i . If v is newly created in iteration $i-1$, it would not have a suffix link yet. In that case, walk up to parent v' of v . Let β denote the label of the edge connecting v' and v . Let $u' = SL(v')$ unless v' is the root, in which case let u' be the root itself. It follows that $\text{path-label}(u')$ is a prefix of suff_i . Furthermore, it is guaranteed that there is a path below u' that matches the next $|\beta|$ characters of suff_i . Traverse $|\beta|$ characters along this path and either find an internal node u or insert an internal node u if one does not already exist. In either case, set $SL(v) = u$. Continue by starting character comparisons skipping the first $|\alpha|$ characters of suff_i .

The above procedure requires two different types of traversals—one in which it is known that there exists a path below that matches the next $|\beta|$ characters of suff_i (type I), and the other in which it is unknown how many subsequent characters of suff_i match a path below (type II). In the latter case, the comparison must proceed character by character until a mismatch occurs. In the former case, however, the traversal can be done by spending only $O(1)$ time per edge irrespective of the length of the edge label. At an internal node during such a traversal, the decision of which edge to follow next is made by comparing the next character of suff_i with the first characters of the edge labels connecting the node to its children. However, once the edge is selected, the entire label or the remaining length of β must match, whichever is shorter. Thus, the traversal can be done in constant time per edge, and if the traversal stops within an edge label, the stopping position can also be determined in constant time.

The insertion procedure during iteration i can now be described as follows: Start with the internal node v to which suff_{i-1} is attached as a leaf. If v has a suffix link, follow it and perform a type II traversal to insert suff_i . Otherwise, walk up to v 's parent, take the suffix link from it unless it is the root, and perform a type I traversal to either find or create the node u which will be linked from v by a suffix link. Continue with a type II traversal below u to insert suff_i .

Lemma 30.2

The total time spent in type I traversals over all iterations is $O(n)$.

Proof. A type I traversal is performed by walking down along a path from root to a leaf in $O(1)$ time per edge. Each iteration consists of walking up at most one edge, following a suffix link, and then performing downward traversals (either type II or both type I and type II). Recall that if $SL(v) = u$, then $\text{tree-depth}(u) \geq \text{tree-depth}(v) - 1$. Thus, following a suffix link may reduce the

depth in the tree by at most one. It follows that the operations that may cause moving to a higher level in the tree cause a decrease in depth of at most 2 per iteration. As both type I and type II traversals increase the depth in the tree and there are at most n levels in ST , the total number of edges traversed by type I traversals over all the iterations is bounded by $3n$. ■

Lemma 30.3

The total time spent in type II traversals over all iterations is $O(n)$.

Proof. In a type II traversal, a suffix of the string $suff_i$ is matched along a path in T_{i-1} until there is a mismatch. When a mismatch occurs, an internal node is created if there does not exist one already. Then, the remaining part of $suff_i$ becomes the edge label connecting leaf labeled i to the internal node. Charge each successful comparison of a character in $suff_i$ to the corresponding character in the original string s . Note that a character that is charged with a successful comparison is never charged again as part of a type II traversal. Thus, the total time spent in type II traversals is $O(n)$. ■

The above lemmas prove that the total run-time of McCreight's algorithm is $O(n)$. McCreight's algorithm is suitable for constant sized alphabets. The dependence of the run-time and space for storing suffix trees on the size of the alphabet $|\Sigma|$ is as follows: A simple way to allocate space for internal nodes in a suffix tree is to allocate $|\Sigma| + 1$ pointers for children, one for each distinct character with which an edge label may begin. With this approach, the edge label beginning with a given character, or whether an edge label exists with a given character, can be determined in $O(\log |\Sigma|)$ time. However, as all $|\Sigma| + 1$ pointers are kept irrespective of how many children actually exist, the total space is $O(|\Sigma|n)$. If the tree is stored such that each internal node points only to its leftmost child and each node also points to its next sibling, if any, the space can be reduced to $O(n)$, irrespective of $|\Sigma|$. With this, searching for a child connected by an edge label with the appropriate character takes $O(|\Sigma|)$ time. Thus, McCreight's algorithm can be run in $O(n \log |\Sigma|)$ time using $O(n|\Sigma|)$ space, or in $O(n|\Sigma|)$ time using $O(n)$ space.

30.2.2.2 Generalized Suffix Trees

McCreight's algorithm can be easily adapted to build the generalized suffix tree for a set $\mathcal{S} = \{s_1, s_2, \dots, s_k\}$ of strings of total length N in $O(N)$ time. A simple way to do this is to construct the string $S = s_1\$s_2\$s_3\dots s_k\$k$, where each $\$i$ is a unique string termination character that does not occur in any string in \mathcal{S} . Using McCreight's algorithm, $ST(S)$ can be computed in $O(N)$ time. This differs from $GST(\mathcal{S})$ in the following way: Consider a suffix $suff_j$ of string s_i in $GST(\mathcal{S})$. The corresponding suffix in $ST(S)$ is $s_i[j..|s_i|]\$i s_{i+1}\$_{i+1} \dots s_k\$k$. Let v be the last internal node on the path from root to leaf representing this suffix in $ST(S)$. As each $\$i$ is unique and $path-label(v)$ must be a common prefix of at least two suffixes in S , $path-label(v)$ must be a prefix of $s_i[j..|s_i|]$. Thus, by simply shortening the edge label below v to terminate at the end of the string s_i and attaching a common termination character $\$$ to it, the corresponding suffix in $GST(\mathcal{S})$ can be generated in $O(1)$ time. Additionally, all suffixes in $ST(S)$ that start with some $\$i$ should be removed and replaced by a single suffix $\$\$$ in $GST(\mathcal{S})$. Note that the suffixes to be removed are all directly connected to the root in $ST(S)$, allowing easy $O(1)$ time removal per suffix. Thus, $GST(\mathcal{S})$ can be derived from $ST(S)$ in $O(N)$ time.

Instead of first constructing $ST(S)$ and shortening edge labels of edges connecting to leaves to construct $GST(\mathcal{S})$, the process can be integrated into the tree construction itself to directly compute $GST(\mathcal{S})$. When inserting the suffix of a string, directly set the edge label connecting to the newly created leaf to terminate at the end of the string, appended by $\$$. As each suffix that begins with $\$i$ in $ST(S)$ is directly attached to the root, execution of McCreight's algorithm on S will always result in a downward traversal starting from the root when a suffix starting from the first character of a string is being inserted. Thus, we can simply start with an empty tree, insert all the suffixes of one string using McCreight's algorithm, insert all the suffixes of the next string, and continue this procedure until all strings are inserted. To insert the first suffix of a string, start by matching the unique path in the current tree that matches with a prefix of the string until no more matches are possible, and insert the suffix by branching at this point. To insert the remaining suffixes, continue as described in constructing the tree for one string.

This procedure immediately gives an algorithm to maintain the generalized suffix tree of a set of strings in the presence of insertions and deletions of strings. Insertion of a string is the same as executing McCreight's algorithm on the current tree, and takes time proportional to the length of the string being inserted. To delete a string, we must locate the leaves corresponding to all the suffixes of the string. By mimicking the process of inserting the string in GST using McCreight's algorithm, all the corresponding leaf nodes can be reached in time linear in the size of the string to be deleted. To delete a suffix, examine the corresponding leaf. If it is multiply labeled, it is enough to remove the label corresponding to the suffix. If it has only one label, the leaf and edge leading to it must be deleted. If the parent of the leaf is left with only one child after deletion, the parent and its two incident edges are deleted by connecting the surviving child directly to its grandparent with an edge labeled with the concatenation of the labels of the two edges deleted. As the adjustment at each leaf takes $O(1)$ time, the string can be deleted in time proportional to its length.

Suffix trees were invented by Weiner [2], who also presented the first linear time algorithm to construct them for a constant sized alphabet. McCreight's algorithm is a more space - economical linear time construction algorithm [3]. A linear time on-line construction algorithm for suffix trees is invented by Ukkonen [4]. In fact, our presentation of McCreight's algorithm also draws from ideas developed by Ukkonen. A unified view of these three suffix tree construction algorithms is studied by Giegerich and Kurtz [5]. Farach [6] presented the first linear time algorithm for strings over integer alphabets. The algorithm recursively constructs suffix trees for all odd and all even suffixes, respectively, and uses a clever strategy for merging them. The complexity of suffix tree construction algorithms for various types of alphabets is explored in [7].

30.2.3 Linear Time Construction of Suffix Arrays

Suffix arrays were proposed by Manber and Myers [8] as a space - efficient alternative to suffix trees. While suffix arrays can be deduced from suffix trees, which immediately implies any of the linear time suffix tree construction algorithms can be used for suffix arrays, it would not achieve the purpose of economy of space. Until recently, the fastest known direct construction algorithms for suffix arrays all required $O(n \log n)$ time, leaving a frustrating gap between asymptotically faster construction algorithms for suffix trees, and asymptotically slower construction algorithms for suffix arrays, despite the fact that suffix trees contain all the information in suffix arrays. This gap is successfully closed by a number of researchers in 2003, including Käräkkanen and Sanders [9], Kim et al. [10], and Ko and Aluru [11]. All three algorithms work for the case of integer alphabet. Given the simplicity and/or space efficiency of some of these algorithms, it is now preferable to construct suffix trees via the construction of suffix arrays.

30.2.3.1 Käräkkanen and Sanders' Algorithm

Käräkkanen and Sanders' algorithm is the simplest and most elegant algorithm to date to construct suffix arrays , and by implication suffix trees, in linear time. The algorithm also works for the case of an integer alphabet. Let s be a string of length n over the alphabet $\Sigma = \{1, 2, \dots, n\}$. For convenience, assume n is a multiple of three and $s[n+1] = s[n+2] = 0$. The algorithm has the following steps:

1. Recursively sort the $(2/3)n$ suffixes suff_i with $i \bmod 3 \neq 0$.
2. Sort the $(1/3)n$ suffixes suff_i with $i \bmod 3 = 0$ using the result of step (1).
3. Merge the two sorted arrays.

To execute step (1), first perform a radix sort of the $(2/3)n$ triples $(s[i], s[i+1], s[i+2])$ for each $i \bmod 3 \neq 0$ and associate with each distinct triple its rank $\in \{1, 2, \dots, (2/3)n\}$ in sorted order. If all triples are distinct, the suffixes are already sorted. Otherwise, let suff'_i denote the string obtained by taking suff_i and replacing each consecutive triplet with its corresponding rank. Create a new string s' by concatenating suff'_1 with suff'_2 . Note that all suff'_i with $i \bmod 3 = 1$ ($i \bmod 3 = 2$, respectively) are suffixes of suff'_1 (suff'_2 , respectively). A lexicographic comparison of two suffixes in s' never crosses the boundary between suff'_1 and suff'_2 because the corresponding suffixes in the original string can be lexicographically distinguished. Thus, sorting s' recursively gives the sorted order of suff_i with $i \bmod 3 \neq 0$.

Step (2) can be accomplished by performing a radix sort on tuples $(s[i], \text{rank}(\text{suff}_{i+1}))$ for all $i \bmod 3 = 0$, where $\text{rank}(\text{suff}_{i+1})$ denotes the rank of suff_{i+1} in sorted order obtained in step (1).

Merging of the sorted arrays created in steps (1) and (2) is done in linear time, aided by the fact that the lexicographic order of a pair of suffixes, one from each array, can be determined in constant time. To compare suff_i ($i \bmod 3 = 1$) with suff_j ($i \bmod 3 = 0$), compare $s[i]$ with $s[j]$. If they are unequal, the answer is clear. If they are identical, the ranks of suff_{i+1} and suff_{j+1} in the sorted order obtained in step (1) determines the answer. To compare suff_i ($i \bmod 3 = 2$) with suff_j ($i \bmod 3 = 0$), compare the first two characters of the two suffixes. If they are both identical, the ranks of suff_{i+2} and suff_{j+2} in the sorted order obtained in step (1) determines the answer.

The run - time of this algorithm is given by the recurrence $T(n) = T(\lceil 2n/3 \rceil) + O(n)$, which results in $O(n)$ run - time. Note that the $2/3:1/3$ split is designed to make the merging step easy. A $1/2:1/2$ split does not allow easy merging because when comparing two suffixes for merging, no matter how many characters are compared, the remaining suffixes will not fall in the same sorted array, where ranking determines the result without need for further comparisons. Kim et al.'s linear time suffix array construction algorithm is based on a $1/2:1/2$ split, and the merging phase is handled in a clever way so as to run in linear time. This is much like Farach's algorithm for constructing suffix trees [6] by constructing suffix trees for even and odd positions separately and merging them. Both the above linear time suffix array construction algorithms partition the suffixes based on their starting positions in the string. A completely different way of partitioning suffixes based on the lexicographic ordering of a suffix with its right neighboring suffix in the string is used by Ko and Aluru to derive a linear time algorithm [11]. This reduces solving a problem of size n to that of solving a problem of size no more than $\lceil n/2 \rceil$, while eliminating the complex merging step. The algorithm can be made to run in only $2n$ words plus $1.25n$ bits for strings over constant alphabet. Algorithmically, Käräkkanen and Sanders' algorithm is akin

to mergesort and Ko and Aluru's algorithm is akin to quicksort. Algorithms for constructing suffix arrays in external memory are investigated by Crauser and Ferragina [12].

It may be more space efficient to construct a suffix tree by first constructing the corresponding suffix array, deriving the Lcp array from it, and using both to construct the suffix tree. For example, while all direct linear time suffix tree construction algorithms depend on constructing and using suffix links, these are completely avoided in the indirect approach. Furthermore, the resulting algorithms have an alphabet independent run - time of $O(n)$ while using only the $O(n)$ space representation of suffix trees. This should be contrasted with the $O(|\Sigma|n)$ run - time of either McCreight's or Ukkonen's algorithms.

30.2.4 Space Issues

Suffix trees and suffix arrays are space efficient in an asymptotic sense because the memory required grows linearly with input size. However, the actual space usage is of significant concern, especially for very large strings. For example, the human genome can be represented as a large string over the alphabet $\Sigma = \{A, C, G, T\}$ of length over 3×10^9 . Because of linear dependence of space on the length of the string, the exact space requirement is easily characterized by specifying it in terms of the number of bytes per character. Depending on the number of bytes per character required, a data structure for the human genome may fit in main memory, may need a moderate sized disk, or might need a large amount of secondary storage. This has significant influence on the run - time of an application as access to secondary storage is considerably slower. It may also become impossible to run an application for large data sizes unless careful attention is paid to space efficiency.

Consider a naive implementation of suffix trees. For a string of length n , the tree has n leaves, at most $n - 1$ internal nodes, and at most $2n - 2$ edges. For simplicity, count the space required for each integer or a pointer to be one word, equal to 4 bytes on most current computers. For each leaf node, we may store a pointer to its parent, and store the starting index of the suffix represented by the leaf, for $2n$ words of storage. Storage for each internal node may consist of 4 pointers, one each for parent, leftmost child, right sibling and suffix link, respectively. This will require approximately $4n$ words of storage. Each edge label consists of a pair of integers, for a total of at most $4n$ words of storage. Putting this all together, a naive implementation of suffix trees takes $10n$ words or $40n$ bytes of storage.

Several techniques can be used to considerably reduce the naive space requirement of 40 bytes per character. Many applications of interest do not need to use suffix links. Similarly, a pointer to the parent may not be required for applications that use traversals down from the root. Even otherwise, note that a depth first search traversal of the suffix tree starting from the root can be conducted even in the absence of parent links, and this can be utilized in applications where a bottom - up traversal is needed. Another technique is to store the internal nodes of the tree in an array in the order of their first occurrence in a depth first search traversal. With this, the leftmost child of an internal node is found right next to it in the array, which removes the need to store a child pointer. Instead of storing the starting and ending positions of a substring corresponding to an edge label, an edge label can be stored with the starting position and length of the substring. The advantage of doing so is that the length of the edge label is likely to be small. Hence, one byte can be used to store edge labels with lengths < 255 and the number 255 can be used to denote edge labels with length at least 255. The actual values of such labels can be stored in an exceptions list, which is expected to be fairly small. Using several such techniques, the space required per character can be roughly cut in half to about 20 bytes [13].

A suffix array can be stored in just one word per character, or 4 bytes. Most applications using suffix arrays also need the Lcp array. Similar to the technique employed in storing edge labels on suffix trees, the entries in Lcp array can also be stored using one byte, with exceptions handled using an ordered exceptions list. Provided most of the lcp values fit in a byte, we only need 5 bytes per character, significantly smaller than what is required for suffix trees. Further space reduction can be achieved by the use of compressed suffix trees and suffix arrays and other data structures [14,15]. However, this often comes at the expense of increased run - time complexity.

30.3 Applications

In this section, we present algorithms for several string problems using suffix trees and suffix arrays. While the same run - time bounds can be achieved for many interesting applications with either a suffix tree or a suffix array, there are others which involve a space vs. time trade off. Even in cases where the same run - time bound can be achieved, it is often easier to design the algorithm first for a suffix tree, and then think if the implementation can be done using a suffix array. For this reason, we largely concentrate on suffix trees. The reader interested in reading more on applications of suffix arrays is referred to [16,17].

30.3.1 Pattern Matching

Given a pattern P and a text T , the pattern matching problem is to find all occurrences of P in T . Let $|P| = m$ and $|T| = n$. Typically, $n \gg m$. Moreover, T remains fixed in many applications and the query is repeated for many different patterns. For example,

T could be a text document and P could represent a word search. Or, T could be an entire database of DNA sequences and P denote a substring of a query sequence for homology (similarity) search. Thus, it is beneficial to preprocess the text T so that queries can be answered as efficiently as possible.

30.3.1.1 Pattern Matching using Suffix Trees

The pattern matching problem can be solved in optimal $O(m + k)$ time using $ST(T)$, where k is the number of occurrences of P in T . Suppose P occurs in T starting from position i . Then, P is a prefix of $suff_i$ in T . It follows that P matches the path from root to leaf labeled i in ST . This property results in the following simple algorithm: Start from the root of ST and follow the path matching characters in P , until P is completely matched or a mismatch occurs. If P is not fully matched, it does not occur in T . Otherwise, each leaf in the subtree below the matching position gives an occurrence of P . The positions can be enumerated by traversing the subtree in time proportional to the size of the subtree. As the number of leaves in the subtree is k , this takes $O(k)$ time. If only one occurrence is of interest, the suffix tree can be preprocessed in $O(n)$ time such that each internal node contains the label of one of the leaves in its subtree. Thus, the problem of whether P occurs in T or the problem of finding one occurrence can be answered in $O(m)$ time.

30.3.1.2 Pattern Matching using Suffix Arrays

Consider the problem of pattern matching when the suffix array of the text, $SA(T)$, is available. As before, we need to find all the suffixes that have P as a prefix. As SA is a lexicographically sorted order of the suffixes of T , all such suffixes will appear in consecutive positions in it. The sorted order in SA allows easy identification of these suffixes using binary search. Using a binary search, find the smallest index i in SA such that $suff_{SA[i]}$ contains P as a prefix, or determine that no such suffix is present. If no suffix is found, P does not occur in T . Otherwise, find the largest index $j(\geq i)$ such that $suff_{SA[j]}$ contains P as a prefix. All the elements in the range $SA[i..j]$ give the starting positions of the occurrences of P in T .

A binary search in SA takes $O(\log n)$ comparisons. In each comparison, P is compared with a suffix to determine their lexicographic order. This requires comparing at most $|P| = m$ characters. Thus, the run - time of this algorithm is $O(m \log n)$. Note that while this run - time is inferior to the run - time using suffix trees, the space required by this algorithm is only n words for SA apart from the space required to store the string. Note that the Lcp array is not required. Assuming 4 bytes per suffix array entry and one byte per character in the string, the total space required is only $5n$ bytes.

The run - time can be improved to $O(m + \log n)$, by using slightly more space and keeping track of appropriate lcp information. Consider an iteration of the binary search. Let $SA[L..R]$ denote the range in the suffix array where the binary search is focused. To begin with, $L = 1$ and $R = n$. At the beginning of an iteration, the pattern P is known to be lexicographically greater than or equal to $suff_{SA[L]}$ and lexicographically smaller than or equal to $suff_{SA[R]}$. Let $M = \lceil L + R/2 \rceil$. During the iteration, a lexicographic comparison between P and $suff_{SA[M]}$ is made. Depending on the result, the search range is narrowed to either $SA[L..M]$ or $SA[M..R]$. Assume that $l = |lcp(P, suff_{SA[L]})|$ and $r = |lcp(P, suff_{SA[R]})|$ are known at the beginning of the iteration. Also, assume that $|lcp(suff_{SA[L]}, suff_{SA[M]})|$ and $|lcp(suff_{SA[M]}, suff_{SA[R]})|$ are known. From these values, we wish to determine $|lcp(P, suff_{SA[M]})|$ for use in next iteration, and consequently determine the relative lexicographic order between P and $suff_{SA[M]}$. As SA is a lexicographically sorted array, P and $suff_{SA[M]}$ must agree on at least $\min(l, r)$ characters. If l and r are equal, then comparison between P and $suff_{SA[M]}$ is done by starting from the $(l + 1)$ th character. If l and r are unequal, consider the case when $l > r$.

Case I: $l < |lcp(suff_{SA[L]}, suff_{SA[M]})|$. In this case, P is lexicographically greater than $suff_{SA[M]}$ and $|lcp(P, suff_{SA[M]})| = |lcp(P, suff_{SA[L]})|$. Change the search range to $SA[M..R]$. No character comparisons are needed.

Case II: $l > |lcp(suff_{SA[L]}, suff_{SA[M]})|$. In this case, P is lexicographically smaller than $suff_{SA[M]}$ and $|lcp(P, suff_{SA[M]})| = |lcp(Suff_{SA[L]}, suff_{SA[M]})|$. Change the search range to $SA[L..M]$. Again, no character comparisons are needed.

Case III: $l = |lcp(suff_{SA[L]}, suff_{SA[M]})|$. In this case, P agrees with the first l characters of $suff_{SA[M]}$. Compare P and $suff_{SA[M]}$ starting from $(l + 1)$ th character to determine $|lcp(P, suff_{SA[M]})|$ and the relative lexicographic order of P and $suff_{SA[M]}$.

Similarly, the case when $r > l$ can be handled such that comparisons between P and $suff_{SA[M]}$, if at all needed, start from $(r + 1)$ th character. To start the execution of the algorithm, $lcp(P, suff_{SA[1]})$ and $lcp(P, suff_{SA[n]})$ are computed directly using at most $2|P|$ character comparisons. This ensures $|lcp(P, suff_{SA[L]})|$ and $|lcp(P, suff_{SA[R]})|$ are known at the beginning of the first iteration. This property is maintained for each iteration as L or R is shifted to M but $|lcp(P, suff_{SA[M]})|$ is computed. For now, assume that the required $|lcp(suff_{SA[L]}, suff_{SA[M]})|$ and $|lcp(suff_{SA[R]}, suff_{SA[M]})|$ values are available.

Lemma 30.4

The total number of character comparisons made by the algorithm is $O(m + \log n)$.

Proof. The algorithm makes at most $2m$ comparisons in determining the longest common prefixes between P and $\text{suff}_{SA[1]}$ and between P and $\text{suff}_{SA[n]}$. Classify the comparisons made in each iteration to determine the longest common prefix between P and $\text{suff}_{SA[M]}$ into *successful* and *failed* comparisons. A comparison is considered successful if it contributes the longest common prefix. There is at most one failed comparison per iteration, for a total of at most $\log n$ such comparisons over all iterations. As for successful comparisons, note that the comparisons start with $(\max(l, r) + 1)$ th character of P , and each successful comparison increases the value of $\max(l, r)$ for next iteration. Thus, each character of P is involved only once in a successful comparison. The total number of character comparisons is at most $3m + \log n = O(m + \log n)$. ■

It remains to be described how the $|\text{lcp}(\text{suff}_{SA[L]}, \text{suff}_{SA[M]})|$ and $|\text{lcp}(\text{suff}_{SA[R]}, \text{suff}_{SA[M]})|$ values required in each iteration are computed. Suppose the Lcp array of T is known. For any $1 \leq i < j \leq n$

$$|\text{lcp}(\text{suff}_{SA[i]}, \text{suff}_{SA[j]})| = \min_{k=i}^{j-1} Lcp[k]$$

The lcp of two suffixes can be computed in time proportional to the distance between them in the suffix array. In order to find the lcp values required by the algorithm in constant time, consider the binary tree corresponding to all possible search intervals used by any execution of the binary search algorithm. The root of the tree denotes the interval $[1..n]$. If $[i..j]$ ($j - i \geq 2$) is the interval at an internal node of the tree, its left child is given by $[i..[i + j/2]]$ and its right child is given by $[[i + j/2]..j]$. The execution of the binary search tree algorithm can be visualized as traversing a path in the binary tree from root to a leaf. If lcp value for each interval in the tree is precomputed and recorded, any required lcp value during the execution of the algorithm can be retrieved in constant time. The leaf level in the binary tree consists of intervals of the type $[i..i + 1]$. The lcp values for these $n - 1$ intervals is already given by the Lcp array. The lcp value corresponding to an interval at an internal node is given by the smaller of the lcp values at the children. Using a bottom - up traversal, the lcp values can be computed in $O(n)$ time. In addition to the Lcp array, $n - 2$ additional lcp values are required to be stored. Assuming approximately 1 byte per lcp value, the algorithm requires approximately $2n$ bytes of additional space. As usual, lcp values larger than or equal to 255, if any, are stored in an exceptions list and the size of such list should be very small in practical applications.

Thus, pattern matching can be solved in $O(m \log n)$ time using $5n$ bytes of space, or in $O(m + \log n)$ time using $7n$ bytes of space. Abouelhoda et al. [17] reduce this time further to $O(m)$ time by mimicking the suffix tree algorithm on a suffix array with some auxiliary information. Using clever implementation techniques, the space is reduced to approximately $6n$ bytes. An interesting feature of their algorithm is that it can be used in other applications based on a top - down traversal of suffix tree.

30.3.2 Longest Common Substrings

Consider the problem of finding a longest substring common to two given strings s_1 of size m and s_2 of size n . To solve this problem, first construct the GST of strings s_1 and s_2 . A longest substring common to s_1 and s_2 will be the path - label of an internal node with the greatest string depth in the suffix tree which has leaves labeled with suffixes from both the strings. Using a traversal of the GST , record the string - depth of each node, and mark each node if it has suffixes from both the strings. Find the largest string - depth of any marked node. Each marked internal node at that depth gives a longest common substring. The total run - time of this algorithm is $O(m + n)$.

The problem can also be solved by using the suffix tree of one of the strings and suffix links. Without loss of generality, suppose the suffix tree of s_2 is given. For each position i in s_1 , we find the largest substring of s_1 starting at that position that is also a substring of s_2 . For position 1, this is directly computed by matching suff_1 of s_1 starting from the root of the suffix tree until no more matches are possible. To determine the longest substring match from position 2, simply walk up to the first internal node, follow the suffix link, and walk down as done in McCreight's algorithm. A similar proof shows that this algorithm runs in $O(m + n)$ time.

Now consider solving the longest common substring problem using the GSA and Lcp array for strings s_1 and s_2 . First, consider a one string variant of this problem—that of computing the longest repeat in a string. This is given by the string depth of the deepest internal node in the corresponding suffix tree. All children of such a node must be leaves. Any consecutive pair of such leaves have the longest repeat as their longest common prefix. Thus, each largest value in the Lcp array reveals a longest repeat in the string. The number of occurrences of a repeat is one more than the number of consecutive occurrences of the corresponding largest value in the Lcp array. Thus, all distinct longest repeats, and the number and positions of their occurrences can be determined by a linear scan of the Lcp array.

To solve the longest common substring problem, let v denote an internal node with the greatest string depth that contains a suffix from each of the strings. Because such a pair of suffixes need not be consecutive in the suffix array, it might appear that one has to look at nonconsecutive entries in the Lcp array. However, the subtree of any internal node that is a child of v can only consist of suffixes from one of the strings. Thus, there will be two consecutive suffixes in the subtree under v , one from each

string. Therefore, it is enough to look at consecutive entries in the GSA and Lcp arrays, find the largest lcp value that corresponds to two consecutive suffixes, one from each string. This gives the length of a longest common substring. The starting positions of the suffixes reveals the positions in the strings where the longest common substring occurs. The algorithm runs in $O(m + n)$ time.

30.3.3 Text Compression

Compression of text data is useful for data transmission and for compact storage. A simple, not necessarily optimal, data compression method is the Ziv - Lempel compression [18,19]. In this method, the text to be compressed is considered a large string, and a compact representation is obtained by identifying repeats in the string. A simple algorithm following this strategy is as follows: Let T denote the text to be compressed and let $|T| = n$. At some stage during the execution of the compression algorithm, suppose that the string $T[1..i - 1]$ is already compressed. The compression is extended by finding the length l_i of a largest prefix of $suff_i$ that is a substring of $T[1..i - 1]$. Two cases arise:

1. $l_i = 0$. In this case, a compressed representation of $T[1..i]$ is obtained by appending $T[i]$ to the compressed representation of $T[1..i - 1]$.
2. $l_i > 0$. In this case, a compressed representation of $T[1..i + l_i - 1]$ is obtained by appending (i, l_i) to the compressed representation of $T[1..i - 1]$.

The algorithm is initiated by setting $T[1]$ to be the compressed representation of $T[1..1]$, and continuing the iterations until the entire string is compressed. For example, executing the above algorithm on the string *mississippi* yields the compressed string *mis(3,1)(2,3)(2,1)p (9,1)(2,1)*. The decompression method for such a compressed string is immediate.

Suffix trees can be used to carry out the compression in $O(n)$ time [20]. They can be used in obtaining l_i , the length of the longest prefix of $suff_i$ that is a substring of the portion of the string already seen, $T[1..i - 1]$. If j is the starting position of such a substring, then $T[j..j + l_i - 1] = T[i..i + l_i - 1]$ and $i \geq j + l_i$. It follows that $|lcp(suff_j, suff_i)| \geq l_i$. Let $v = lca(i, j)$, where i and j are leaves corresponding to $suff_i$ and $suff_j$, respectively. It follows that $T[i..i + l_i - 1]$ is a prefix of $path-label(v)$. Consider the unique path from the root of $ST(T)$ that matches $T[i..i + l_i - 1]$. Node v is an internal node in the subtree below, and hence j is a leaf in the subtree below. Thus, l_i is the largest number of characters along the path $T[i..n]$ such that \exists leaf j in the subtree below with $j + l_i \leq i$. Note that any j in the subtree below that satisfies the property $j + l_i \leq i$ is acceptable. If such a j exists, the smallest leaf number in the subtree below certainly satisfies this property, and hence can be chosen as the starting position j .

This strategy results in the following algorithm for finding l_i : First, build the suffix tree of T . Using an appropriate linear time tree traversal method, record the string depth of each node and mark each internal node with the smallest leaf label in its subtree. Let $\min(v)$ denote the smallest leaf label under internal node v . To find l_i , walk along the path $T[i..n]$ to identify two consecutive internal nodes u and v such that $\min(u) + string-depth(u) < i$ and $\min(v) + string-depth(v) \geq i$. If $\min(v) + string-depth(u) > i$, then set $l_i = string-depth(u)$ and set the starting position to be $\min(u)$. Otherwise, set $l_i = i - \min(v)$ and set the starting position to be $\min(v)$.

To obtain $O(n)$ run - time, it is enough to find l_i in $O(l_i)$ time as the next l_i characters of the string are compressed into an $O(1)$ space representation of an already seen substring. Therefore, it is enough to traverse the path matching $T[i..n]$ using individual character comparisons. However, as the path is guaranteed to exist, it can be traversed in $O(1)$ time per edge, irrespective of the length of the edge label.

30.3.4 String Containment

Given a set of strings $\mathcal{S} = \{s_1, s_2, \dots, s_k\}$ of total length N , the string containment problem is to identify each string that is a substring of some other string. An example application could be that the strings represent DNA sequence fragments, and we wish to remove redundancy. This problem can be easily solved using suffix trees in $O(N)$ time. First, construct the $GST(\mathcal{S})$ in $O(N)$ time. To find if a string s_i is contained in another, locate the leaf labeled $(s_i, 1)$. If the label of the edge connecting the leaf to its parent is labeled with the string $\$$, s_i is contained in another string. Otherwise, it is not. This can be determined in $O(1)$ time per string.

30.3.5 Suffix-Prefix Overlaps

Suppose we are given a set of strings $\mathcal{S} = \{s_1, s_2, \dots, s_k\}$ of total length N . The suffix-prefix overlap problem is to identify, for each pair of strings (s_i, s_j) , the longest suffix of s_i that is a prefix of s_j . Suffix-prefix overlaps are useful in algorithms for finding the shortest common superstring of a given set of strings. They are also useful in applications such as genome assembly where significant suffix-prefix overlaps between pairs of fragments are used to assemble fragments into much larger sequences.

The suffix-prefix overlap problem can be solved using $GST(\mathcal{S})$ in optimal $O(N + k^2)$ time. Consider the longest suffix α of s_i that is a prefix of s_j . In $GST(\mathcal{S})$, α is an initial part of the path from the root to leaf labeled $(j, 1)$ that culminates in an internal node. A leaf that corresponds to a suffix from s_i should be a child of the internal node, with the edge label $\$$. Moreover, it must be the deepest internal node on the path from root to leaf $(j, 1)$ that has a suffix from s_i attached in this way. The length of the corresponding suffix - prefix overlap is given by the string depth of the internal node.

Let M be a $k \times k$ output matrix such that $M[i, j]$ should contain the length of the longest suffix of s_i that overlaps a prefix of s_j . The matrix is computed using a depth first search (DFS) traversal of $GST(\mathcal{S})$. The GST is preprocessed to record the string depth of every node. During the DFS traversal, k stacks A_1, A_2, \dots, A_k are maintained, one for each string. The top of the stack A_i contains the string depth of the deepest node along the current DFS path that is connected with edge label $\$$ to a leaf corresponding to a suffix from s_i . If no such node exists, the top of the stack contains zero. Each stack A_i is initialized by pushing zero onto an empty stack, and is maintained during the DFS as follows: When the DFS traversal visits a node v from its parent, check to see if v is attached to a leaf with edge label $\$$. If so, for each i such that string s_i contributes a suffix labeling the leaf, *push string-depth(v)* on to stack A_i . The string depth of the current node can be easily maintained during the DFS traversal. When the DFS traversal leaves the node v to return back to its parent, again identify each i that has the above property and *pop* the top element from the corresponding stack A_i .

The output matrix M is built one column at a time. When the DFS traversal reaches a leaf labeled $(j, 1)$, the top of stack A_j contains the longest suffix of s_i that matches a prefix of s_j . Thus, column j of matrix M is obtained by setting $M[i, j]$ to the top element of stack A_j . To analyze the run - time of the algorithm, note that each *push* (similarly, *pop*) operation on a stack corresponds to a distinct suffix of one of the input strings. Thus, the total number of *push* and *pop* operations is bounded by $O(N)$. The matrix M is filled in $O(1)$ time per element, taking $O(k^2)$ time. Hence, all suffix - prefix overlaps can be identified in optimal $O(N + k^2)$ time.

30.4 Lowest Common Ancestors

Consider a string s and two of its suffixes $suff_i$ and $suff_j$. The longest common prefix of the two suffixes is given by the path label of their lowest common ancestor. If the string - depth of each node is recorded in it, the length of the longest common prefix can be retrieved from the lowest common ancestor. Thus, an algorithm to find the lowest common ancestors quickly can be used to determine longest common prefixes without a single character comparison. In this section, we describe how to preprocess the suffix tree in linear time and be able to answer lowest common ancestor queries in constant time [21].

30.4.1 Bender and Farach's *lca* algorithm

Let T be a tree of n nodes. Without loss of generality, assume the nodes are numbered $1 \dots n$. Let $lca(i, j)$ denote the lowest common ancestor of nodes i and j . Bender and Farach's algorithm performs a linear time preprocessing of the tree and can answer *lca* queries in constant time.

Let E be an Euler tour of the tree obtained by listing the nodes visited in a depth first search of T starting from the root. Let L be an array of level numbers such that $L[i]$ contains the tree - depth of the node $E[i]$. Both E and L contain $2n - 1$ elements and can be constructed by a depth first search of T in linear time. Let R be an array of size n such that $R[i]$ contains the index of the first occurrence of node i in E . Let $RMQ_A(i, j)$ denote the position of an occurrence of the smallest element in array A between indices i and j (inclusive). For nodes i and j , their lowest common ancestor is the node at the smallest tree - depth that is visited between an occurrence of i and an occurrence of j in the Euler tour. It follows that

$$lca(i, j) = E[RMQ_L(R[i], R[j])]$$

Thus, the problem of answering *lca* queries transforms into answering range minimum queries in arrays. Without loss of generality, we henceforth restrict our attention to answering range minimum queries in an array A of size n .

To answer range minimum queries in A , do the following preprocessing: Create $\lfloor \log n \rfloor + 1$ arrays $B_0, B_1, \dots, B_{\lfloor \log n \rfloor}$ such that $B_j[i]$ contains $RMQ_A(i, i + 2^j)$, provided $i + 2^j \leq n$. B_0 can be computed directly from A in linear time. To compute $B_l[i]$, use $B_{l-1}[i]$ and $B_{l-1}[i + 2^{l-1}]$ to find $RMQ_A(i, i + 2^{l-1})$ and $RMQ_A(i + 2^{l-1}, i + 2^l)$, respectively. By comparing the elements in A at these locations, the smallest element in the range $A[i..i + 2^l]$ can be determined in constant time. Using this method, all the $\lfloor \log n \rfloor + 1$ arrays are computed in $O(n \log n)$ time.

Given an arbitrary range minimum query $RMQ_A(i, j)$, let k be the largest integer such that $2^k \leq (j - i)$. Split the range $[i..j]$ into two overlapping ranges $[i..i + 2^k]$ and $[j - 2^k..j]$. Using $B_k[i]$ and $B_k[j - 2^k]$, a smallest element in each of these overlapping ranges can be located in constant time. This will allow determination of $RMQ_A(i, j)$ in constant time. To avoid a direct computation of k , the largest power of 2 that is smaller than or equal to each integer in the range $[1..n]$ can be precomputed and stored in $O(n)$

time. Putting all of this together, range minimum queries can be answered with $O(n \log n)$ preprocessing time and $O(1)$ query time.

The preprocessing time is reduced to $O(n)$ as follows: Divide the array A into $2n/\log n$ blocks of size $1/2\log n$ each. Preprocess each block such that for every pair (i, j) that falls within a block, $\text{RMQ}_A(i, j)$ can be answered directly. Form an array B of size $2n/\log n$ that contains the minimum element from each of the blocks in A , in the order of the blocks in A , and record the locations of the minimum in each block in another array C . An arbitrary query $\text{RMQ}_A(i, j)$ where i and j do not fall in the same block is answered as follows: Directly find the location of the minimum in the range from i to the end of the block containing it, and also in the range from the beginning of the block containing j to index j . All that remains is to find the location of the minimum in the range of blocks completely contained between i and j . This is done by the corresponding range minimum query in B and using C to find the location in A of the resulting smallest element. To answer range queries in B , B is preprocessed as outlined before. Because the size of B is only $O(n \log n)$, preprocessing B takes $O(n/\log n \log n/\log n) = O(n)$ time and space.

It remains to be described how each of the blocks in A is preprocessed to answer range minimum queries that fall within a block. For each pair (i, j) of indices that fall in a block, the corresponding range minimum query is precomputed and stored. This requires computing $O(\log^2 n)$ values per block and can be done in $O(\log^2 n)$ time per block. The total run - time over all blocks is $2n/\log n \times O(\log^2 n) = O(n \log n)$, which is unacceptable. The run - time can be reduced for the special case where the array A contains level numbers of nodes visited in an Euler Tour, by exploiting its special properties. Note that the level numbers of consecutive entries differ by $+1$ or -1 . Consider the $2n/\log n$ blocks of size $1/2\log n$. Normalize each block by subtracting the first element of the block from each element of the block. This does not affect the range minimum query. As the first element of each block is 0 and any other element differs from the previous one by $+1$ or -1 , the number of distinct blocks is $2^{1/2\log n - 1} = 1/2\sqrt{n}$. Direct preprocessing of the distinct blocks takes $1/2\sqrt{n} \times O(\log^2 n) = O(n)$ time. The mapping of each block to its corresponding distinct normalized block can be done in time proportional to the length of the block, taking $O(n)$ time over all blocks.

Putting it all together, a tree T of n nodes can be preprocessed in $O(n)$ time such that lca queries for any two nodes can be answered in constant time. We are interested in an application of this general algorithm to suffix trees. Consider a suffix tree for a string of length n . After linear time preprocessing, lca queries on the tree can be answered in constant time. For a given pair of suffixes in the string, the string - depth of their lowest common ancestor gives the length of their longest common prefix. Thus, the longest common prefix can be determined in constant time, without resorting to a single character comparison! This feature is exploited in many suffix tree algorithms.

30.5 Advanced Applications

30.5.1 Suffix Links from Lowest Common Ancestors

Suppose we are given a suffix tree and it is required to establish suffix links for each internal node. This may become necessary if the suffix tree creation algorithm does not construct suffix links but they are needed for an application of interest. For example, the suffix tree may be constructed via suffix arrays, completely avoiding the construction and use of suffix links for building the tree. The links can be easily established if the tree is preprocessed for lca queries.

Mark each internal node v of the suffix tree with a pair of leaves (i, j) such that leaves labeled i and j are in the subtrees of different children of v . The marking can be done in linear time by a bottom - up traversal of the tree. To find the suffix link from an internal node v (other than the root) marked with (i, j) , note that $v = \text{lca}(i, j)$ and $\text{lcp}(\text{suff}_i, \text{suff}_j) = \text{path-label}(v)$. Let $\text{path-label}(v) = c\alpha$, where c is the first character and α is a string. To establish a suffix link from v , node u with path label α is needed. As $\text{lcp}(\text{suff}_{i+1}, \text{suff}_{j+1}) = \alpha$, node u is given by $\text{lca}(i+1, j+1)$, which can be determined in constant time. Thus, all suffix links can be determined in $O(n)$ time. This method trivially extends to the case of a generalized suffix tree.

30.5.2 Approximate Pattern Matching

The simpler version of approximate pattern matching problem is as follows: Given a pattern P ($|P| = m$) and a text T ($|T| = n$), find all substrings of length $|P|$ in T that match P with at most k mismatches. To solve this problem, first construct the GST of P and T . Preprocess the GST to record the string - depth of each node, and to answer lca queries in constant time. For each position i in T , we will determine if $T[i..i+m-1]$ matches P with at most k mismatches. First, use an lca query $\text{lca}((P, 1), (T, i))$ to find the largest substring from position i of T that matches a substring from position 1 and P . Suppose the length of this longest exact match is l . Thus, $P[1..l] = T[i..i+l-1]$, and $P[l+1] \neq T[i+l]$. Count this as a mismatch and continue by finding $\text{lca}((P, l+2), (T, i+l+1))$. This procedure is continued until either the end of P is reached or the number of mismatches crosses k . As each lca query takes constant time, the entire procedures takes $O(k)$ time. This is repeated for each position i in T for a total run - time of $O(kn)$.

Now, consider the more general problem of finding the substrings of T that can be derived from P by using at most k character insertions, deletions or substitutions. To solve this problem, we proceed as before by determining the possibility of such a match for every starting position i in T . Let $l = \text{string-depth}(\text{lca}((P, 1), (T, i)))$. At this stage, we consider three possibilities:

1. Substitution— $P[l+1]$ and $T[i+l]$ are considered a mismatch. Continue by finding $\text{lca}((P, l+2), (T, i+l+1))$.
2. Insertion— $T[i+l]$ is considered an insertion in P after $P[l]$. Continue by finding $\text{lca}((P, l+1), (T, i+l+1))$.
3. Deletion— $P[l+1]$ is considered a deletion. Continue by finding $\text{lca}((P, l+2), (T, i+l))$.

After each lca computation, we have three possibilities corresponding to substitution, insertion and deletion, respectively. All possibilities are enumerated to find if there is a sequence of k or less operations that will transform P into a substring starting from position i in T . This takes $O(3^k)$ time. Repeating this algorithm for each position i in T takes $O(3^k n)$ time.

The above algorithm always uses the longest exact match possible from a given pair of positions in P and T before considering the possibility of an insertion or deletion. To prove the correctness of this algorithm, we show that if there is an approximate match of P starting from position i in T that does not use such a longest exact match, then there exists another approximate match that uses only longest exact matches. Consider an approximate match that does not use longest exact matches. Consider the leftmost position j in P and the corresponding position $i+k$ in T where the longest exact match is violated. That is, $P[j] = T[i+k]$ but this is not used as part of an exact match. Instead, an insertion or deletion is used. Suppose that an exact match of length r is used after the insertion or deletion. We can come up with a corresponding approximate match where the longest match is used and the insertion/deletion is taken after that. This will either keep the number of insertions/deletions the same or reduce the count. If the value of k is small, the above algorithms provide a quick and easy way to solve the approximate pattern matching problem. For sophisticated algorithms with better run - times, see [22,23].

30.5.3 Maximal Palindromes

A string is called a palindrome if it reads the same forwards or backwards. A substring $s[i..j]$ of a string s is called a maximal palindrome of s , if $s[i..j]$ is a palindrome and $s[i-1] \neq s[j+1]$ (unless $i=1$ or $j=n$). The maximal palindrome problem is to find all maximal palindromes of a string s .

For a palindrome of odd length, say $2k+1$, define the center of the palindrome to be the $(k+1)$ th character. For a palindrome of even length, say $2k$, define the center to be the position between characters k and $k+1$ of the palindrome. In either case, the palindrome is said to be of radius k . Starting from the center, a palindrome is a string that reads the same in both directions. Observe that each maximal palindrome in a string must have a distinct center. As the number of possible centers for a string of length n is $2n-1$, the total number of maximal palindromes of a string is $2n-1$. All such palindromes can be identified in linear time using the following algorithm.

Let s^r denote the reverse of string s . Construct a GST of the strings s and s^r and preprocess the GST to record string depths of internal nodes and for answering lca queries. Now, consider a character $s[i]$ in the string. The maximal odd length palindrome centered at $s[i]$ is given by the length of the longest common prefix between suff_{i+1} of s and suff_{n-i+2} of s^r . This is easily computed as the string - depth of $\text{lca}((s, i+1), (s^r, n-i+2))$ in constant time. Similarly, the maximal even length palindrome centered between $s[i]$ and $s[i+1]$ is given by the length of the longest common prefix between suff_{i+1} of s and suff_{n-i+1} of s^r . This is computed as the string - depth of $\text{lca}((s, i+1), (s^r, n-i+1))$ in constant time.

These and many other applications involving strings can be solved efficiently using suffix trees and suffix arrays. A comprehensive treatise of suffix trees, suffix arrays and string algorithms can be found in the textbooks by Gusfield [24], and Crochemore and Rytter [25].

31.1 Introduction

Searching for occurrences of a substring in a text is a common operation familiar to anyone who uses a text editor, word processor, or web browser. It is also the case that algorithms for analyzing textual databases can generate a large number of searches. If a text, such as a portion of the genome of an organism, is to be searched repeatedly, it is sometimes the case that it pays to preprocess the text to create a data structure that facilitates the searches. The suffix tree [1] and suffix array [2] discussed in Chapter 30 are examples.

In this chapter, we give some alternatives to these data structures that have advantages over them in some circumstances, depending on what type of searches or analysis of the text are desired, the amount of memory available, and the amount of effort to be invested in an implementation.

In particular, we focus on the problem of finding the locations of all occurrences of a string x in a text t , where the letters of t are drawn from a fixed alphabet Σ , such as the ASCII letter codes.

The *length* of a string x , denoted $|x|$, is the number of characters in it. The *empty string*, denoted λ is the string of length 0 that has no characters in it. If $t = a_1 a_2, \dots, a_n$ is a text and $p = a_i a_{i+1} \dots a_j$ is a substring of it, then i is a *starting position* of p in t and j is an *ending position* of p in t . For instance, the starting positions of *abc* in *aabcabcaac* are {2, 5}, and its ending positions are {5, 8}. We consider the empty string to have starting and ending positions at $\{0, 1, 2, \dots, n\}$, once at each position in the text, and once at position 0, preceding the first character of the text. Let $\text{EndPositions}(p, t)$ denote the ending positions of p in t ; when t is understood, we may denote it $\text{EndPositions}(p)$.

A *deterministic finite automaton* on Σ is a directed graph where each directed edge is labeled with a letter from Σ , and where, for each node, there is at most one edge directed out of the node that is labeled with any given letter. Exactly one of the nodes is designated as a *start node*, and some of the nodes are designated as *accept nodes*. The *label* of a directed path is the word given by the sequence of letters on the path. A deterministic finite automaton is used for representing a set of words, namely, the set of labels of paths from the start node to an accept node.

The first data structure that we examine is the *directed acyclic word graph* (DAWG). The DAWG is just a deterministic finite automaton representing the language of subwords of a text t , which is finite, hence regular. All of its states except for one are accept states. There is no edge from the nonaccepting state to any accepting state, so it is convenient to omit the nonaccept state when representing the DAWG. In this representation, a string p is a substring of t iff it is the label of a directed path originating at the start node.

There exists a labeling of each node of the DAWG with a set of positions so that the DAWG has the following property:

- Whenever p is a substring of t , its ending positions in t are given by the label of the last node of the path of label p that originates at the start node.

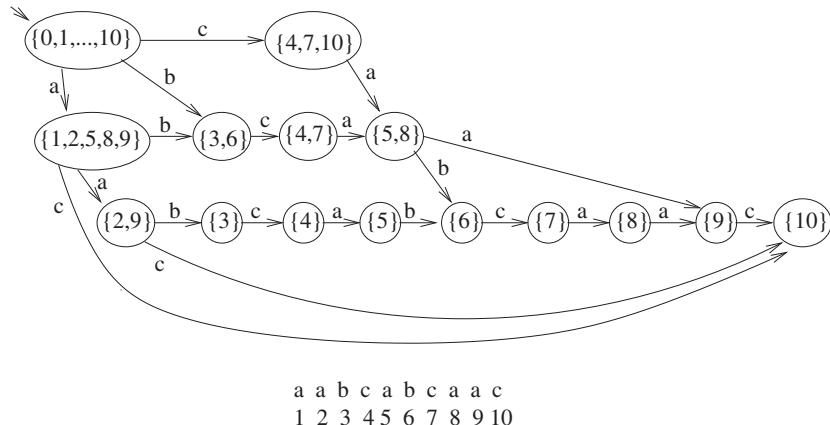

FIGURE 31.1 The DAWG of the text *aabcabcaac*. The starting node is at the upper left. A string p is a substring of the text if and only if it is the label of a path originating at the start node. The nodes can be labeled so that whenever p is the label of such a path, the last node of the path gives $\text{EndPositions}(p)$. For instance, the strings that lead to the state labeled $\{5, 8\}$ are ca , bca , and $abca$, and these have occurrences in the text with their last letter at positions 5 and 8.

To find the locations where p occurs, one need only begin at the start node, follow edges that match the letters of p in order, and retrieve the set of positions at the node where this process halts.

In view of the fact that there are $\Theta(|t|^2)$ intervals on t , each of which represents a substring that is contained in the interval, it is surprising that the number of nodes and edges of the DAWG of t is $O(|t|)$. The reason for this is that all possible query strings fall naturally into *equivalence classes*, which are sets of strings such that two strings are in the same set if they have the same set of ending positions. The size of an equivalence class can be large, and this economy makes the $O(|t|)$ bound possible.

In an application such as a search engine, one may be interested not in the locations of a string in a text, but the number of occurrences of a string in the text. This is one criterion for deciding which texts are most relevant to a query. Since all strings in an equivalence class have the same number of occurrences, each state can be labeled not with the position set, but with the cardinality of its position set. The label of the node reached on the path labeled p originating at the start node tells the number of occurrences of p in t in $O(|p|)$ time. This variant requires $O(|t|)$ space and can be constructed in $O(|t|)$ time.

Unfortunately, the sum of cardinalities of the position sets of the nodes of the DAWG of t is not $O(|t|)$. However, a second data structure that we describe, called the *compact DAWG* does use $O(|t|)$ space. If a string p has k occurrences in t , then it takes $O(|p| + k)$ time to return the set of occurrences where p occurs in t , given the compact DAWG of t . It can be built in $O(|t|)$ time. These bounds are the same as that for the suffix tree and suffix array, but the compact DAWG requires substantially less space in most cases. An example is illustrated in Figure 31.2.

Another important issue is the ease with which a programmer can understand and program the construction algorithm. Like the computer time required for queries, the time spent by a programmer understanding, writing, and maintaining a program is also a resource that must be considered. The third data structure that we present, called the *position heap*, has worse worst-case bounds for construction and queries, but has the advantage of being as easy to understand and construct as elementary data structures such as unbalanced binary search trees and heaps. One trade-off is that the worst-case bounds for a query is $O(|p|^2 + k)$, rather than $O(|p| + k)$. However, on randomly generated strings, the expected time for a query is $O(|p| + k)$, and on most practical applications, the query time can be expected not to differ greatly from this. Like the other structures, it can be constructed in linear time. However, an extremely simple implementation takes $O(|t| \log |t|)$ expected time on randomly generated strings and does not depart much from this in most practical applications. Those who wish to expend minimal programming effort may wish to consider this simple variant of the construction algorithm.

The position heap for the string of Figure 31.1 is illustrated in Figure 31.3.

More recently, an alternative to the construction algorithm given here has been given in Reference 3. That algorithm can be considered online, since it can construct the position heap incrementally as characters are appended to the text. The algorithm we give here can construct it as characters are prepended to the text. The case where they are appended can be reduced to the case where they are prepended, by working with the reverse of the text and reversing query strings before each query. The algorithm of Reference 3 is more natural for this and contributes additional algorithmic insights.

This analysis assumes that the size of the alphabet is a constant, which is a reasonable assumption for genomic sequences, for example. Recently, an algorithm that takes linear time, independently of the size of the alphabet, has been given in Reference 4. However, a step of that algorithm is construction of the suffix tree, hence it is conceptually more difficult than the one given here.

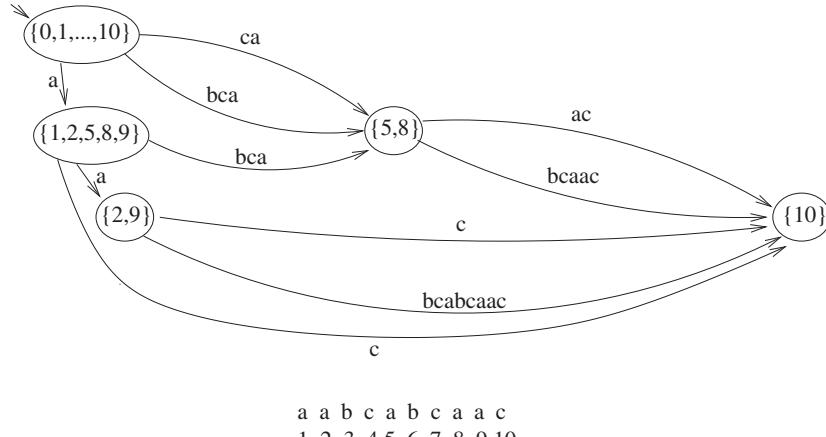

FIGURE 31.2 The compact DAWG of the text *aabcabcaac* (cf. Figure 31.1) The labels depicted in the nodes are the ending positions of the corresponding principal nodes of the DAWG. The compact DAWG is obtained from the DAWG by deleting nodes that have only one outgoing edge, and representing deleted paths between the remaining nodes with edges that are labeled with the path's label.

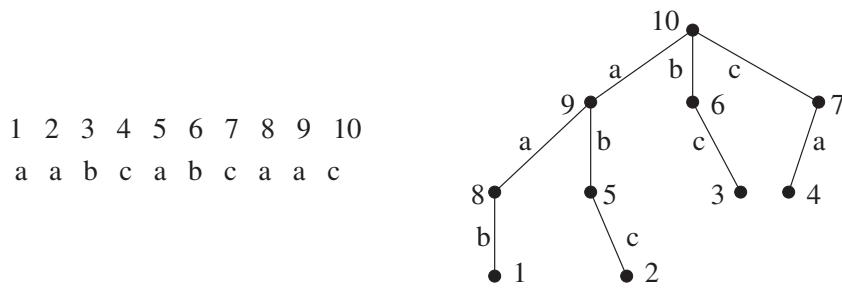

FIGURE 31.3 The position heap of *aabcabcaa*.

Linear-time construction of the position heap for a set of strings stored as a trie is given in Reference 5.

31.2 Preliminaries

The infinite set of all strings that can be formed from letters of an alphabet Σ is denoted as Σ^* . If $a \in \Sigma$, let a^n denote the string that consists of n repetitions of a .

If x is a string, then for $1 \leq j \leq |x|$, let x_j denote the character in position j . Thus x can be written as $x_1 x_2, \dots, x_{|x|}$. The reversal x^R of x is the string $x_{|x|} x_{|x|-1} \dots x_1$. Let $x[i:j]$ denote the substring $x_i x_{i+1}, \dots, x_j$.

The *prefixes* of a string $x = x_1 x_2, \dots, x_k$ are those with a starting position at the leftmost position of x , namely, the empty string and those strings of the form $x[1:j]$ for $1 \leq j \leq k$. Its *suffixes* are those with an ending position at the rightmost position of x , namely, the empty string and those of the form $x[j:k]$.

A *trie* on Σ is a deterministic finite automaton that is a rooted tree whose start node is the root.

Given a family \mathcal{F} of subsets of a domain \mathcal{V} , the *transitive reduction* of the subset relation can be viewed as a pointer from each $X \in \mathcal{F}$ to each $Y \in \mathcal{F}$ such that $X \subset Y$ and there exists no Z such that $X \subset Z \subset Y$. This is sometimes referred to as the *Hasse diagram* of the subset relation on the family. The Hasse diagram is a tree if $V \in \mathcal{F}$, $\emptyset \notin \mathcal{F}$, and for each $X, Y \in \mathcal{F}$, either $X \subseteq Y$, $Y \subset X$, or $X \cap Y = \emptyset$.

31.3 The DAWG

Lemma 31.1

Let x and y be two strings such that $\text{EndPositions}(x) \cap \text{EndPositions}(y) \neq \emptyset$. One of x and y must be a suffix of the other, and either $\text{EndPositions}(x) = \text{EndPositions}(y)$, $\text{EndPositions}(x) \subset \text{EndPositions}(y)$, or $\text{EndPositions}(y) \subset \text{EndPositions}(x)$.

Proof. If x and y have a common ending position i , then the two occurrences coincide in a way that forces one to be a suffix of the other. Suppose without loss of generality that y is a suffix of x . Then every occurrence of x contains an occurrence of y inside of it that ends at the same position, so $\text{Endpositions}(x) \subseteq \text{Endpositions}(y)$. ■

For instance, in the string $aabcabcaac$, the string ca has ending positions $\{5, 8\}$, while the string $aabca$ has ending positions $\{5\}$, and ca is a suffix of $aabca$.

Let x 's right-equivalence class in t be the set $\{y | \text{EndPositions}(y) = \text{EndPositions}(x)\}$. The only infinite class is degenerate class of strings with the empty set as ending positions, namely, those elements of Σ^* that are not substrings of t .

The right-equivalence classes on t are a partition of Σ^* : each member of Σ^* is in one and only one right-equivalence class. By Lemma 31.1, whenever two strings are in the same nondegenerate right-equivalence class, then one of them is a suffix of the other. It is easily seen that if y is the shortest string in the class and x is the longest, then the class consists of the suffixes of x whose length is at least $|y|$. For instance, in Figure 31.1, the class of strings with end positions $\{5, 8\}$ consists of $y = ca$, $x = abca$, and since bca is a longer suffix of x than y is.

Lemma 31.2

A text t of length n has at most $2n$ right-equivalence classes.

Proof. The degenerate class is one right equivalence class. All others have nonempty ending positions, and we must show that there are at most $2n - 1$ of them. The set $V = \{0, 1, 2, \dots, n\}$ is the set of ending positions of the empty string. If X and Y are sets of ending positions of two right-equivalence classes, then $X \subseteq Y$, $Y \subseteq X$, or $Y \cap X = \emptyset$, by Lemma 31.1. Therefore, the transitive reduction (Hasse diagram) of the subset relation on the nonempty position sets is a tree rooted at V . For any i such that $\{i\}$ is not a leaf, we can add $\{i\}$ as a child of the lowest set that contains i as a member. The leaves are now a partition of $\{1, 2, \dots, n\}$ so it has at most n leaves. Since each node of the tree has at least two children, there are at most $2n - 1$ nodes. ■

Definition 31.1

The DAWG is defined as follows. The states of the DAWG are the nondegenerate right-equivalence classes that t induces on its substrings. For each $a \in \Sigma$ and $x \in \Sigma^*$ such that xa is a substring of t , there is an edge labeled a from x 's right-equivalence class to xa 's right-equivalence class.

Figure 31.1 depicts the DAWG by labeling each right-equivalence class with its set of ending positions. The set of words in a class is just the set of path labels of paths leading from the source to a class. For instance, the right-equivalence class represented by the node labeled $\{5, 8\}$ is $\{ca, bca, abca\}$.

It would be natural to include the infinite degenerate class of strings that do not occur in t . This would ensure that every state had an outgoing edge for every letter of Σ . However, it is convenient to omit this state when representing the DAWG: for each $a \in \Sigma$, there is an edge from the degenerate class to itself, and this does not need to be represented explicitly. An edge labeled a from a nondegenerate class to the degenerate class is implied by the absence of an edge out of the state labeled a in the representation.

For each node X and each $a \in \Sigma$, there is at most one transition out of X that is labeled a . Therefore, the DAWG is a deterministic finite automaton. Any word p such that $\text{EndPositions}(p) \neq \emptyset$ spells out the labels of a path to the state corresponding to $\text{EndPositions}(p)$. Therefore, all states of the DAWG are reachable from the start state. The DAWG cannot have a directed cycle, as this would allow an infinite set of words to spell out a path, and the set of subwords of t is finite. Therefore, it can be represented by a directed acyclic graph.

A state is a sink if it has no outgoing edges. A sink must be the right-equivalence class containing position n , so there is exactly one sink.

Theorem 31.1

The DAWG for a text of length n has at most $2n - 1$ nodes and $3n - 3$ edges.

Proof. The number of nodes follows from Lemma 31.2. There is a single sink, namely, the one that has position set $\{|t|\}$, this represents the equivalence class containing those suffixes of t that have a unique occurrence in t . Let T be a directed spanning tree of the DAWG rooted at the start state. T has one fewer edges than the number of states, hence $2n - 2$ edges. For every $e \notin T$, let $P_1(e)$ denote the path in T from the start state to the tail of e , let $P_2(e)$ denote an arbitrary path in the DAWG from the head of e to the sink, and let $P(e)$ denote the concatenation of $(P_1(e), e, P_2(e))$. Since $P(e)$ ends at the sink, the labels of its edges yield a suffix of t . For $e_1, e_2 \notin T$ with $e_1 \neq e_2$, $P(e_1) \neq P(e_2)$, since they differ in their first edge that is not in T . One suffix is given by

the labels of the path in T to the sink. Each of the remaining $n - 1$ suffixes is the sequence of labels of $P(e)$ for at most one edge $e \notin T$, so there are at most $n - 1$ edges not in T .

The total number of edges of the DAWG is bounded by $2n - 2$ tree edges and $n - 1$ nontree edges. ■

To determine whether a string p occurs as a substring of t , one may begin at the start state and either find the path that spells out the letters of p , thereby accepting p , or else reject p if there is no such path. This requires finding, at each node x , the transition labeled a leaving x , where a is the next letter of p . If $|\Sigma| = O(1)$, this takes $O(1)$ time, so it takes $O(|p|)$ time to determine whether p is a subword of t . Note that, in contrast to naive approaches to this problem, this time bound is independent of the length of t .

If the nodes of the DAWG are explicitly labeled with the corresponding end positions, as in Figure 31.1, then it is easy to find the positions where a substring occurs: it is the label of the state reached on the substring. However, doing this is infeasible if one wishes to build the DAWG in $O(|t|)$ time and use $O(|t|)$ storage, since the sum of cardinalities of the position sets can be greater than this. For this problem, it is preferable to use the compact DAWG that is described below.

For the problem of finding the number of occurrences of a substring in t , it suffices to label each node with the *number* of positions in its position set. This may be done in postorder in a depth-first search, starting at the start node, and applying the following rule: the label of a node v is the sum of labels of its outneighbors, which have already been labeled by the time one must label v . Handling v takes time proportional to the number of edges originating at v , which we have already shown is $O(|t|)$.

31.3.1 A Simple Algorithm for Constructing the DAWG

Definition 31.2

If x is a substring of t , let us say that x 's *redundancy* in t is the number of ending (or beginning) positions it has in t . If i is a position in t , let $h(i)$ be the longest substring x of t with an ending position at i whose redundancy is at least as great as its length, $|x|$. Let $h(t)$ be the average of $h(i)$ over all i , namely $\left(\sum_{i=1}^{|t|} h(i)\right) / |t|$.

Clearly, $h(t)$ is a measure of how redundant t is; the greater the value of $h(t)$, the less information it can contain.

In this section, we give an $O(|t|h(t))$ algorithm for constructing the DAWG of a string t . This is quadratic in the worst case, which is illustrated by the string $t = a^n$, consisting of n copies of one letter. However, we claim that the algorithm is a practical one for most applications, where $h(t)$ is rarely large even when t has a long repeated substring. In most applications, $h(t)$ can be expected to behave like an $O(\log|t|)$ function.

The algorithm explicitly labels the nodes of the DAWG with their ending positions, as illustrated in Figure 31.1. Each set of ending positions is represented with a list, where the positions appear in ascending order. It begins by creating a start node, and then iteratively processes an unprocessed node by creating its neighbors. To identify an unprocessed node, it is convenient to keep a list of the unprocessed nodes, insert a node in this list, and remove a node from the front of the list when it is time to process a new node.

Algorithm 31.1

```

DAWGBuild( $t$ )
  Create a start node with position set  $\{0, 1, \dots, n\}$ 
  While there is an unprocessed node  $v$ 
    Create a copy of  $v$ 's position set
    Add 1 to every element of this set
    Remove  $n + 1$  from this copy if it occurs
    Partition the copy into sets of positions that have a common letter
    For each partition class  $W$ 
      If  $W$  is already the position set of a node, then let  $w$  denote that node
      Else create a new node  $w$  with position set  $W$ 
      Let  $a$  be the letter that occurs at the positions in  $W$ 
      Install an edge labeled  $a$  from  $v$  to  $w$ 
```

Figure 31.4 gives an illustration. For the correctness, it is easy to see by induction on k that every substring w of the text that has length k leads to a node whose position set is the ending positions of w .

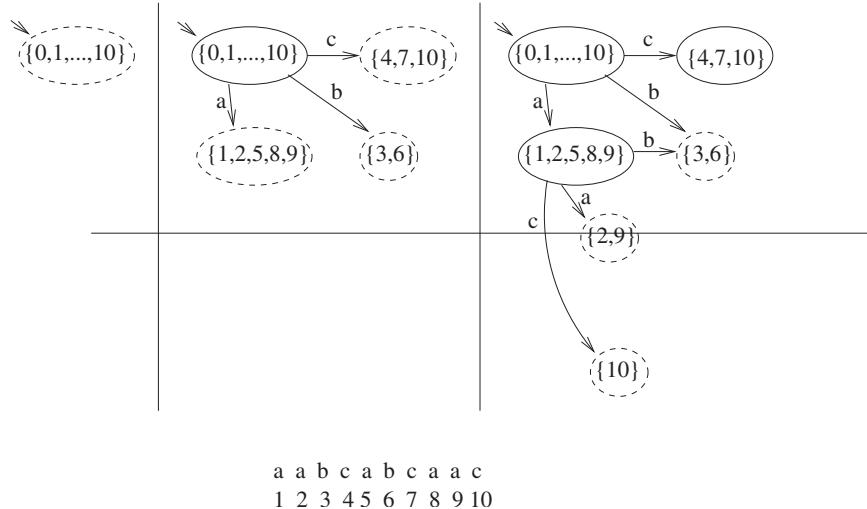

FIGURE 31.4 Illustration of the first three iterations of Algorithm 31.1 on $aabcbabcac$. Unprocessed nodes are drawn with dashed outlines. The algorithm initially creates a start state with position set $\{0, 1, \dots, n\}$ (left figure). To process the start node, it creates a copy of this position set and adds 1 to each element, yielding $\{1, 2, \dots, n+1\}$. It discards $n+1$, yielding $\{1, 2, \dots, n\}$. It partitions this into the set $\{1, 2, 5, 8, 9\}$ of positions that contain a , the set $\{3, 6\}$ of positions that contain b , and the set $\{4, 7, 10\}$ of positions that contain c , creates a node for each, and installs edges labeled with the corresponding letters to the new nodes (middle figure). To process the node v labeled $\{1, 2, 5, 8, 9\}$, it adds 1 to each element of this set to obtain $\{2, 3, 6, 9, 10\}$, and partitions them into $\{2, 9\}$, $\{3, 6\}$, and $\{10\}$. Of these, $\{2, 9\}$ and $\{10\}$ are new position sets, so a new node is created for each. It then installs edges from v to the nodes with these three position sets.

Lemma 31.3

The sum of cardinalities of the position sets of the nodes of the DAWG is $O(|t|h(t))$.

Proof. For a position i , let $N(i)$ be the number of ending position sets in which position i appears. By Lemma 31.1, position sets that contain i form a chain $\{X_1, X_2, \dots, X_{N(i)}\}$, where for each i from 1 to $N(i) - 1$, $|X_i| > |X_{i+1}|$, and a string with X_i as its ending positions must be shorter than one with X_{i+1} as its ending positions. Therefore, $|X_{\lfloor N(i)/2 \rfloor}| \geq N(i)/2$, and any string with this set as its ending position set must have length at least $\lfloor (N(i)/2) - 1 \rfloor$. This is a string whose set of ending positions is at least as large as its length, so $N(i) = O(h(t))$.

The sum of cardinalities of the position sets is given by $\sum_{i=0}^{|t|} N(i)$, since each appearance of i in a position set contributes 1 to the sum, and this sum is $O(|t|h(t))$. ■

It is easy to keep the classes as sorted linked lists. When a class X is partitioned into smaller classes, these fall naturally into smaller sorted lists in time linear in the size of X . A variety of data structures, such as tries, are suitable for looking up whether the sorted representation of a class W already occurs as the position set of a node. The time is therefore linear in the sum of cardinalities of the position sets, which is $O(|t|h(t))$ by Lemma 31.3.

31.3.2 Constructing the DAWG in Linear Time

The linear-time algorithm given in Reference 6 to construct the DAWG works incrementally by induction on the length of the string. The DAWG of a string of length 0 (the null string) is just a single start node. For $k = 0$ to $n - 1$, it iteratively performs an *induction step* that modifies the DAWG of $t[1:k]$ to obtain the DAWG of $t[1:k+c]$.

To gain insight into how the induction step must be performed, consider Figure 31.5. An occurrence of a substring of t can be specified by giving its ending position and its length. For each occurrence of a substring, it gives the number of times the substring occurs up to that point in the text, indexed by length and position. For instance, the string that has length 3 and ends at position 5 is bca . The entry in row 3, column 5 indicates that there is one occurrence of it up through position 5 of the text. There is another at position 8, and the entry at row 3 column 8 indicates that it has two occurrences up through position 8.

The lower figure, which we may call the *incremental landscape*, gives a simplified representation of the table, by giving an entry only if it differs from the entry immediately above it. Let $L[i, j]$ denote the entry in row i , column j of the incremental landscape. Some of these entries are blank; the implicit value of such an entry is the value of the first nonblank entry above it.

Ending position										
Length	0	1	2	3	4	5	6	7	8	9
	10	9	8	7	6	5	4	3	2	1
	Number of occurrences									
		1	1	1	1	1	1	1	1	1
					1	1	1	1	1	1
						1	1	1	1	1
							1	1	1	1
								1	1	1
									1	1
										1
	a	a	b	c	a	b	c	a	a	c

FIGURE 31.5 Displaying the number of occurrences of substrings in a text. In the upper figure, the entry in row i column j corresponds to the substring of length j that ends at position i in the text t , and gives the number of occurrences of the substring at position i or before. That is, it gives the number of occurrences of the substring in $t[1:i]$. Row 0 is included to reflect occurrences of the null substring, which has occurrences at $\{0, 1, \dots, n\}$.

Column k has one entry for each right-equivalence class of $t[1:k]$ that has k as an ending position. For instance, in column 8, we see the following:

1. $L[0, 8]$: A right-equivalence class for the suffix of $t[1:8]$ of length 0, namely, the empty string, which has nine occurrences ($\{0, 1, \dots, 8\}$) in $t[1:8]$.
2. $L[1, 8]$: A right-equivalence class for the suffix of $t[1:8]$ of length 1, namely, the suffix a , which has four occurrences ($\{1, 2, 5, 8\}$) in $t[1:8]$.
3. $L[4, 8]$: A right-equivalence class for suffixes of $t[1:8]$ of lengths 2 through 4, namely, $\{ca, bca, abca\}$, which have two occurrences ($\{5, 8\}$) in $t[1:8]$. The longest of these, $abca$, is given by the nonblank entry at $L[4, 8]$, and membership of the others in the class is given implicitly by the blank entries immediately below it.
4. $L[8, 8]$: A right-equivalence class for suffixes of $t[1:k]$ of lengths 5 through 8, namely, $\{cabca, bcabca, abcabc, abcabca\}$ that have one occurrence in $t[1:8]$.

We may therefore treat nonblank entries in the incremental landscape as nodes of the DAWG. Let the *height* of a node denote the length of the longest substring in its right-equivalence class; this is the height (row number) where it appears in the incremental landscape.

When modifying the DAWG of $t[1:k]$ to obtain the DAWG of $t[1:k+1]$, all new nodes that must be added to the DAWG appear in column $k+1$. However, not every node in column $k+1$ is a new node, as some of the entries reflect nodes that were created earlier.

For instance, consider Figure 31.7, which shows the incremental step from $t[1:6]$ to $t[1:7]$. One of the nodes, which represents the class $\{cabca, bcabca, abcabc, aabcabc\}$ of substrings of $t[1:7]$ that are not substrings of $t[1:6]$. It is the top circled node of column 7 in Figure 31.6. Another represents the class $Z_2 = \{c, bc, abc\}$. This appears in $L[3, 7]$. To see why this is new, look at the previous occurrence of its longest substring, abc , which is represented by $L[3, 4]$, which is blank. Therefore, in the DAWG of $t[1:6]$, it is part of a right-equivalence Z , which appears at $L[4, 4]$, and which contains a longer word, $aabc$. Since $\{c, bc, abc\}$ are suffixes of $t[1:7]$ and $aabc$ is not, they cease to be right-equivalent in $t[1:7]$. Therefore, Z must be split into two right-equivalence classes, $Z_2 = \{c, bc, abc\}$ and $Z_1 = Z - Z_2 = \{aabc\}$. Let us call this operation a *split*.

Let us say that a node is *new* in column k if it is created when the DAWG of $t[1:k]$ is modified to obtain the DAWG of $t[1:k+1]$. In Figure 31.6, a node in a column is circled if it is new in that column. In general, a node is new in column k iff it is the top node of the column or the previous occurrence of its longest member corresponds to a blank space in the incremental landscape.

An important point is that only the top two nodes of a column can be new.

Lemma 31.4

If a new node is the result of a split, only one node lies above it in its column.

Proof. Let a be the character that causes the split, and let xa be the largest string in Z_2 , and let bxa be the smallest string in $Z_1 = Z - Z_2$. Since bxa previously had the same set of ending positions as xa and now it does not, it must be that xa occurs as a suffix

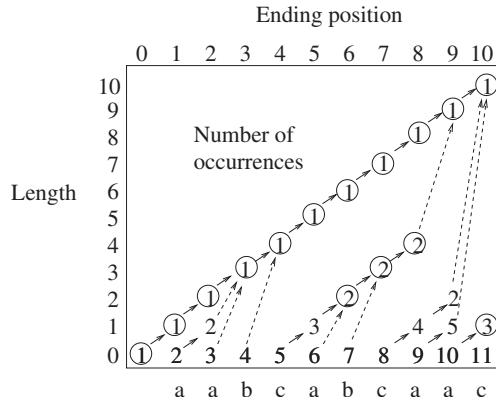

FIGURE 31.6 The incremental landscape is a simplification of the table of Figure 31.5, where an entry is displayed only if it differs from the entry above it. The entries in column i are right-equivalence classes of $t[1:i]$. These are right-equivalence classes that may be affected during the induction step, when the DAWG of $t[1:i-1]$ is modified to obtain the DAWG of $t[1:i]$. Equivalence classes of $t[i:1]$ that are not right-equivalence classes in $t[1:i]$ are circled; these correspond to nodes of the DAWG that must be created during the induction step. Edges of the DAWG of $t[1:i]$ from classes in column $i-1$ are depicted as arrows. (The distinction between solid and dashed arrows is used in the proof of Theorem 31.2.)

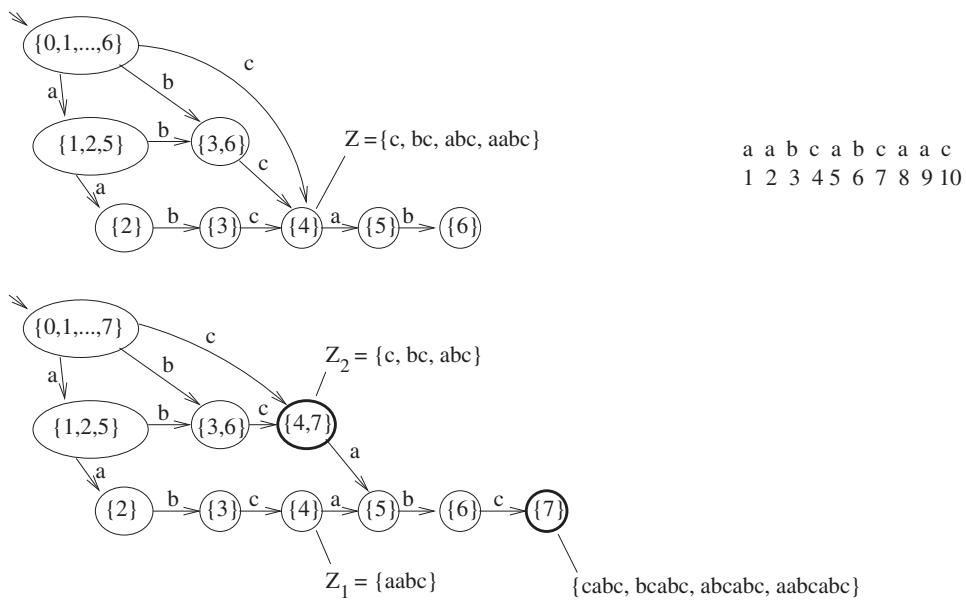

FIGURE 31.7 Modifying the DAWG of $t[1:6] = aabca$ to obtain the DAWG of $t[1:7] = aabcabc$. New nodes are shown with bold outlines. The sixth column of the incremental landscape, from top to bottom, consists of the nodes $\{6\}$, $\{3,6\}$, and the start node. The seventh column, from top to bottom, consists of $\{7\}$, $\{4,7\}$, and the start node. The node $\{4,7\}$ is split from $\{4\}$; of the strings $\{c, bc, abc, aabc\}$ that end at node $\{4\}$, only $\{c, bc, abc\}$ also occur at position 7, so these must now be handled by a different node from the one that handles $aabc$. All edges from nodes in the previous column to $\{4\}$ are redirected to the new node $\{4,7\}$.

of t_k , but bxa does not. Let cxa be the smallest string in the next higher class C in column $k+1$. On all previous occurrences of xa , it was inside bxa , so the first occurrence of cxa is at position $k+1$. The frequency of the strings in C must be 1, so C is the top class of the column. ■

The foregoing shows how nodes must be added to the DAWG in the inductive step. In order to understand how the edges of the DAWG must be modified, note that every edge directed into a node in column $k+1$ comes from a node in column k . These edges are given by the following rule:

Lemma 31.5

In the DAWG of $t[1:k+1]$, a node of height i in column k has an edge labeled t_{k+1} to the lowest node of column $k+1$ that has height greater than i .

These edges are drawn in as solid and dashed arrows in [Figure 31.6](#). According to the figure, when the DAWG of $t[1:7]$ is obtained from $t[1:6]$, the new top node in the column must have an incoming edge from the top node of column 6, which is labeled $\{6\}$ in [Figure 31.7](#). The second new node in column 7, which is labeled $\{4, 7\}$ in the figure, must have edges from the nodes at $L[0, 6]$ and $L[2, 6]$, which are the source and the node labeled $\{3, 6\}$. These are obtained by diverting edges into Z .

The induction step consists of implicitly marching in parallel down columns k and $k+1$, creating the required nodes in column t_{k+1} and installing the appropriate edges from right-equivalence classes in column k to right-equivalence classes of column $k+1$, as well as the appropriate outgoing edges and parent pointers on each right-equivalence class in column $k+1$ that is new in t_{k+1} . The new nodes in column $k+1$ are the one with frequency one, and possibly one other, Z_2 , that results from a split. By Lemma 31.4, this requires marching down through at most two nodes of column $k+1$, but possibly through many nodes of column k .

To facilitate marching down a column k efficiently, the algorithm needs a *suffix pointer* $\text{Suffix}(x)$ on each node x of column k to the next lower node in column k . If $y = y_1y_2y_3 \dots y_j$ is the shortest string in the x 's right-equivalence class, then $\text{Suffix}(x)$ points to the right-equivalence class that contains the longest proper suffix $y_2y_3 \dots y_j$ of y . The suffix pointer for each node is uniquely defined, so the algorithm ensures that suffix pointers are available on nodes of column k by keeping suffix pointers current on all nodes of the DAWG.

The induction step is given in Algorithm 31.2. The algorithm does not build the incremental landscape. However, we may identify the nodes by where they would go in the incremental landscape. The meanings of the variables can be summarized as follows. Top_k is the top node of column k , and Top_{k+1} is the top node of column $k+1$. Mid denotes the highest node of column k that already has an outgoing labeled with the $(k+1)^{\text{th}}$ letter. The variable curNode is a looping variable that travels down through nodes of column k , becoming undefined if it travels past the bottom node of the column.

Algorithm 31.2

`Update(Top_k): Update the DAWG of $t[1:k]$ to obtain the DAWG of $t[1:k+1]$.`

```

Create a node  $\text{Top}_{k+1}$  of frequency 1 and height  $k+1$ 
Let  $\text{curNode} = \text{Top}_k$ 
While  $\text{curNode}$  is defined and has no outgoing edge labeled  $t_{k+1}$ 
    Install an edge labeled  $t_{k+1}$  from  $\text{curNode}$  to  $\text{Top}_{k+1}$ 
     $\text{curNode} := \text{Suffix}(\text{curNode})$ 
If  $\text{curNode}$  is defined
     $\text{Mid} := \text{curNode}$ 
    Let  $Z$  be the neighbor of  $\text{Mid}$  on  $t_{k+1}$ 
    Define  $\text{Suffix}(\text{Top}_{k+1})$  to be  $Z$ 
    If  $\text{height}(Z) > \text{height}(\text{Mid}) + 1$ 
        Split( $k, \text{Mid}, Z$ ); Create a second new node in Column  $k+1$ 
    Else define  $\text{Suffix}(\text{Top}_{k+1})$  to be the start node
Return  $\text{Top}_{k+1}$ 
```

`Procedure $\text{Split}(k, \text{Mid}, Z)$`

Create a copy Z_2 of the node representing Z , together with its outgoing edges

Let the height of Z_2 be one plus the height of Mid

Let $\text{curNode} = \text{Mid}$

While curNode is defined and Z is its neighbor on t_{k+1}

Divert curNode 's edge labeled t_{k+1} so that it points to Z_2

$\text{curNode} := \text{Suffix}(\text{curNode})$

Redefine $\text{Suffix}(Z_2)$ to be $\text{Suffix}(Z)$

Redefine $\text{Suffix}(Z)$ to be Z_2

Theorem 31.2

It takes $O(|t|)$ time to build the DAWG of a text t of length n .

Proof. No node is ever discarded once it is created, and the final DAWG has $O(|t|)$ nodes. Therefore, the cost of creating nodes is $O(|t|)$. Once an edge is created it remains in the DAWG, though it might be diverted in calls to `Split`. No edge is ever discarded and the final DAWG has $O(|t|)$ edges, so the cost of creating edges is $O(|t|)$.

It remains to bound the cost of diverting edges in calls to `Split`. Let an edge that appears in the incremental landscape be *solid* if it goes from a node of height i to one of height $i + 1$, and *dashed* otherwise (see Figure 31.6). We may partition the edges in the landscape into *terminating paths*, each of which starts in row 0, and contains zero or more solid edges, and either followed by a dashed edge or ending in the last column. At most one terminating path begins in any column, and every dashed edge terminates a path. Thus there are at most n dashed edges.

When Z_2 is created in `Split`, at most one of the edges diverted into it is solid. The cost of diverting this edge is subsumed in the cost of creating Z_2 . The cost of diverting other edges is $O(|t|)$ over all calls to `Split`, since each of them is one of the at most n dashed edges that appear in the incremental landscape. ■

31.4 The Compact DAWG

By Theorem 31.1 and Lemma 31.3, we cannot assume that the DAWG requires linear space if the nodes are explicitly labeled with their position sets. The algorithm for building the DAWG in linear time does not label the nodes with their position sets. However, without the labels, it is not possible to use the DAWG to find the k locations where a substring p occurs in t in $O(|p| + k)$ time.

One remedy for this problem is to label a node with a position i if it represents the smallest position set that contains i as a member. The total number of these labels is n . We can reverse the directions of the suffix pointers that are installed during the DAWG construction algorithm, yielding a tree on the position sets. If a node represents a set X of positions, the members of X can be returned in $O(|X|)$ time by traversing the subtree rooted at X , assembling a list of these labels. (This tree is isomorphic to the suffix tree of the reverse of the text, but there is no need to adopt the common practice of labeling each of its edges with a string.)

Another alternative, which has considerable advantage in space requirements over the suffix tree, is to “compact” the DAWG, yielding a smaller data structure that still supports a query about the positions of a substring $O(|p| + k)$ time. The algorithm for compacting it runs in $O(|t|)$ time.

If x is a substring of t , let $\alpha(x)$ denote the longest string y such every ending position of x is also an ending position of yx . That is, y is the maximal string that precedes every occurrence of x in t . Note that $\alpha(x)$ may be the null string. Similarly, let $\beta(x)$ denote the longest string z such that every starting position of x is a starting position of xz . This is the longest string that follows every occurrence of x .

For instance, if $t = aabcabcaac$ and $x = b$, then $\alpha(x) = a$ and $\beta(x) = ca$.

Lemma 31.6

1. For x and y in a right-equivalence class, $\alpha(x)x = \alpha(y)y$ is the longest string in the class.
2. For x and y in a right-equivalence class, $\beta(x) = \beta(y)$.

Let a substring x of t be *prime* if $\alpha(x)$ and $\beta(x)$ are both the empty string. For any substring x of t , $\alpha(x)x\beta(x)$ is prime; this is the *prime implicant* of x . If x is prime, it is its own prime implicant.

Definition 31.3

The *compact DAWG* of a text t is defined as follows. The nodes are the prime substrings of t . If x is a prime substring, then for each $a \in \Sigma$ such that xa is a substring of t , let $y = \alpha(xa)$ and $z = a\beta(xa)$. There is an edge labeled z from x to the prime implicant yxz of xa .

If a right-equivalence class contains a prime substring x , then x is the longest member of the class. Stretching the terminology slightly, let us call a class *prime* if it contains a prime substring. If C is a right-equivalence class in t , we may define $\beta(C) = \beta(x)$ such that $x \in C$. By Part 2 of Lemma 31.6, $\beta(C)$ is uniquely defined. We may define C 's *prime implicant* to be the right-equivalence class D that contains $x\beta(x)$ for $x \in C$. D is also uniquely defined and contains the prime implicant of the members of C .

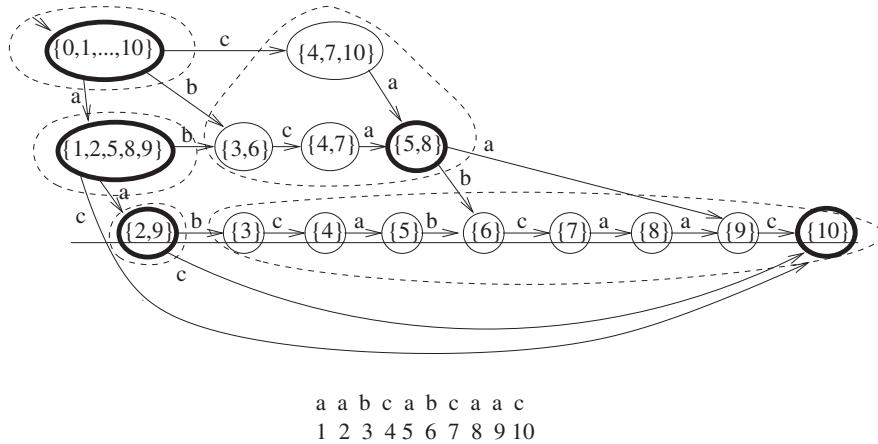

FIGURE 31.8 Partition of nodes into groups with the same prime implicant.

The nodes of the DAWG may therefore be partitioned into groups that have the same prime implicant. This is illustrated in Figure 31.8.

Lemma 31.7

A right-equivalence class is nonprime if and only if it has exactly one outgoing edge in the DAWG.

We now describe how to obtain the compact DAWG from the DAWG in linear time. For ease of presentation, we describe how to carry it out in four depth-first traversals of the DAWG. However, in practice, only two depth-first traversals are required, since the operations of the first three traversals can be carried out during a single depth-first traversal.

In the first depth-first traversal, we may label each class with a single position from its set of ending positions. This is done in postorder: when retreating from a node, copy its label from the label of any of its successors, which have already been labeled, and subtract 1 from it.

By Lemma 31.7, the prime implicant of a class is the class itself if it is prime; otherwise, it is the unique successor that is prime. Let the *distance* to its prime implicant be the length of this unique path.

In postorder during the second traversal, we may label each node with a pointer to its prime implicant and label this pointer with the distance to the prime implicant. If the class C is a sink or has more than one outgoing edge, this is just a pointer from C to itself with distance label 0. Otherwise, C has a unique successor D , which is already labeled with a pointer to D 's prime implicant A with distance label i . Label C with a pointer to A with distance label $i + 1$.

In the third traversal, we install the compact DAWG edges. If we label the edges explicitly with their string labels, we will exceed linear time and storage. Instead, we may take advantage of the fact that the label of every edge is a substring of t . We label each edge with the length of its label (see Figure 31.9). When retreating from a prime node B during the traversal, for each DAWG edge (BC) out of B , let D be C 's prime implicant, let i be the distance of D from C . Install a compact DAWG edge from B to D that has length label $i + 1$.

On the final traversal, we may remove the DAWG nodes, DAWG edges, and the prime implication pointers.

31.4.1 Using the Compact DAWG to Find the Locations of a String in the Text

Let v be a node of the compact DAWG, and let x be the corresponding prime implicant. Let the *total length* of a path from v to the sink be the sum of the length labels of the edges on the path. Observe that there is a path of total length i from v to the sink iff x has an ending position at $n - i + 1$.

Lemma 31.8

Let x be a prime substring of t , and let k be the number of occurrences of x in t . Given x 's node in the compact DAWG of t , it takes $O(k)$ time to retrieve the ending positions of x in t .

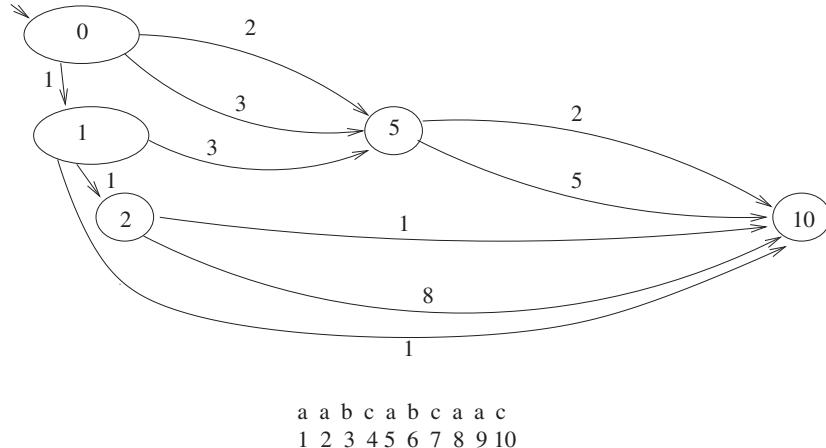

FIGURE 31.9 Representing the edge labels of the compact DAWG (cf. Figure 31.2) Each edge label is a substring of t with end positions at the end position labels of the principal nodes. The label of the edge can therefore be represented implicitly by labeling each node with one member of its position set, and labeling each edge with the length of its label. For instance, the edge labeled 3 from the source to the node labeled “5” is labeled with the substring of length 3 that ends at position 5, hence, the one occupying positions 3, 4, and 5 of the text. Since the text can be randomly accessed, the text can be used to look up the label of the edge. This ensures that the edge labels take $O(|t|)$ space, since they take $O(1)$ for each node and edge.

Proof. Recursively explore all paths out of the node, and whenever the sink is encountered, subtract the total length of the current path from $n + 1$ and return it.

The running time follows from the following observations. One position is returned for each leaf of the recursion tree; the sets of positions returned by recursive calls are disjoint; and every internal node of the recursion tree has at least two children since every node of the compact DAWG has at least two outgoing edges. ■

The representation of Figure 31.9 is therefore just as powerful as that of Figure 31.2: The edge labels are implied by accessing t using the numbers on edges and nodes, while the position labels of the vertices can be retrieved in linear time by the algorithm of Lemma 31.8.

The representation of Figure 31.9 now gives an $O(|p| + k)$ algorithm for finding the k occurrences of a substring p in a text t . One must index into the compact DAWG from the source, matching letters of p with letters of the implicit word labels of the compact edges. If a letter of p cannot be matched, then p does not occur as a subword of t . Otherwise, p is the concatenation of a set of word labels on a path, followed by part of the word label of a final edge (u, v) . This takes $O(|p|)$ time. Let i be the number of remaining unmatched letters of the word label of (u, v) . The k ending positions of p are given by subtracting i from the k ending positions of v , which can be retrieved in $O(k)$ time using the algorithm of Lemma 31.8.

For instance, using the compact DAWG of Figure 31.2 to find the locations where abc occurs, we match a to the label a of an edge out of the source to the node with position set $\{1, 2, 5, 8, 9\}$, then bc to the word label of the edge to the node labeled $\{5, 8\}$. Though the node is labeled with the position set in the picture, this position set is not available in the linear-space data structure. Instead, we find two paths of length 2 and 5 from this node to the sink, and subtracting 2 and 5 from $n = 10$ yields the position set $\{5, 8\}$. Then, since one letter in the word label bca remains unmatched, we subtract 1 from each member of $\{5, 8\}$ to obtain $\{4, 7\}$, which is the desired answer.

31.4.2 Variations and Applications

In Reference 6, a variation of the compact DAWG is given for a collection $\{t_1, t_2, \dots, t_k\}$ of texts and can be used to find the k occurrences of a string p in the texts in $O(|p| + k)$ time.

That paper also gives a symmetric version of the compact DAWG. By the symmetry in the definition of the prime subwords of t , the set of prime subwords of the reversal of t are given by reversing the set of prime subwords of t . The compact DAWG of t and of the reversal of t therefore have essentially the same set of nodes; only the edges are affected by the reversal. The symmetric version has a single set of nodes and two sets of edges, one corresponding to the edges of the compact DAWG of t and one corresponding to the edges of the reversal of t . The utility of this structure as a tool for exploring the subword structure of t is described in the paper.

Another variant occurs when t is a cyclic ordering of characters, rather than a linear one. A string p has an occurrence anywhere where it matches the subword contained in an interval on this cycle. A variant of the DAWG, compact DAWG, and compact symmetric DAWG for retrieving occurrences of subwords for t in this case is given in Reference 6. The paper gives algorithms that have time bounds analogous to those given here.

Variations of landscapes, such as that of Figure 31.6, are explored in Reference 7. They give a graphical display of the structure of repetitions in a text. The suffix tree can be used to find the longest common substring of two texts t_1 and t_2 efficiently. The paper gives $O(|t|h(t))$ algorithms that use the DAWG to generate the landscape of t (see Definition 31.2), which can be used to help identify functional units in a genomic sequence. One variation of the landscape explored in the paper inputs two texts t_1 and t_2 , and gives a graphical display of the number of occurrences of every substring of t_1 in t_2 , which has obvious applications to the study of evolutionary relationships among organisms.

Mehta and Sahni give a generalization of the compact DAWG and the compact symmetric DAWG to circular sequences is given in Reference 8, and give techniques for analyzing and displaying the structure of strings using the compact symmetric DAWG in References 9 and 10.

31.5 The Position Heap

We now give a data structure that gives much simpler algorithms, at a cost of slightly increasing the worst-case time required for a query. The algorithms can easily be programmed by undergraduate data structure students.

The data structure is a trie and has one node for each position in the text. The data structures and algorithms can be modified to give the same bounds for construction and searching, but this undermines the principal advantages, which are simplicity and low memory requirements.

The data structure is closely related to trees that are used for storing hash keys in Reference 11.

31.5.1 Building the Position Heap

Let a string be *represented* by a trie if it is the label of a path from the root in the trie.

For analyzing the position heap we adopt the convention of indexing the characters of t in descending order, so $t = t_n t_{n-1} \dots t_1$. In this case, we let $t[i:j]$ denote $t_i t_{i-1} \dots t_j$.

The algorithm for constructing the position heap can be described informally as follows. The positions of t are visited from right to left as a trie is built. At each position i , a new substring z is added to the set of words represented by the trie. To do this, the longest prefix $t[i:j]$ of $t[i:1]$ that is already represented in the trie is found by indexing into the trie from the root, using the leading letters of $t[i:1]$, until one can advance no further. A leaf child of the last node of this path is added, and the edge to it is labeled t_{i+1} .

The procedure, `PHBuild`, is given in Algorithm 31.3. Figure 31.10 gives an illustration.

$$\begin{array}{cccccccccc} 10 & 9 & 8 & 7 & 6 & 5 & 4 & 3 & 2 & 1 \\ b & b & a & b & b & b & a & a & b & a \end{array}$$

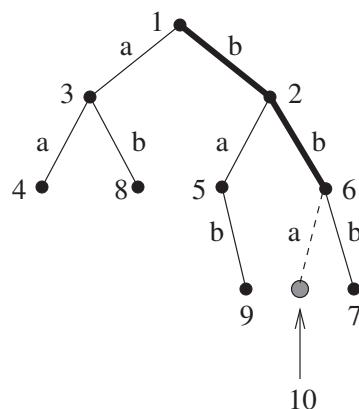

FIGURE 31.10 Construction of the position heap with `PHBuild` (see Algorithm 31.3). The solid edges reflect the recursively constructed position heap for the suffix $t[9:1]$ of t . To get the position heap for $t[10:1]$, we use the heap to find the largest prefix bb of $t[10:1]$ that is the label of a path in the tree, and add a new child at this spot to record the next larger prefix bba .

Algorithm 31.3

Constructing the Position Heap for a String $t = t_i t_{i-1} \dots t_1$

$\text{PHBuild}(t, i)$

If $i = 1$ return a single tree node labeled 1

Else

 Recursively construct the position heap H' for the suffix $t[i - 1, 1]$

 Let $t' = t[i : k]$ be the maximal prefix of t that is the

 label of a path originating at the root in the tree

 Let u be the last node of this path

 Add a child of u to the tree on edge labeled t_{k-1} , and give it label i

31.5.2 Querying the Position Heap

Algorithm 31.4 gives a procedure, PHFind , to find all starting positions of p in t , and Figure 31.11 gives an illustration. The worst-case running time of $O(|p|^2 + k)$ to find the k occurrences of p is worse than the $O(|p| + k)$ bound for the suffix tree or DAWG.

Algorithm 31.4

Find All Places in a Text t Where a Substring p Occurs, Given the Position Heap H for t

$\text{PHFind}(p, t, H)$

 Let p' be the maximal prefix of p that is the label of a path P' from the root of H

S_1 be the set of position labels in P'

 Let S_2 be the subset of S_1 that are the positions of occurrences of p in t

 If $p' \neq p$ then let S_3 be the empty set

 Else let S_3 be the position labels of descendants of the last node of P'

 Return $S_2 \cup S_3$

T: a b a a a b a b b a b a a b a

Search strings: aba and baba

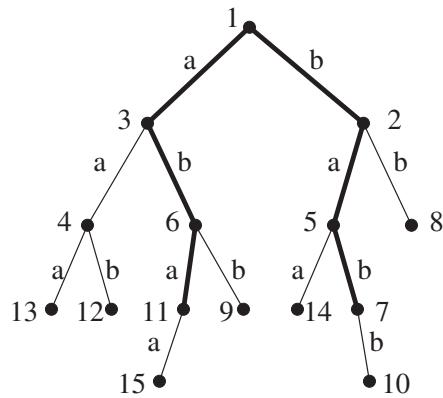

FIGURE 31.11 Searching for occurrences of a string in the text t in $O(|p|^2 + k)$ time with PHFind (see Algorithm 31.4). How the search is conducted depends on whether the search string is the path label of a node in the position heap. One case is illustrated by search string aba , which is the path label of position 11. The only places where aba may match t are at positions given by ancestors and descendants of 11. The descendants $\{11, 15\}$ do not need to be verified, but the proper ancestors $\{1, 3, 6\}$ must be verified against t at those positions. Of these, only 3 and 6 are matches. The algorithm returns $\{3, 6, 11, 15\}$. The other case is illustrated by $baba$, which is not the path label of a node. Indexing on it yields position 7 and path label $bab \neq baba$. Only the ancestors $\{2, 5, 7\}$ are candidates, and they must be verified against t . Of these, only 7 is a match. The algorithm returns $\{7\}$. Since the ancestor positions occur on the search path, there are $O(|p|)$ of them, and each takes $O(|p|)$ time to verify each of them against t . Descendants can be more numerous, but take $O(1)$ time apiece to retrieve and return, since they do not need to be verified.

Lemma 31.9

`PHFind` returns all positions where p occurs in t .

Proof. Let $p = p_1 p_2 \dots p_m$ and let $t = t_n t_{n-1} \dots t_1$. Suppose that i is a position in t where p does not occur. Then $i \notin S_2$. Any node u with position label i has a path label that is a prefix of $t[i:1]$. Since p is not a prefix of this string, it is not a prefix of the path label of u , so $i \notin S_3$. We conclude that i is not among the positions returned by `PHFind`.

Next, let h be the position of an occurrence of p . Let $x = p[1:j]$ be the maximal prefix of p that is represented in the position heap of $t[h-1:1]$, where $j = 0$ if $x = \lambda$. If $x \neq p$, then `PHBuild` created a node with position label h and path label $x p_{j+1}$. This is a prefix of p , so $h \in S_1$, and, since p occurs at position h , $h \in S_2$. If $x = p$, let $y = t[h:k]$ be the largest prefix of $t[h:1]$ that is active in $t[h-1:1]$. Then `PHBuild` created a node with position label h and path label $y t_{k-1}$, and $h \in S_3$. In either case, h is returned as a position where P occurs. ■

31.5.3 Time Bounds**Lemma 31.10**

`PHFind` takes $O(|p|^2 + k)$ worst-case time to return the k occurrences of p in t .

Proof. The members of S_3 can be retrieved in $O(1)$ time apiece using a depth-first traversal of the subtree rooted at the last node on path P' . Since all nodes of S_1 occur on a path whose label is a prefix of p , there are at most $m + 1$ members of S_1 . Checking them against t to see which are members of S_2 takes $O(|p|)$ time apiece, for a total of $O(|p|^2)$ time in the worst case. ■

This time bound overstates what can be expected in practice, since, in most cases, the string is known to match on a prefix, but there is no reason to expect that it will be similar to the position that it is supposed to match in the region beyond this prefix. A good heuristic is to match the string from the end, rather than from the beginning, since the string has a prefix that is already known to match at the position. Checking to see whether a string matches at a given position will usually require examining one or two characters, discovering a mismatch, and rejecting the string.

Lemma 31.11

`PHBuild` takes $O(|t|h(t^R))$ time.

Proof. If $P = (v_0, v_1, \dots, v_k)$ be a path from the root v_0 in the position heap, let $P_1 = (v_0, v_1, \dots, v_{\lfloor k/2 \rfloor})$, and let $P_2 = (v_{\lfloor k/2 \rfloor + 1}, v_{\lfloor k/2 \rfloor + 2}, \dots, v_k)$ be the remainder of the path. Let i be the position label of v_k , and let $h'(i)$ denote the length of the maximum prefix x of $t[i:1]$ that occurs at least $|x|$ times in t . The path label y of P_1 has an occurrence at the position labels of each of its descendants, including those on P_2 , of which there are at least $|y|$. Therefore, $|y| = O(h'(i))$. The time spent by the algorithm at position i of t is proportional to the length of P , which is $O(|y|)$. Therefore, the time spent by the algorithm adding the node for position i is $O(h'(i))$, hence the time to build the whole heap is $O(\sum_{i=1}^{|t|} h'(i)) = O(|t|h(t^R))$ by Definition 31.2. ■

As with the $O(|t|h(t))$ algorithm for building the DAWG, this time bound is a practical one in most settings, since $h(t)$ is relatively insensitive to long repeated strings or localized areas of the string with many repetitions. Only strings where most areas of the string are repeated many times elsewhere have high values of $h(t)$, and $h(t)$ can be expected to behave like an $O(\log n)$ function in most settings.

31.5.4 Improvements to the Time Bounds

In this section, we give an algorithm for constructing the position heap to $O(|t|)$. We also sketch an approach for finding the occurrences of a string p in t to $O(|p| + k)$ using position heaps. Each of these has trade-off costs, such as having greater space requirements and being harder to understand.

The position heap has a dual, which we may call the **dual heap** (see Figure 31.12). They have the same node set: a node has path label x in the heap iff its path label in the dual is the reversal x^R of x . We will refer to the position heap as the **primal heap** when we wish to contrast it to the dual.

It is tempting to think that the dual is just the position heap of the reversal t^R of t , but this is not the case. As in the primal heap, the rightmost positions of t are near the root of the dual, but in the primal heap of t^R , the leftmost positions of t are near the root. In the primal heap of t^R the heap order is inverted, which affects the shape of the tree. Neither the primal nor the dual heap of t is necessarily isomorphic to the primal or dual heap of t^R .

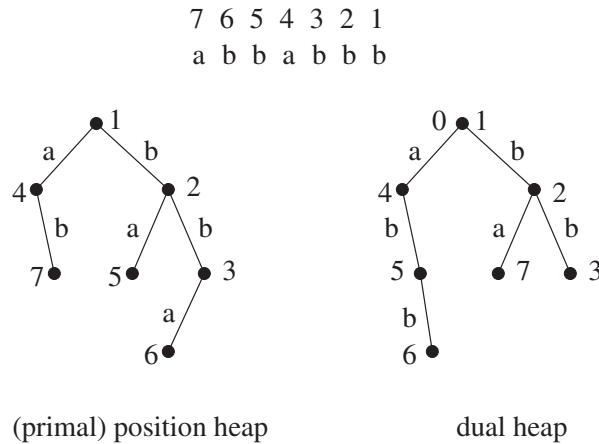

FIGURE 31.12 The position heap and the dual heap of the string *abbabbb*. The node set of both heaps is the same, but the label of the path leading to a node in the dual heap is the reverse of the label of the path leading to it in the position heap.

Algorithm 31.5

Construct the Position Heap H and its Dual D for a String $t[i : 1]$. Return (H, D, y) , Where y Is A Pointer to the Node with Position Label i .

FastPHBuild (T, i)

If $i = 1$, return a single tree node labeled 1

Let $(H', D', \nu) = \text{FastPHBuild}(t, i - 1)$

Search upward from v in H' to find the lowest ancestor v' of v that has

a child u on edge labeled t_i in the dual

Let w be the penultimate node on this path

Let $d = d_w$ be the depth of w in the heap

Create a new child y of u in the position heap on edge labeled t_{i-d}

Make y be the child of w in the dual on edge labeled t_i .

Give y position label i

Give γ depth label $d_\gamma = d + 1$

Return the modified position heap, the modified dual, and y

For `PHBuild`, the bottleneck is finding the node u whose path label is $t' = t_i t_{i+1} \dots t_k$. The dual heap allows us to carry out this step more efficiently. We get an $O(|t|)$ time bound for constructing the position heap by simultaneously constructing the position heap and its dual. It is also necessary to label each node v with its depth d_v during construction, in addition to its position label, p_v . This gives a compact representation of the path label of v if v is not the root: it is $t[p_v : p_v - d_v + 1]$.

During construction, the primal edges are directed from child to parent, while the dual edges are directed from parent to child. The modified procedure, `FastPHBuild`, is given in Algorithm 31.5.

Lemma 31.12

Fast PHBuild is correct.

Proof. The path label of v is $t[i-1:i-1-d_v+1] = t[i-1:i-d_v]$. Let $d = d_w$ be the depth of w . Since w is an ancestor of v , its path label is a prefix of this, so w 's path label is $t[i-1:i-d]$. Since v' is the parent of w , the path label of v' is the next shorter prefix, $t[i-1:i-d+1]$. The path label of v' in the dual is the reversal of this, and since u is reachable on the dual edge out of v' that is labeled t_i , the path label of u is the reversal of $t[i:i-d+1]$ in the dual, hence $t[i:i-d+1]$ in the primal heap. Since w has no child labeled t_i in the dual, there is no node whose path label in the dual is the reversal of $t[i:i-d]$, hence no node whose path label is $t[i:i-d]$ in the primal heap.

Therefore, u has path label $t[i:i-d+1]$ and has no child in the primal graph on t_{i-d} . It follows that updating the primal heap to reflect $t[i:1]$ requires adding a new child y labeled t_{i-d_2} to u in the primal heap. Since w 's path label is the longest proper suffix of y 's path label, w must be the parent of y in the dual. Since its depth is one greater than w 's, $d_y = d + 1$. ■

Lemma 31.13

`FastPHBuild` takes $O(|t|)$ time.

Proof. The inductive step takes $O(1)$ time, except for the cost of searching upward from v to find v' . Let k be the distance from v' to v and let $k' = k - 1$. The cost of searching upward is $O(k)$. The depth of the new node y is $d_{v'} + 2$, so it is $d_v - k + 2 \leq d_v + 1$. Since v is the node added just before y , the depth of each successive node added increases by at most one and decreases by $\Theta(k)$. The total increases are $O(|t|)$, so the sum of k 's overall recursive calls is bounded by this, hence also $O(|t|)$. ■

On tests we have run on several megabyte texts, `FastPHBuild` is noticeably faster than `PHBuild`. This advantage must be weighed against the fact that the algorithm is slightly more difficult to understand and uses more memory during construction, to store the dual edges.

By contrast, the algorithm we describe next for finding the positions of p in t in $O(|p| + k)$ time is unlikely to compete in practice with `PHFind`, since the worst-case bound of $O(|p|^2 + k)$ for `PHFind` overstates the typical case. However, it is interesting from a theoretical standpoint.

Let $\#$ be a character that is not in Σ . Let $t\#t$ denote the concatenation of two copies of t with the special character $\#$ in between. To obtain the time bound for `PHFind`, we may build the position heap of $t\#t$ in $O(|t|)$ time using `FastPHBuild`. Index the positions from $|t|$ to $-|t|$ in descending order. This gives 0 as the position of the $\#$ character (see Figure 31.13).

To find the starting positions of p in t , it suffices to find only its positive starting positions in $t\#t$. Suppose that there is a path labeled p that has at most one node with a positive position number. Finding the last node v of the path takes $O(|p|)$ time, and all k positive starting positions are descendants. We can retrieve them in $O(k)$ time. Since we are not required to find negative position numbers where p occurs, we do not have the $\Theta(|p|^2)$ cost of finding which ancestors of v are actual matches. This gives an $O(|p| + k)$ bound in this case.

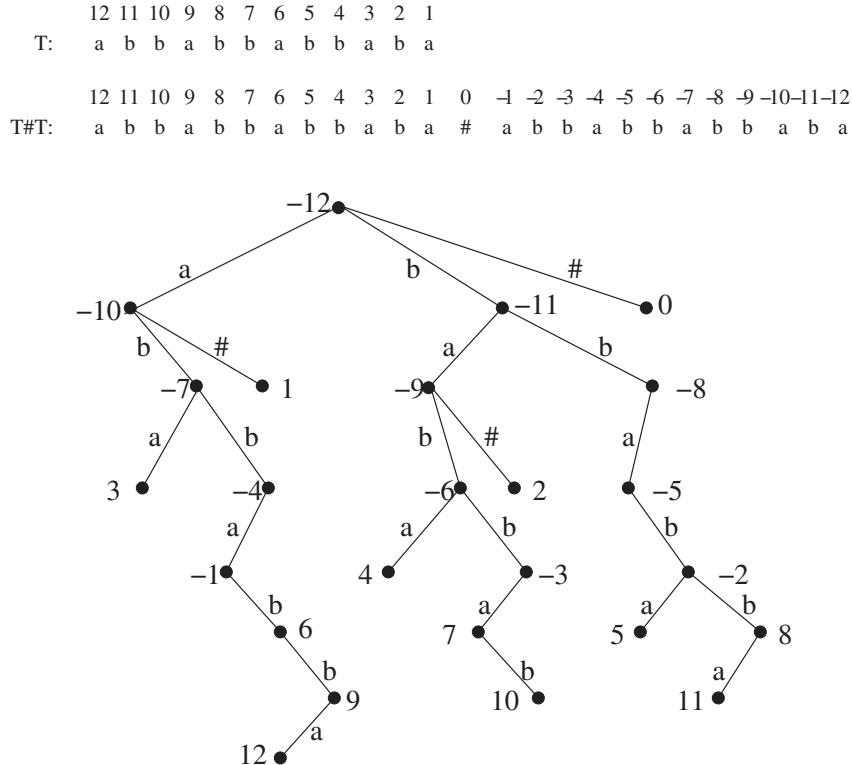

FIGURE 31.13 Finding occurrences of p in t in $O(|p| + k)$ time, using a position heap. Because of the extra memory requirements and the good expected performance of the $O(|p|^2 + k)$ approach, the algorithm is of theoretical interest only. The trick is to build the position heap of $t\#t$, indexing so that positions in the second occurrence are indexed with negative numbers. To find the occurrences of p in t , it suffices to return only its positive positions in $t\#t$. Indexing into the heap is organized so that positive positions are descendants of nodes that are indexed to. Negative occurrences, which are ancestors, do not need to be verified against the text, eliminating the $\Theta(|p|^2)$ step of the simpler algorithm.

Otherwise, the problem can be solved by chopping p into segments $\{x_1, x_2, \dots, x_k\}$ such that each x_i is the label of a path from the root in the heap that has exactly one node v_i with a positive position number, namely, the last node of the path. Every positive position of x_i is matched by a negative position, which must correspond to an ancestor of v_i . Since there are at most $|x_i|$ ancestors of v_i , v_i has at most $|x_i|$ (positive) descendants, which can be retrieved in $O(|x_i|)$ time.

To see that this implies an $O(|p|)$ time bound to return all occurrences of p in t , the reader should first note that a family \mathcal{F} of k sets X_1, X_2, \dots, X_k of integers are represented with sorted lists, it takes $O(|X_1| + |X_2| + \dots + |X_k|)$ time to find their intersection. The key to this insight is that when two sets in \mathcal{F} are merged, replacing them with their intersection, the sum of cardinalities of sets in \mathcal{F} drops by an amount proportional to the time to perform the intersection. Therefore, the bound for all intersections is proportional to the sum of cardinalities of the initial lists. The problem of finding the occurrences of p reduces to this one as follows. Let X_i denote the positive positions of segment x_i of p . Shift these positions to the left by $|x_1 x_2 \dots x_{i-1}|$ to find the candidate positions they imply for the left endpoint of p in t . Intersecting the sets of candidates gives the locations of p in t .

To find the substrings $\{x_1, x_2, \dots, x_k\}$ of p , index from the root of the position heap on the leading characters of p until a positive node is reached. The label of this path is x_1 , and recursing on the remaining suffix of p gives $\{x_2, x_3, \dots, x_{k-1}\}$. It doesn't give x_k , since an attempt to produce x_k in this way it may run out of characters of p before a node with a positive position number is reached. Instead, find x_k by indexing from the right end of p using the dual heap until a positive position number is reached. Therefore, $\{x_1, x_2, \dots, x_{k-1}\}$ represent disjoint intervals of p , while x_{k-1} and x_k can represent overlapping intervals of p . The sum of their lengths is therefore $O(|p|)$, giving an $O(|p|)$ bound to find all occurrences of p in t in this case.

32.1 Introduction

Binary decision diagrams (BDDs) are a powerful means for computer processing of Boolean functions because in many cases, with BDDs, smaller memory space is required for storing Boolean functions, and values of functions can be calculated faster than with truth tables or logic expressions. The BDD-based techniques are now used in many application areas in computer science, for example, hardware/software system design, fault analysis of large-scale systems, constraint satisfaction problems, data mining/knowledge discovery, machine learning/classification, bioinformatics, and web data analysis.

Systematic methods for Boolean function manipulation were first studied by Shannon in 1938 [40], who applied Boolean algebra to logic network design. The concept of BDD was devised by Lee in 1959 [22]. Binary decision programs that Lee discussed are essentially BDDs. Then, in 1978, its usefulness for expression Boolean functions was shown by Akers [1]. But since the epoch-making paper by Bryant in 1986 [6], BDD-based methods have been extensively used for many practical applications.

BDD was originally developed for the efficient Boolean function manipulation required in VLSI logic design, but Boolean functions are also used for modeling many kinds of combinatorial problems. Zero-suppressed BDD (ZDD) [29] is a variant of BDD, customized for manipulating “sets of combinations.” ZDDs have been successfully applied not only for VLSI design but also for solving various combinatorial problems, such as constraint satisfaction, frequent pattern mining, and graph enumeration. Recently, BDD and ZDD become more widely known, since Knuth intensively discussed BDD/ZDD-based algorithms in a volume of his book series [19].

Although a quarter of a century has passed since Bryant first put forth his idea, there are still many interesting research topics related to BDD and ZDD. For example, Knuth presented a very fast algorithm “SimpPath” [19] to construct a ZDD which represents all the paths connecting two points in a given graph structure. This work is important since it may have many useful applications. Another example of recent activity is to extend BDDs to represent other kinds of discrete structures, such as sequences and permutations. In this context, new variants of BDDs called sequence BDD [22] and π DD [32] have recently been proposed and the scope of BDD-based techniques is now increasing.

In this chapter, we discuss the basic data structures and algorithms for manipulating BDDs. Then we describe the variable ordering problem, which is important for the effective use of BDDs. Finally we give a brief overview of the recent research activities related to BDDs.

32.2 Basic Concepts

From a truth table, we can easily derive the corresponding BDD. For example, the truth table in Figure 32.1a can be converted into the BDD in Figure 32.1b. But there are generally many BDDs for a given truth table, that is, the Boolean function expressed by

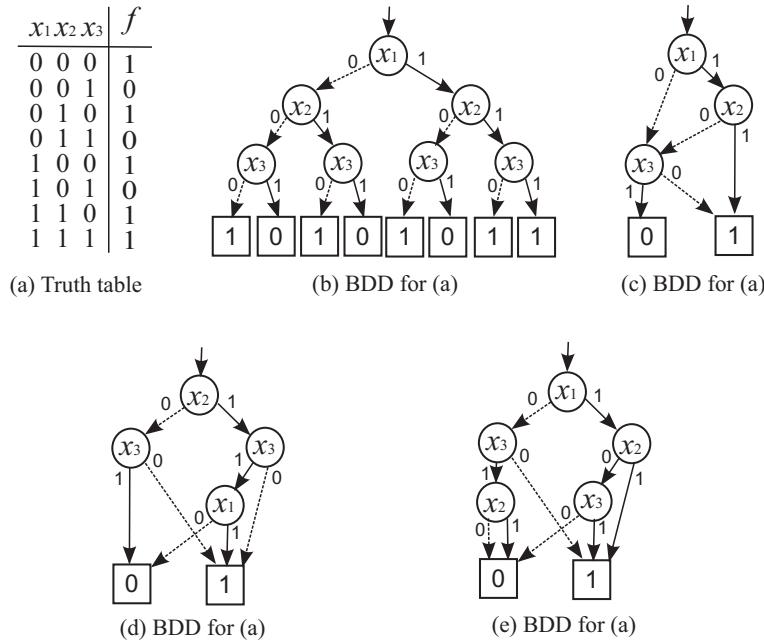

FIGURE 32.1 Truth table and BDDs for $(x_1 \wedge x_2) \vee \bar{x}_3$.

this truth table. For example, all BDDs shown in Figure 32.1c–e represent the Boolean function that the truth table in Figure 32.1a expresses. Here, note that in each of Figures 32.1b–d, the variables appear in the same order and none of them appears more than once in every path from the top node. But in (e), they appear in different orders in different paths. BDDs in Figures 32.1b–d are called **ordered BDDs** (or OBDDs). But the BDD in Figure 32.1(e) is called an **unordered BDD**. These BDDs can be reduced into a simple BDD by the following procedure.

In a BDD, the top node is called the **root** that represents the given function $f(x_1, x_2, \dots, x_n)$. Rectangles that have 1 or 0 inside are called **terminal nodes**. They are also called **1-terminal** and **0-terminal**. Other nodes are called **nonterminal nodes** (or **decision nodes**) denoted by circles with variables inside. They are also called simply **nodes**, differentiating themselves from the 0- and 1-terminals. From a node with x_i inside, two lines go down. The solid line is called **1-edge**, representing $x_i = 1$; and the dotted line is called **0-edge**, representing $x_i = 0$.

In an OBDD, the value of the function f can be evaluated by following a path of edges from the root node to one of the terminal nodes. If the nodes in every path from the root node to a terminal node are assigned with variables, x_1, x_2, \dots , and x_n , in this order, then f can be expressed as follows, according to the Shannon expansion. By branching with respect to x_1 from the root node, $f(x_1, x_2, \dots, x_n)$ can be expanded as follows, where $f(0, x_2, \dots, x_n)$ and $f(1, x_2, \dots, x_n)$ are functions that the nodes at the low ends of 0-edge and 1-edge from the root represent, respectively:

$$f(x_1, x_2, \dots, x_n) = (\bar{x}_1 \wedge f(0, x_2, \dots, x_n)) \vee (x_1 \wedge f(1, x_2, \dots, x_n))$$

Then, by branching with respect to x_2 from each of the two nodes that $f(0, x_2, \dots, x_n)$ and $f(1, x_2, \dots, x_n)$ represent, each $f(0, x_2, \dots, x_n)$ and $f(1, x_2, \dots, x_n)$ can be expanded as follows:

$$f(0, x_2, \dots, x_n) = (\bar{x}_2 \wedge f(0, 0, x_2, \dots, x_n)) \vee (x_2 \wedge f(0, 1, x_2, \dots, x_n))$$

and

$$f(1, x_2, \dots, x_n) = (\bar{x}_2 \wedge f(1, 0, x_2, \dots, x_n)) \vee (x_2 \wedge f(1, 1, x_2, \dots, x_n))$$

and so on.

As we go down from the root node toward the 0- or 1-terminal, more variables of f are set to 0 or 1. Each term excluding x_i or \bar{x}_i in each of these expansions (i.e., $f(0, x_2, \dots, x_n)$ and $f(1, x_2, \dots, x_n)$ in the first expansion, $f(0, 0, \dots, x_n)$ and $f(0, 1, \dots, x_n)$ in the second expansion, etc.), are called **cofactors**. Each node at the low ends of 0-edge and 1-edge from a node in an OBDD represents cofactors of the **Shannon expansion** of the Boolean function at the node, from which these 0-edge and 1-edge come down.

Procedure 32.1

Reduction of a BDD

1. For the given BDD, apply the following steps in any order.
 - a. Sharing equivalent nodes: If two nodes v_a and v_b , that represent the same variable x_i , branch to the same nodes in a lower level for each of $x_i = 0$ and $x_i = 1$, then combine them into one node that still represents variable x_i (see [Figure 32.2](#)). Similarly, two terminal nodes with the same value, 0 or 1, are merged into one terminal node with the same original value.
 - b. Deleting redundant nodes: If a node that represents a variable x_i branches to the same node in a lower level for both $x_i = 0$ and $x_i = 1$, then that node is deleted, and the edges that come down to the former are extended to the latter (see [Figure 32.3](#)).
2. When we cannot apply any step after repeatedly applying these steps (a) and (b), the **reduced ordered BDD** (i.e., ROBDD) or simply called the **reduced BDD** is obtained for the given function.

In [Figure 32.4](#), we show an example of applying the BDD reduction rules, starting from the same BDD shown in [Figure 32.1b](#).

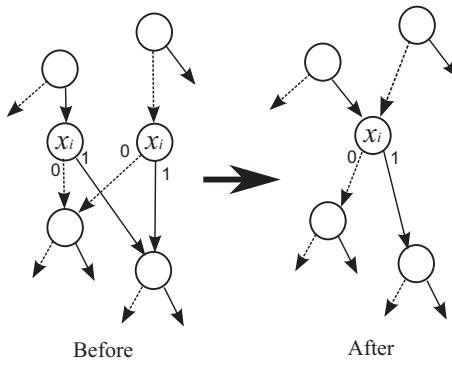

FIGURE 32.2 Step 1(a) of Procedure 32.1 (node sharing rule).

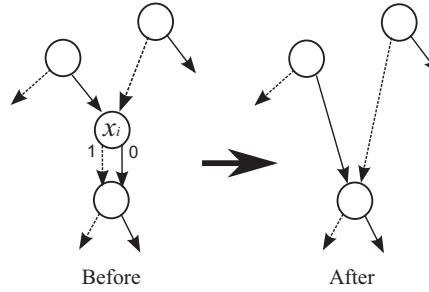

FIGURE 32.3 Step 1(b) of Procedure 32.1 (node deletion rule).

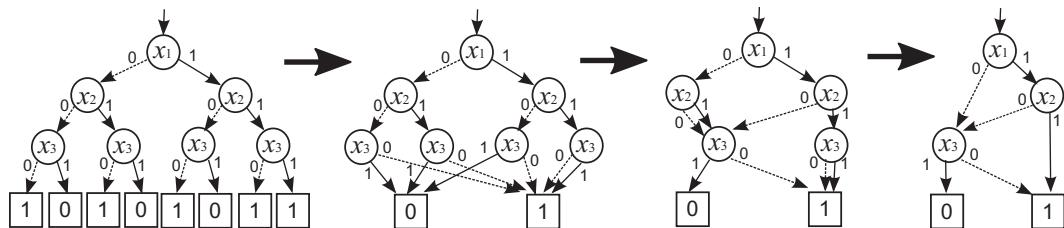

FIGURE 32.4 An example of applying node reduction rules.

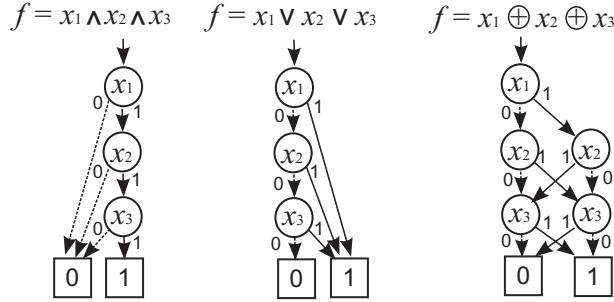

FIGURE 32.5 BDDs for typical Boolean functions.

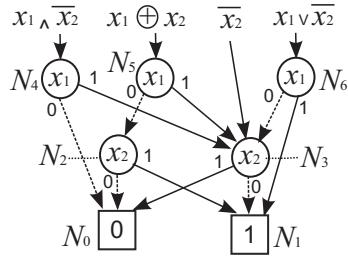

FIGURE 32.6 A shared BDD.

Theorem 32.1

Any Boolean function has a unique reduced ordered BDD and any other ordered BDD for the function in the same variable order (i.e., not reduced) has more nodes.

According to this theorem, the ROBDD is unique for a given Boolean function when the order of the variables is fixed. Thus ROBDDs give canonical forms for Boolean functions. This property is very important to practical applications, as we can easily check the equivalence of two Boolean functions by only checking the isomorphism of their ROBDDs. **Henceforth in this chapter, ROBDDs will be referred to as BDDs for the sake of simplicity.**

It is known that a BDD for an n -variable function requires an exponentially increasing memory space in the worst cases, as n increases [6]. However, the size of memory space for the BDD varies with the types of functions, unlike truth tables which always require memory space proportional to 2^n . But many Boolean functions that we encounter in design practice can be represented in BDDs without large memory space. This is an attractive feature of BDDs. Figure 32.5 shows the BDDs representing typical functions, AND, OR, and the parity function with three input variables. The parity function for n variables, $x_1 \oplus x_2 \oplus \dots \oplus x_n$, can be represented in the BDD of $2(n - 1) +$ decision nodes and 2 terminals, whereas, if a truth table or a logic expression is used, the size increases exponentially as n increases.

A set of BDDs representing many functions can be obtained into a graph that consists of BDDs sharing subgraphs among them, as shown in Figure 32.6. This idea saves time and space for duplicating isomorphic BDDs. By sharing all the isomorphic subgraphs completely, no two nodes that express the same function coexist in the graph. We call it **shared BDDs** [29] or **multirooted BDDs**. In a shared BDD, no two root nodes express the same function.

Shared BDDs are now widely used and those algorithms are more concise than ordinary BDDs. In the remainder of this chapter, we deal with shared BDD only.

32.3 Data Structure

In a typical realization of a BDD manipulator, all the nodes are stored in a single table in the main memory of the computer. Figure 32.7 is a simple example of realization for the shared BDD shown in Figure 32.6. Each node has three basic attributes: input variable and the next nodes accessed by 0- and 1-edges. Also, 0- and 1-terminals are first allocated in the table as special nodes. The other nonterminal nodes are created one by one during the execution of logic operations.

(nodeID)	variable	0-edge	1-edge	(function)
N_0	—	—	—	$\leftarrow \emptyset$
N_1	—	—	—	$\leftarrow \top$
N_2	x_2	N_0	N_1	$\leftarrow \bar{x}_2$
N_3	x_2	N_1	N_0	$\leftarrow x_1 \wedge \bar{x}_2$
N_4	x_1	N_0	N_3	$\leftarrow x_1 \oplus x_2$
N_5	x_1	N_2	N_3	$\leftarrow x_1 \vee \bar{x}_2$
N_6	x_1	N_3	N_1	

FIGURE 32.7 Table-based realization of a shared BDD.

Before creating a new node, we check the reduction rules of Procedure 32.1. If the 0- and 1-edges go to the same next node (Step 1(b) of Procedure 32.1) or if an equivalent node already exists (Step 1(a) of Procedure 32.1), then we do not create a new node but simply copy the pointer to the existing node. To find an equivalent node, we check a table which displays all the existing nodes. The hash table technique is very effective to accelerate this checking. (It can be done in a constant time for any large-scale BDDs, unless the table overflows in main memories.) The procedure to get a decision node is summarized as follows.

Procedure 32.2

GetNode(variable x , 0-edge to f_0 , 1-edge to f_1)

1. If ($f_0 = f_1$), just return f_0 .
2. Check the hash table, and if an equivalent node f is found, then return f .
3. If no more available space, return by memory overflow error, otherwise, create a new node f with the attribute (x, f_0, f_1) and return f .

In manipulating BDDs for practical applications, we sometimes generate many intermediate (or temporary) BDDs. It is important for memory efficiency to delete such unnecessary BDDs. In order to determine the necessity of the nodes, a **reference counter** is attached to each node, which shows the number of incoming edges to the node.

In a typical implementation, the BDD manipulator consumes 30–40 bytes of memory for each node. Today, there are personal computers with 32 or 64 Gbytes of memory, and those facilitate us to generate BDDs containing as many as billions of nodes. However, the BDDs still grow beyond the memory capacity in some practical applications.

32.4 Construction of BDDs from Boolean Expressions

Procedure 32.1 shows a way of constructing compact BDDs from the truth table for a function f of n variables. This procedure, however, is not efficient because the size of its initial BDD is always of the order of 2^n , even for a very simple function. In order to avoid this problem, Bryant [6] presented a method of constructing BDDs by applying a sequence of logic operations in a Boolean expression.

Figure 32.8 summarizes the list of primitive operations for constructing and manipulating BDDs. Using these operations, we can construct BDDs for an arbitrary Boolean expression. This method is generally far more efficient than that based on a truth table.

\emptyset	Returns the constant-0 function. (0-terminal node)
\top	Returns the constant-1 function. (1-terminal node)
$var(x)$	Returns a primitive function for the variable x . (a single decision node)
$f \wedge g$	Logical AND operation.
$f \vee g$	Logical OR operation.
$f \oplus g$	EXOR operation.
\bar{f}	Logical NOT operation.
$f_{(x=0)}, f_{(x=1)}$	Returns a sub-function of f when variable $x = 0$ or $x = 1$, respectively.
$f.top$	Returns the variable of the root node of f .
$f.count$	Returns the number of input assignments that satisfy $f = 1$.

FIGURE 32.8 Primitive operations for BDD manipulation.

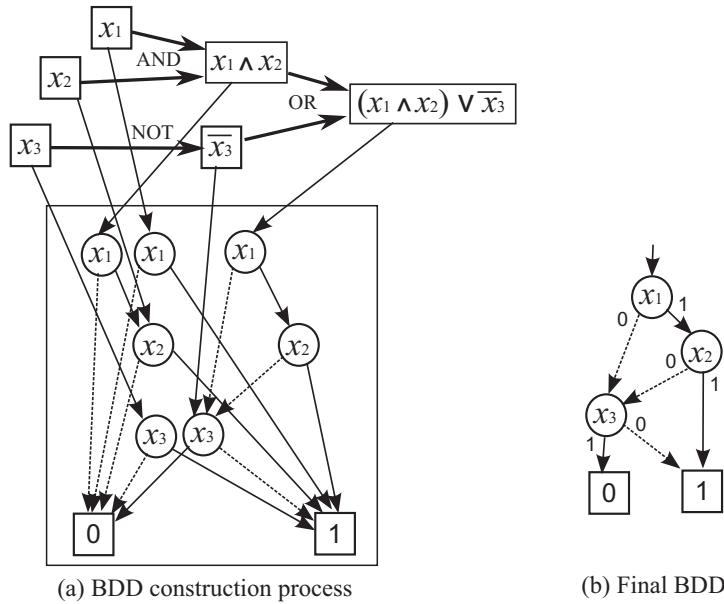

FIGURE 32.9 Constructing BDDs for $f = (x_1 \wedge x_2) \vee \overline{x_3}$.

Figure 32.9 shows a simple example of constructing a BDD for $f = (x_1 \wedge x_2) \vee \overline{x_3}$. First, trivial BDDs for x_1, x_2 , and x_3 are created in Figure 32.9a. Next, applying the AND operation between x_1 and x_2 , the BDD for $(x_1 \wedge x_2)$ is then generated. The BDD for $\overline{x_3}$ can be derived by applying NOT operation to the BDD for x_3 . Then the BDD for the entire expression is obtained as the result of the OR operation between $(x_1 \wedge x_2)$ and $\overline{x_3}$. After deleting the nodes that are not on the paths from the root node for f toward the 0- or 1-terminal, the final BDD is obtained as shown in Figure 32.9b.

In the following, we describe a formal procedure for generating a BDD by applying binary logic operation between two BDDs.

32.4.1 Binary Logic Operation

Suppose we perform a binary operation between two functions f and g , and this operation is denoted by $f \circ g$, where \circ is one of OR, AND, EXOR, and others. Then by the Shannon expansion of a function explained previously, $f \circ g$ can be expanded as follows:

$$f \circ g = \overline{x_i} (f_{(x_i=0)} \circ g_{(x_i=0)}) \vee x_i (f_{(x_i=1)} \circ g_{(x_i=1)})$$

with respect to variable x_i , which is the variable of the node that is in the highest level among all the nodes in f and g . This expansion creates a new decision node with the variable x_i having 0- and 1-edges pointing to the two nodes generated by suboperations $(f_{(x_i=0)} \circ g_{(x_i=0)})$ and $(f_{(x_i=1)} \circ g_{(x_i=1)})$. This formula means that the operation can be expanded to the two sub-operations $(f_{(x_i=0)} \circ g_{(x_i=0)})$ and $(f_{(x_i=1)} \circ g_{(x_i=1)})$. Repeating this expansion recursively for all the variables, as we go down toward the 0- or 1-terminal, we will have eventually trivial operations, such as $f \cdot 1 = f, f \oplus f = 0$, and $0 \vee g = g$, and the result is obtained.

The procedure of constructing $h \circ f \circ g$ is summarized as follows. Here f_0 and f_1 are the BDDs pointed to by the 0- and 1-edges from the root node of f .

Procedure 32.3

Construction of a BDD for Function $h \circ f \circ g$, given BDDs for f and g

1. When f or g is a constant or when $f = g$:
return a result according to the type of the operation
(e.g., $f \cdot 1 = f, f \oplus f = 0, 0 \vee g = g$)
2. If $f.top$ and $g.top$ are identical:
 $h_0 \leftarrow f_0 \circ g_0; h_1 \leftarrow f_1 \circ g_1;$
 $h \leftarrow \text{GetNode}(f.top, h_0, h_1)$
3. If $f.top$ is higher than $g.top$:
 $h_0 \leftarrow f_0 \circ g; h_1 \leftarrow f_1 \circ g;$
 $h \leftarrow \text{GetNode}(f.top, h_0, h_1)$

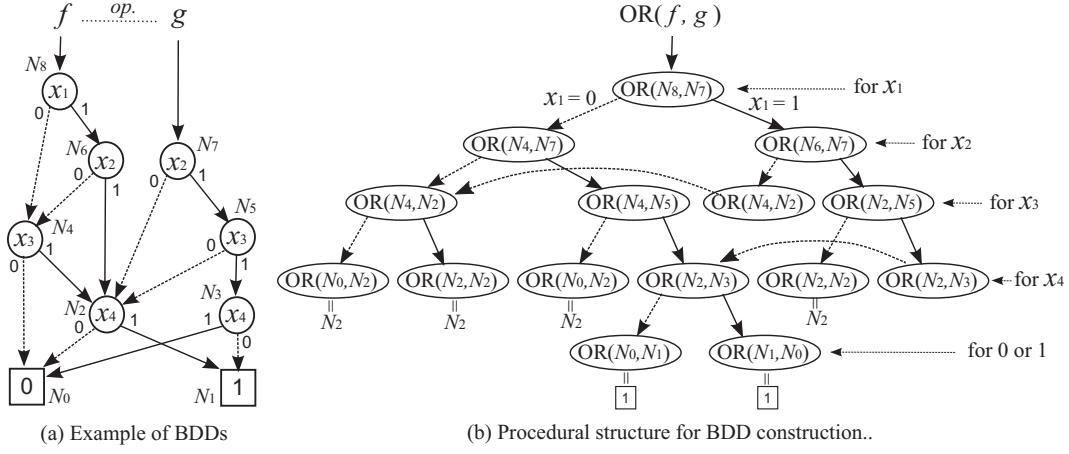

FIGURE 32.10 Procedural structure of generating BDDs for $h = f \vee g$.

4. If $f.top$ is lower than $g.top$:
compute similarly to 3 by exchanging f and g .

As mentioned in the previous section, we check the BDD reduction rules before creating a new nodes to avoid duplication of the equivalent nodes.

Figure 32.10a shows an example of execution. When we perform the operation between the node N_8 and N_7 , the procedure is broken down into the binary tree, as shown in Figure 32.10b. We usually execute the procedure calls according to this tree structure in a depth-first manner, and it may require an exponential time for the number of variables. However, some of these subtrees may be redundant; for instance, the operations of $N_4 - N_2$ and $N_2 - N_3$ appear more than once. We can accelerate the procedure by using a hash-based cache that memorizes the results of recent operations. We call it **operation cache**. By referring to the operation cache before every recursive call, we can avoid duplicate executions for equivalent suboperations. This technique enables the binary logic operations to be executed in a time almost proportional to the total size of BDDs for f , g , and h . (For detailed discussions, refer the article [45].)

It is too memory-consuming to keep all the operation results for any different pairs of BDD nodes, therefore, we usually prepare a limited size of the operation cache. If some of operation results have been lost, then some number of redundant suboperations may be called, but anyway, the correct BDD can be constructed by applying BDD reduction rules. The size of operation cache has a significant influence to the performance of BDD manipulation. If the cache size is insufficient, the more redundant procedure calls increase, the more results are overwritten, and the total execution time grows rapidly. Usually we set up the cache size empirically, for instance, it is proportional to the total number of BDD nodes created in the system.

32.4.2 Complement Edges

A BDD for \bar{f} , the complement of f , has a form similar to that of the BDD for f : just the 0- and the 1-terminals are exchanged. Complemental BDDs contain the same number of nodes, in contrast to the conjunctive/disjunctive normal forms (CNFs/DNFs), which sometimes suffer an exponential increase of the data size.

By using binary logic operation ($f \oplus 1$), we can generate a BDD for \bar{f} in a linear time for the BDD size. However, the operation is improved to a constant time by using **complemented edges**. The complemented edge is a technique to reduce computation time and space for BDDs by using attributed edges that indicate to complement the function of the subgraph pointed to by the edge, as shown in Figure 32.11a. This idea was first shown by Akers [1] and later discussed by Madre et al. [23]. Today, this technique is commonly used in most of BDD packages. The use of complement edges brings the following outstanding merits:

- The BDD size is reduced by up to half.
- NOT operation can be performed in a constant time.
- Binary logic operations are sped up by applying the rules, such as $f \wedge \bar{f} = 0$, $f \vee \bar{f} = 1$, and $f \oplus \bar{f} = 1$.

Use of complement edges may break the uniqueness of BDDs. Therefore, we have to put the two rules as illustrated in Figure 32.11b:

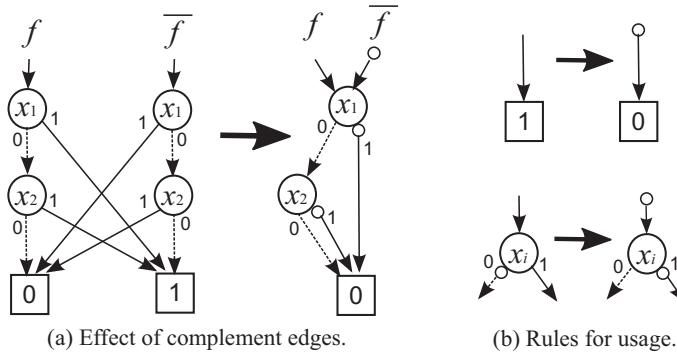

FIGURE 32.11 Complement edges.

- Using the 0-terminal only
- Not using a complement edges at the 0-edge of any node (i.e., it can be used at 1-edge only). If necessary, the complement edges can be carried over to higher nodes.

32.5 Variable Ordering for BDDs

BDDs are a canonical representation of Boolean functions under a fixed order of input variables. A change of the order of variables, however, may yield different BDDs of significantly different sizes for the same function. The effect of variable ordering depends on Boolean functions, sometimes dramatically changing the size of BDDs. Variable ordering is an important problem in using BDDs.

It is generally very time-consuming to find the best order. Friedman et al. presented an algorithm [15] of $O(n^2 3^n)$ time based on dynamic programming, where n is the number of variables. Although this algorithm has been improved [12], existing methods are limited to run on the small size of BDDs with up to about 20 variables. This problem is known as an NP-complete problem [44], and it would be difficult to find the best order for larger problems in reasonably short processing time. However, if we can find a fairly good order, it is useful for practical applications. There are many research works on heuristic methods of variable ordering.

Empirically, the following properties are known on the variable ordering.

1. Closely-related variables:

Variables that are in close relationship in a Boolean expression should be close in variable order. For example, the Boolean function of AND-OR two-level logic $(x_1 \wedge x_2) \vee (x_3 \wedge x_4) \vee \dots \vee (x_{2n-1} \wedge x_{2n})$ has a BDD with $2n$ decision nodes in the best order as shown for $n=4$ in Figure 32.12a, while it needs $(2^{(n+1)} - 2)$ nodes in the worst order, as shown in Figure 32.12b.

2. Influential variables:

The variables that greatly influence the nature of a function should be at higher position. For example, the 8-to-1 data selector shown in Figure 32.13a can be represented by a linear size of BDD when the three control inputs are ordered high, but when the order is reversed, it becomes of exponentially increasing size as the number of variables increases, as shown in Figure 32.13b.

Based on empirical rules like this, Fujita et al. [13] and Malik et al. [25] presented methods; in these methods, an output of the given logic networks is reached, traversing in a depth-first manner, then an input variable that can be reached by going back toward the inputs of the network is placed at highest position in variable ordering. Minato [33] devised another heuristic method based on a weight propagation procedure for the given logic network. Butler et al. [5] proposed another heuristic based on a measure which uses not only the connection configuration of the network but also the output functions of the network. These methods probably find a good order before generating BDDs. They find good orders in many cases, but there is no method that is always effective to a given network.

Another approach reduces the size of BDDs by reordering input variables. A greedy local exchange (swapping adjacent variables) method was developed by Fujita et al. [14]. Minato [28] presented another reordering method which measures the width of BDDs as a cost function. In many cases, these methods find a fairly good order using no additional information. A drawback of the approach of these methods is that they cannot start if an initial BDD is too large.

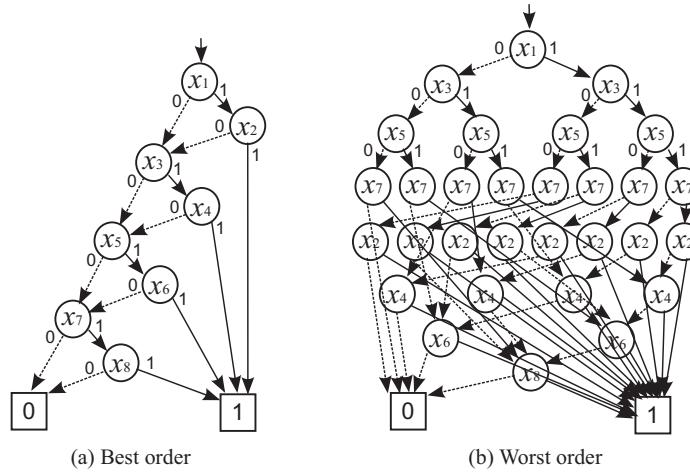

FIGURE 32.12 BDDs for $(x_1 \wedge x_2) \vee (x_3 \wedge x_4) \vee (x_5 \wedge x_6) \vee (x_7 \wedge x_8)$.

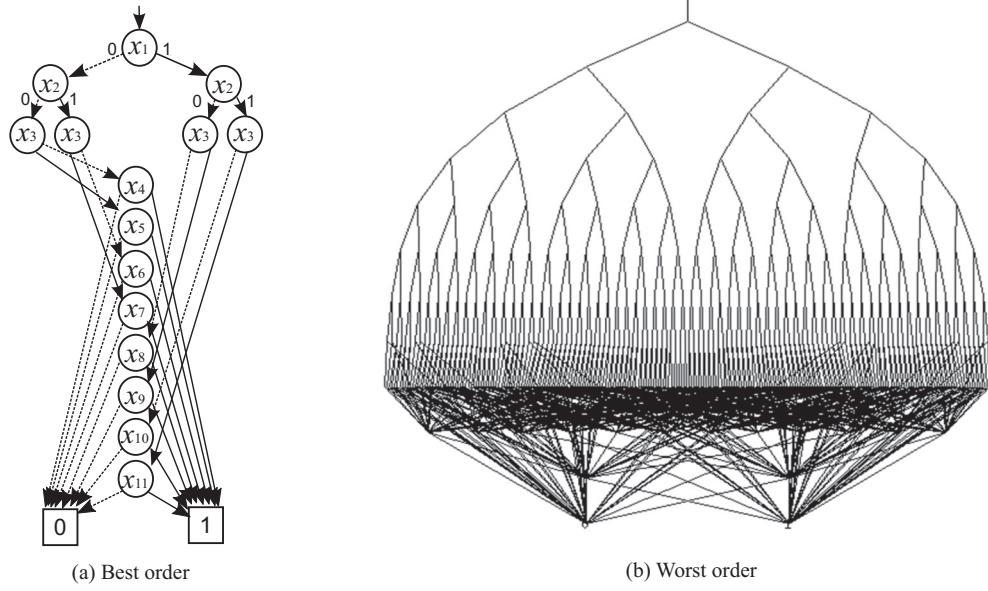

FIGURE 32.13 BDDs for 8-to-1 data selector.

One remarkable work is **dynamic variable ordering**, presented by Rudell [39]. In this technique, the BDD manipulation system itself determines and maintains the variable order. Every time the BDD grows to a certain size, the reordering process is invoked automatically. This method is very effective in terms of the reduction of BDD size, although it sometimes takes a long computation time.

Unfortunately, there are some hard examples where variable ordering is powerless. For example, Bryant [6] proved that an n -bit multiplier function requires an exponentially increasing number of BDD nodes for any variable order, as n increases. From a theoretical viewpoint, the total number of different n -input Boolean functions is 2^{2^n} , and the number of permutation of n variables is only $n!$, which is much less than 2^{2^n} . This means that after variable ordering, the variation of Boolean functions is still a double exponential number, and we still need exponential size of data structure in the worst case to distinguish all the functions. Thus we expect that the variable ordering methods would not be effective for generally randomized functions. However, empirically we can say that, for many practical functions, the variable ordering methods are very useful for generating a small size of BDDs in a reasonably short time.

32.6 Zero-Suppressed BDDs

BDDs are originally developed for handling Boolean function data, however, they can also be used for implicit representation of combinatorial sets. Here we call **set of combinations** for a set of elements each of which is a combination out of n items. This data model often appears in real-life problems, such as combinations of switching devices, Boolean item sets in the database, and combinatorial sets of edges or nodes in the graph data model.

A set of combinations can be mapped into Boolean space of n input variables. If we choose any one combination of items, a Boolean function determines whether the combination is included in the set of combinations. Such Boolean functions are called *characteristic functions*. The set operations such as union, intersection, and difference can be performed by logic operations on characteristic functions. [Figure 32.14](#) shows an example of the Boolean function corresponding to the set of combinations $F = \{ac, b\}$.

By using BDDs for characteristic functions, we can manipulate sets of combinations efficiently. They can be generated and manipulated within a time roughly proportional to the BDD size. When we handle many combinations including similar patterns (subcombinations), BDDs are greatly reduced by node sharing effect, and sometimes an exponential reduction benefit can be obtained.

Zero-suppressed BDD (ZDD or ZBDD) [29,30] is a special type of BDD for efficient manipulation of sets of combinations. [Figure 32.15](#) shows an example of BDD and ZDD for the same set of combinations $F = \{ac, b\}$.

ZDDs are based on the following special reduction rules:

- Delete all nodes whose 1-edge directly points to the 0-terminal node, and jump through to the 0-edge's destination, as shown in [Figure 32.16](#)
- Share equivalent nodes as well as ordinary BDDs.

Notice that we do not delete the nodes whose two edges point to the same node, which used to be deleted by the original rule. The zero-suppressed deletion rule is asymmetric for the two edges, as we do not delete the nodes whose 0-edge points to a terminal node. It is proved that ZDDs also give canonical forms as well as ordinary BDDs under a fixed variable ordering.

Here we summarize the features of ZDDs.

- In ZDDs, the nodes of irrelevant items (never chosen in any combination) are automatically deleted by ZDD reduction rule. In ordinary BDDs, irrelevant nodes still remain and they may cause unnecessary computation.
- ZDDs are especially effective for representing sparse combinations. If the average appearance ratio of each item is 1%, ZDDs are possibly up to 100 times more compact than ordinary BDDs. Such situations often appear in real-life problems,

a	b	c	F
0	0	0	0
0	0	1	0
0	1	0	1
0	1	1	0
1	0	0	0
1	0	1	1
1	1	0	0
1	1	1	0

As a Boolean function:

$$F = (a \wedge \bar{b} \wedge c) \vee (\bar{a} \wedge b \wedge \bar{c})$$

As a set of combinations:

$$F = \{ac, b\}$$

FIGURE 32.14 Correspondence of Boolean function and set of combinations.

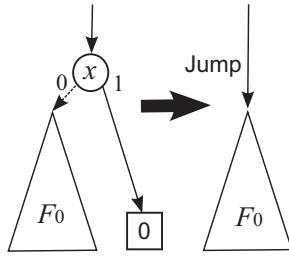

FIGURE 32.16 Reduction rule for ZDDs.

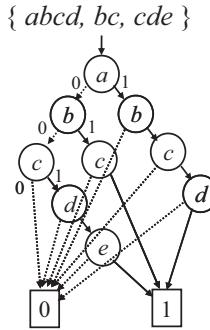

FIGURE 32.17 Explicit representation with ZDD.

for example, in a supermarket, the number of items in a customer's basket is usually much less than the number of all the items displayed.

- Each path from the root node to the 1-terminal node corresponds to each combination in the set. Namely, the number of such paths in the ZDD equals to the number of combinations in the set. In ordinary BDDs, this property does not always hold.
- When no equivalent nodes exist in a ZDD, that is the worst case, the ZDD structure explicitly stores all items in all combinations, as well as using an explicit linear linked list data structure. Namely, (the order of) ZDD size never exceeds the explicit representation. An example is shown in Figure 32.17. If more nodes are shared, the ZDD is more compact than linear list. Ordinary BDDs have larger overhead to represent sparser combinations while ZDDs have no such overhead.

Figure 32.18 shows an example of constructing ZDDs. As well as ordinary BDDs, any set of combinations can be generated by a sequence of primitive operations. Figure 32.19 summarizes most of the primitive operations of the ZDDs. In these operations,

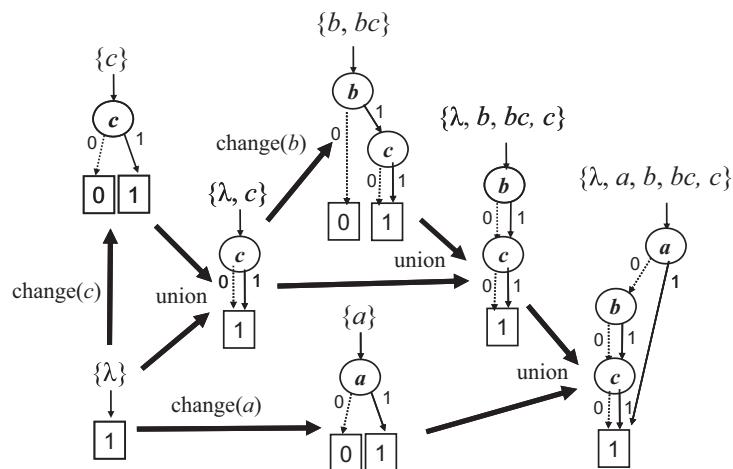

FIGURE 32.18 Example of constructing ZDDs.

Primitive operations corresponding to Boolean algebra	
\emptyset	Returns empty set. (0-terminal node)
$\{\lambda\}$	Returns the set of a null-combination. (1-terminal node)
$F.\text{offset}(x)$	Subset of combinations not including item x .
$F.\text{onset}(x)$	Gets $F \setminus F.\text{offset}(x)$ and then deletes x from each combination.
$F.\text{change}(x)$	Inverts the existence of x (add/delete) on each combination.
$F \cup G$	Returns the union set.
$F \cap G$	Returns the intersection set.
$F \setminus G$	Returns the difference set. (in F but not in G .)
$F.\text{top}$	Returns the item of the root node of F .
$F.\text{count}$	Counts number of combinations.

Extended operations for sets of combinations [29]	
$F * G$	Cartesian product of F and G .
F/G	Quotient of F divided by G .
$F \% G$	Remainder of F divided by G .

FIGURE 32.19 Primitive ZDD operations.

\emptyset , $\{\lambda\}$, and $F.\text{top}$ can be obtained in constant time. Here λ means a null combination. $F.\text{offset}(x)$, $F.\text{onset}(x)$, and $F.\text{change}(x)$ operations require a constant time if x is the top variable of F , otherwise they require a time linear in the number of ZDD nodes located at a higher position than x . The union, intersection, and difference operations can be performed in a time that is linear in the size of the ZDDs in many practical cases.

The last three operations in the table constitute an interesting algebra for sets of combinations with multiplication and division. Knuth has been inspired by this idea and has developed more various algebraic operations, such as $F \sqcap G$, $F \sqcup G$, $F \boxplus G$, $F \nearrow G$, $F \searrow G$, F^\uparrow , and F^\downarrow . He called these ZDD-based operations a “Family Algebra” in the recent fascicle of his book series [19].

The original BDD was developed for VLSI logic design, but ZDD is now recognized as the most important variant of BDD, and is widely used in various kinds of problems in computer science [10,17,21,35].

32.7 Related Research Activities

In the last section of this chapter, we present an overview of research activities related to BDDs and ZDDs. Of course, it is impossible to cover all the research activities in this limited space, so there may be many other interesting topics which are not shown here.

In 1986, Bryant proposed the algorithm called “Apply” [6]. It was the origin of much work on the use of BDDs as modern data structures and algorithms for efficient Boolean function manipulation. Just after Bryant’s paper, implementation techniques for the BDD manipulation, such as hash-table operations and memory management techniques, emerged [4,33]. A BDD is a unique representation of a given Boolean function. However, if the order of input variables is changed, a different BDD is obtained for what is essentially the same Boolean function. Since the size of BDDs greatly depends on the order of input variables, variable ordering methods were intensively developed in the early days [12,14,39,44]. Those practical techniques were implemented in a software library called “BDD package.” Currently, several academic groups provide such packages as open software (e.g., CUDD package [42]).

At first, BDDs were applied to equivalence checking of logic circuits [7,13,25] and logic optimization [26] in VLSI logic design. Next, BDD-based symbolic manipulation techniques were combined with the already known theory of model checking. It was really a breakthrough that formal verification becomes possible for some practical sizes of sequential machines [3,27]. After that, many researchers became involved with formal hardware verification using BDDs, and Clarke received the Turing Award in 2008 for this work. In addition, the BDD-based symbolic model checking method led to the idea of bounded model checking using SAT solvers [2,37,42]. These research produced many practical applications of SAT solvers that are widely utilized today.

ZDDs [29] deal with sets of combinations, representing a model that is different from Boolean functions. However, the original motivation of developing ZDDs was also for VLSI logic design. ZDDs were first used for manipulating very large-scale logic expressions with an AND-OR two-level structure (also called DNF or CNF), namely, representing a set including very large number of combinations of input variables. Sets of combinations often appear not only in VLSI logic design area but also in various areas of computer science. It is known that ZDDs are effective for handling many kinds of constraint satisfaction problems in graph theory and combinatorics [10,38].

After the enthusiastic research activities in 1990s, one can observe a relatively inactive period between 1999 and 2005. We may call these years the “Winter of BDDs.” On that time, most basic implementation techniques had been matured, and BDD applications to VLSI design tools seemed to be almost exhausted. So, many researchers moved from BDD-related work to other research areas, such as actual VLSI chip design issues or SAT-based problem solving.

However, after about 2005, many people understood that BDDs/ZDDs are useful not only for VLSI logic design but also in various other areas, and then BDD-related research activity was revived. For example, we can see some applications to data mining [21,31,36], Bayesian network and probabilistic inference models [17,35], and game theory [43]. More recently, new types of BDD variants, which have not been considered before, have been proposed. Sequence BDDs [22] represent sets of strings or sequences, and π DD [32] represent sets of permutations.

Synchronizing with this new movement, the BDD section of Knuth’s book was published [19]. As Knuth presented the potential for wide-ranging applications of BDDs and ZDDs, these data structures and algorithms were recognized as fundamental techniques for whole fields of information science. In particular, his book includes the “SimpPath” algorithm which constructs a ZDD representing all the connecting paths between two points in a given graph structure, and a surprisingly fast program is provided for public use on his web page. Experimental results suggest that this algorithm is not just an exercise but is the most efficient method using current technology. Based on this method, the author’s research group is now developing extended and generalized algorithms, called “Frontier-based methods,” for efficiently enumerating and indexing various kinds of discrete structures [16,18,46].

As the background of this resurgence and new generation applications, we should note the great progress of the computer hardware system, especially the increase of main memory capacity. Actually, in the early days of using BDDs in 1990s, there was some literature on applications for intelligent information processing. Madre and Coudert proposed a TMS (Truth Maintenance System) using BDDs for automatic logic inference and reasoning [24]. A method of probabilistic risk analysis for large industrial plants was also considered [9]. Coudert also proposed a fast method of constructing BDDs to represent prime sets (minimal support sets) for satisfying Boolean functions [8], which is a basic operation for logic inference. However, at that time, the main memory capacities of high specification computers were only 10–100 megabytes, about 10,000 times smaller than those available today, and thus, only small BDDs could be generated.

In the VLSI design process, the usual approach was that the whole circuit was divided into a number of small submodules, and each submodule was designed individually by hand. So, it was natural that the BDD-based design tools are used for the sufficiently small submodules which could be handled with a limited main memory capacity. With the progress of computer hardware performance, BDD-based methods could gradually be applied to larger submodule. On the other hand, in the applications of data mining or knowledge processing, the input data were stored on a very large hard disks. The processor loaded a small fragment of data from the hard disk into the main memory and executed some meaningful operations on the data in the main memory, then the processed data was saved with the original data on the hard disk. Such procedures were common, but it was very difficult to apply BDD-based methods to hard disk data. After 2000, computers’ main memory capacity grew rapidly, and in many practical cases, all the input data can be stored in the main memory. Thus many kinds of in-memory algorithms could be actively studied for data processing applications. The BDD/ZDD algorithm is a typical instance of such in-memory techniques.

In view of the above technical background, most research on BDDs/ZDDs after the winter period is not just about remaking old technologies. It also compares classical and well-known efficient methods (such as suffix trees, string matching, and frequent pattern mining) with the BDD/ZDD-based methods, in order to propose combined or improved techniques to obtain the current best performance. For example, Darwiche, who is a well-known researcher in data structures of probabilistic inference models, is very interested in the techniques of BDDs, and he recently proposed a new data structure, the SDD (Sentential Decision Diagram) [11], to combine BDDs with the classical data structures of knowledge databases. As shown in this example, we had better collaborate with many researchers in various fields of information science to import the current best known techniques into BDD/ZDD related work, and then we may develop more efficient new data structures and algorithms for discrete structure manipulation.

33.1 Introduction

Think of the initial configuration of a data structure as version zero, and of every subsequent update operation as generating a new version of the data structure. Then a data structure is called *persistent* if it supports access to all versions and it is called *ephemeral* otherwise. The data structure is *partially persistent* if all versions can be accessed but only the newest version can be modified. The structure is *fully persistent* if every version can be both accessed and modified. The data structure is *confluently persistent* if it is fully persistent and has an update operation which combines more than one version. Let the version graph be a directed graph where each node corresponds to a version and there is an edge from node V_1 to a node V_2 if and only if V_2 was created by an update operation to V_1 . For partially persistent data structure the version graph is a path; for fully persistent data structure the version graph is a tree; and for confluently persistent data structure the version graph is a directed acyclic graph (DAG).

A notion related to persistence is that of purely functional data structures. (See [Chapter 41](#) by Okasaki in this handbook.) A purely functional data structure is a data structure that can be implemented without using an assignment operation at all (say using just the functions car, cdr, and cons, of pure lisp). Such a data structure is automatically persistent. The converse, however, is not true. There are data structures which are persistent and perform assignments.

Since the seminal paper of Driscoll, Sarnak, Sleator, and Tarjan (DSST) [1], and over the past fifteen years, there has been considerable development of *persistent* data structures. Persistent data structures have important applications in various areas such as functional programming, computational geometry and other algorithmic application areas.

The research on persistent data structures splits into two main tracks. The first track is of designing general transformations that would make any ephemeral data structure persistent while introducing low overhead in space and time. The second track is on how to make specific data structures, such as lists and search trees, persistent. The seminal work of DSST mainly addresses the question of finding a general transformation to make any data structure persistent. In addition DSST also address the special case of making search trees persistent in particular. For search trees they obtain a result which is better than what one gets by simply applying their general transformation to, say, red-black trees.

There is a *naive scheme* to make any data structure persistent. This scheme performs the operations exactly as they would have been performed in an ephemeral setting but before each update operation it makes new copies of all input versions. Then it performs the update on the new copies. This scheme is obviously inefficient as it takes time and space which is at least linear in the size of the input versions.

When designing an efficient general transformation to make a data structure persistent DSST get started with the so called *fat node method*. In this method you allow each field in the data structure to store more than one value, and you tag each value by

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

the version which assigned it to the field. This method is easy to apply when we are interested only in a partially persistent data structure. But when the target is a fully persistent data structure, the lack of linear order on the versions already makes navigation in a naive implementation of the fat node data structure inefficient. DSST manage to limit the overhead by linearizing the version tree using a data structure of Dietz and Sleator so we can determine fast whether one version precedes another in this linear order.

Even when implemented carefully the fat node method has logarithmic (in the number of versions) time overhead to access or modify a field of a particular node in a particular version. To reduce this overhead DSST described two other methods to make data structures persistent. The simpler one is the *node copying method* which is good to obtain partially persistent data structures. For obtaining fully persistent data structures they suggest the *node splitting method*. These methods simulate the fat node method using nodes of constant size. They show that if nodes are large enough (but still of constant size) then the amount of overhead is constant per access or update of a field in the ephemeral data structure.

These general techniques suggested by DSST have some limitations. First, all these methods, including even the fat node method, fail to work when the data structure has an update operation which combines more than one version, and confluent persistence is desired. Furthermore, the node splitting and node copying methods apply only to pointer based data structures (no arrays) where each node is of constant size. Since the simulation has to add reverse pointers to the data structure the methods require nodes to be of bounded indegree as well. Last, the node coping and the node splitting techniques have $O(1)$ amortized overhead per update or access of a field in the ephemeral data structure. DSST left open the question of how to make this overhead $O(1)$ in the worst case.

These limitations of the transformations of DSST were addressed by subsequent work. Dietz and Raman [2] and Brodal [3] addressed the question of bounding the worst case overhead of an access or an update of a field. For partial persistence Brodal gives a way to implement node coping such that the overhead is $O(1)$ in the worst case. For fully persistence, the question of whether there is a transformation with $O(1)$ worst case overhead is still unresolved.

The question of making data structures that use arrays persistent with less than logarithmic overhead per step has been addressed by Dietz [4]. Dietz shows how to augment the fat node method with a data structure of van Emde Boaz, Kaas, and Zijlstra [5,6] to make an efficient fully persistent implementation of an array. With this implementation, if we denote by m the number of updates, then each access takes $O(\log \log m)$ time, an update takes $O(\log \log m)$ expected amortized time and the space is linear in m . Since we can model the memory of a RAM by an array, this transformation of Dietz can make any data structure persistent with slowdown double logarithmic in the number of updates to memory.

The question of how to make a data structure with an operation that combines versions confluently persistent has been recently addressed by Fiat and Kaplan [7]. Fiat and Kaplan point out the fundamental difference between fully persistent and confluently persistent data structures. Consider the naive scheme described above and assume that each update operation creates constantly many new nodes. Then, as long as no update operation combines more than one version, the size of any version created by the naive scheme is linear in the number of versions. However when updates combine versions the size of a single version can be exponential in the number of versions. This happens in the simple case where we update a linked list by concatenating it to itself n times. If the initial list is of size one then the final list after n concatenations is of size 2^n .

Fiat and Kaplan prove by simple information theoretic argument that for any general reduction to make a data structure confluently persistent there is a DAG of versions which cannot be represented using only constant space per assignment. Specifically, Fiat and Kaplan define the *effective depth of the DAG* which is the logarithm of the maximum number of different paths from the root of the DAG to any particular vertex. They show that the number of bits that may be required for assignment is at least as large as the *effective depth of the DAG*. Fiat and Kaplan also give several methods to make a data structure confluently persistent. The simplest method has time and space overhead proportional to the depth of the DAG. Another method has overhead proportional to the effective depth of the DAG and degenerate to the fat node method when the DAG is a tree. The last method reduces the time overhead to be polylogarithmic in either the depth of the DAG or the effective depth of the DAG at the cost of using randomization and somewhat more space.

The work on making specific data structures persistent has started even prior to the work of DSST. Dobkin and Munro [8] considered a persistent data structure for computing the rank of an object in an ordered set of elements subject to insertions and deletions. Overmars [9] improved the time bounds of Dobkin and Munro and further reduced the storage for the case where we just want to determine whether an element is in the current set or not. Chazelle [10] considered finding the predecessor of a new element in the set. As we already mentioned DSST suggest two different ways to make search trees persistent. The more efficient of their methods has $O(\log n)$ worst case time bound and $O(1)$ worst case space bound for an update.

A considerable amount of work has been devoted to the question of how to make concatenable double ended queues (deques) confluently persistent. Without catenation, one can make deques fully persistent either by the general techniques of DSST or via real-time simulation of the deque using stacks (see [11] and the references there). Once catenation is added, the problem of making stacks or deques persistent becomes much harder, and the methods mentioned above fail. A straightforward use of balanced trees gives a representation of persistent catenable deques in which an operation on a deque or deques of total size n takes $O(\log n)$ time. Driscoll, Sleator, and Tarjan [12] combined a tree representation with several additional ideas to obtain an

implementation of persistent catenable stacks in which the k th operation takes $O(\log \log k)$ time. Buchsbaum and Tarjan [13] used a recursive decomposition of trees to obtain two implementations of persistent catenable deques. The first has a time bound of $2^{O(\log^* k)}$ and the second a time bound of $O(\log^* k)$ for the k th operation, where $\log^* k$ is the iterated logarithm, defined by $\log^{(1)} k = \log_2 k$, $\log^{(i)} k = \log \log^{(i-1)} k$ for $i > 1$, and $\log^* k = \min\{i \mid \log^{(i)} k \leq 1\}$.

Finally, Kaplan and Tarjan [11] gave a real-time, purely functional (and hence confluently persistent) implementation of deques with catenation in which each operation takes $O(1)$ time in the worst case. A related structure which is simpler but not purely functional and has only amortized constant time bound on each operation has been given by Kaplan, Okasaki, and Tarjan [14]. A key ingredient in the results of Kaplan and Tarjan and the result of Kaplan, Okasaki, and Tarjan is an algorithmic technique related to the redundant digital representations devised to avoid carry propagation in binary counting [15]. If removing elements from one side of the deque is disallowed. Okasaki [16] suggested another confluently persistent implementation with $O(1)$ time bound for every operation. This technique is related to path reversal technique which is used in some union-find data structures [17].

Search trees also support catenation and split operations [18] and therefore confluently persistent implementation of search trees is natural to ask for. Search trees can be made persistent and even confluently persistent using the path copying technique [1]. In path copying you copy every node that changes while updating the search tree and its ancestors. Since updates to search trees affect only a single path, this technique results in copying at most one path and thereby costs logarithmic time and space per update. Making finger search trees confluently persistent is more of a challenge, as we want to prevent the update operation to propagate up on the leftmost and rightmost spines of the tree. This allows an update to be made at distance d from the beginning or end of the list in $O(\log d)$ time. Kaplan and Tarjan [19] used the redundant counting technique to make finger search tree confluently persistent. Using the same technique they also managed to reduce the time (and space) overhead of catenation to be $O(\log \log n)$ where n is the number of elements in the larger tree.

The structure of the rest of this chapter is as follows. Section 33.2 describes few algorithms that use persistent data structures to achieve their best time or space bounds. Section 33.3 surveys the general methods to make data structures persistent. Section 33.4 gives the highlights underlying persistent concatenable deques. We conclude in Section 33.5.

33.2 Algorithmic Applications of Persistent Data Structures

The basic concept of persistence is general and may arise in any context where one maintains a record of history for backup and recovery, or for any other purpose. However, the most remarkable consequences of persistent data structures are specific algorithms that achieve their best time or space complexities by using a persistent data structure. Most such algorithms solve geometric problems but there are also examples from other fields. In this section we describe few of these algorithms.

The most famous geometric application is the algorithm for planar point location by Sarnak and Tarjan [20] that triggered the development of the whole area. In the planar point location problem we are given a subdivision of the Euclidean plane into polygons by n line segments that intersect only at their endpoints. The goal is to preprocess these line segments and build a data structure such that given a query point we can efficiently determine which polygon contains it. As common in this kind of computational geometry problem, we measure a solution by three parameters: The space occupied by the data structure, the preprocessing time, which is the time it takes to build the data structure, and the query time.

Sarnak and Tarjan suggested the following solution (which builds upon previous ideas of Dobkin and Lipton [21] and Cole [22]). We partition the plane into vertical slabs by drawing a vertical line through each vertex (intersection of line segments) in the planar subdivision. Notice that the line segments of the subdivision intersecting a slab are totally ordered. Now it is possible to answer a query by two binary searches. One binary search locates the slab that contains the query, and another binary search locates the segment preceding the query point within the slab. If we associate with each segment within a slab, the polygon just above it, then we have located the answer to the query. If we represent the slabs by a binary search tree from left to right, and the segments within each slab by a binary search tree sorted from bottom to top, we can answer a query in $O(\log n)$ time.* However if we build a separate search tree for each slab then the worst case space requirement is $\Omega(n^2)$, when $\Omega(n)$ lines intersect $\Omega(n)$ slabs.

The key observation is that the sets of line segments intersecting adjacent slabs are similar. If we have the set of one particular slab we can obtain the set of the slab to its right by deleting segments that end at the boundary between these slabs, and inserting segments that start at that boundary. As we sweep all the slabs from left to right we get that in total there are n deletions and n insertions; one deletion and one insertion for every line segment. This observation reduces the planar point location to the problem of maintaining partially persistent search trees. Sarnak and Tarjan [20] suggested a simple implementation of partially persistent search tree where each update takes $O(\log n)$ amortized time and consumes $O(1)$ amortized space. Using these search

* Note that testing whether a point is above or below a line takes $O(1)$ time.

trees they obtained a data structure for planar point location that requires $O(n)$ space, takes $O(n \log n)$ time to build, and can answer each query in $O(\log n)$ time.

The algorithm of Sarnak and Tarjan for planar point location in fact suggests a general technique for transforming a 2-dimensional geometric search problem into a persistent data structure problem. Indeed several applications of this technique have emerged since Sarnak and Tarjan published their work [23]. As another example consider the problem of 3-sided range searching in the plane. In this problem we preprocess a set of n points in the plane so given a triple (a, b, c) with $a \leq b$ we can efficiently report all points $(x, y) \in S$ such that $a \leq x \leq b$, and $y \leq c$. The priority search tree of McCreight [24] yields a solution to this problem with $O(n)$ space, $O(n \log n)$ preprocessing time, and $O(\log n)$ time per query. Using persistent data structure, Boroujerdi and Moret [23] suggest the following alternative. Let $y_1 \leq y_2 \leq \dots \leq y_n$ be the y-coordinates of the points in S in sorted order. For each i , $1 \leq i \leq n$ we build a search tree containing all i points $(x, y) \in S$ where $y \leq y_i$, and associate that tree with y_i . Given this collection of search trees we can answer a query (a, b, c) in $O(\log n)$ time by two binary searches. One search uses the y-coordinate of the query point to find the largest i such that $y_i \leq c$. Then we use the search tree associated with y_i to find all points (x, y) in it with $a \leq x \leq b$. If we use partially persistent search trees then we can build the trees using n insertions so the space requirement is $O(n)$, and the preprocessing time is $O(n \log n)$.

This technique of transforming a 2-dimensional geometric search problem into a persistent data structure problem requires only a partially persistent data structure. This is since we only need to modify the last version while doing the sweep. Applications of fully persistent data structures are less common. However, few interesting ones do exist.

One such algorithm that uses a fully persistent data structure is the algorithm of Alstrup et al. for the binary dispatching problem [25]. In object oriented languages there is a hierarchy of classes (types) and method names are overloaded (i.e., a method may have different implementations for different types of its arguments). At run time when a method is invoked, the most specific implementation which is appropriate for the arguments has to be activated. This is a critical component of execution performance in object oriented languages. Here is a more formal specification of the problem.

We model the class hierarchy by a tree T with n nodes, each representing a class. A class A which is a descendant of B is *more specific* than B and we denote this relation by $A \leq B$ or $A < B$ if we know that $A \neq B$. In addition we have m different implementations of methods, where each such implementation is specified by a name, number of arguments, and the type of each argument. We shall assume that $m > n$, as if that is not the case we can map nodes that do not participate in any method to their closest ancestor that does participate in $O(n)$ time. A method invocation is a query of the form $s(A_1, \dots, A_d)$ where s is a method name that has d arguments with types A_1, \dots, A_d , respectively. An implementation $s(B_1, \dots, B_d)$ is applicable for $s(A_1, \dots, A_d)$ if $A_i \leq B_i$ for every $1 \leq i \leq d$. The *most specific* method which is applicable for $s(A_1, \dots, A_d)$ is the method $s(B_1, \dots, B_d)$ such that $A_i \leq B_i$ for $1 \leq i \leq d$, and for any other implementation $s(C_1, \dots, C_d)$ which is applicable for $s(A_1, \dots, A_d)$ we have $B_i \leq C_i$ for $1 \leq i \leq d$. Note that for $d > 1$ this may be ambiguous, that is, we might have two applicable methods $s(B_1, \dots, B_d)$ and $s(C_1, \dots, C_d)$ where $B_i \neq C_i$, $B_j \neq C_j$, $B_i \leq C_i$ and $C_j \leq B_j$. The dispatching problem is to find for each invocation the most specific applicable method if it exists. If it does not exist or in case of ambiguity, “no applicable method” or “ambiguity” has to be reported, respectively. In the binary dispatching problem, $d \neq 2$, that is, we assume that all implementations and invocations have two arguments.

Alstrup et al. describe a data structure for the binary dispatching problem that use $O(m)$ space, $O(m(\log \log m)^2)$ preprocessing time and $O(\log m)$ query time. They obtain this data structure by reducing the problem to what they call the *bridge color problem*. In the bridge color problem the input consists of two trees T_1 and T_2 with edges, called bridges, connecting vertices in T_1 to vertices in T_2 . Each bridge is colored by a subset of colors from C . The goal is to construct a data structure which allows queries of the following form. Given a triple (v_1, v_2, c) where $v_1 \in T_1$, $v_2 \in T_2$, and $c \in C$ finds the bridge (w_1, w_2) such that

1. $v_1 \leq w_1$ in T_1 , and $v_2 \leq w_2$ in T_2 , and c is one of the colors associated with (w_1, w_2) .
2. There is no other such bridge (w', w'') with $v_2 \leq w'' < w_2$ or $v_1 \leq w' < w_1$.

If there is no bridge satisfying the first condition the query just returns nothing and if there is a bridge satisfying the first condition but not the second we report “ambiguity.” We reduce the binary dispatching problem to the bridge color problem by taking T_1 and T_2 to be copies of the class hierarchy T of the dispatching problem. The set of colors is the set of different method names. (Recall that each method name may have many implementations for different pairs of types.) We make a bridge (v_1, v_2) between $v_1 \in T_1$ and $v_2 \in T_2$ whenever there is an implementation of some method for classes v_1 and v_2 . We color the bridge by all names of methods for which there is an implementation specific to the pair of type (v_1, v_2) . It is easy to see now that when we invoke a method $s(A_1, A_2)$ the most specific implementation of s to activate corresponds to the bridge colored s connecting an ancestor of v_1 to an ancestor of v_2 which also satisfies Condition (2) above.

In a way which is somewhat similar to the reduction between static two dimensional problem to a dynamic one dimensional problem in the plane sweep technique above, Alstrup et al. reduce the static bridge color problem to a similar dynamic problem on a single tree which they call the *tree color problem*. In the tree color problem you are given a tree T , and a set of colors C . At any time each vertex of T has a set of colors associated with it. We want a data structure which supports the updates, $\text{color}(v, c)$:

which add the color c to the set associated with v ; and $\text{uncolor}(v, c)$ which deletes the color c from the set associated with v . The query we support is given a vertex v and a color c , find the closest ancestor of v that has color c .

The reduction between the bridge color problem and the tree color problem is as follows. For each node $v \in T_1$ we associate an instance ℓ_v of the tree color problem where the underlying tree is T_2 and the set of colors C is the same as for the bridge color problem. The label of a node $w \in T_2$ in ℓ_v contains color c if w is an endpoint of a bridge with color c whose endpoint in T_1 is an ancestor of v . For each pair (w, c) where $w \in T_2$ and c is a color associated with w in ℓ_v we also keep the closest ancestor v' to v in T_1 such that there is a bridge (v', w) colored c . We can use a large (sparse) array indexed by pairs (w, c) to map each such pair to its associated vertex. We denote this additional data structure associated with v by a_v . Similarly for each vertex $u \in T_2$ we define an instance ℓ_u of the tree color problem when the underlying tree is T_1 , and the associated array a_u .

We can answer a query (v_1, v_2, c) to the bridge color data structure as follows. We query the data structure ℓ_{v_1} with v_2 to see if there is an ancestor of v_2 colored c in the coloring of T_2 defined by ℓ_{v_1} . If so we use the array a_{v_1} to find the bridge (w_1, w_2) colored c where $v_1 \leq w_1$ and $v_2 \leq w_2$, and w_1 is as close as possible to v_1 . Similarly we use the data structures ℓ_{v_2} and a_{v_2} to find the bridge (w_1, w_2) colored c where $v_1 \leq w_1$ and $v_2 \leq w_2$, and w_2 is as close as possible to v_2 , if it exists. Finally if both bridges are identical then we have the answer to the query (v_1, v_2, c) to the bridge color data structure. Otherwise, either there is no such bridge or there is an ambiguity (when the two bridges are different).

The problem of this reduction is its large space requirement if we represent each data structure ℓ_v , and a_v for $v \in T_1 \cup T_2$ independently.* The crucial observation though is that these data structures are strongly related. Thus if we use a dynamic data structure for the tree color problem we can obtain the data structure corresponding to w from the data structure corresponding to its parent using a small number of modifications. Specifically, suppose we have generated the data structures ℓ_v and a_v for some $v \in T_1$. Let w be a child of v in T_1 . We can construct ℓ_w by traversing all bridges whose one endpoint is w . For each such bridge (w, u) colored c , we perform $\text{color}(u, c)$, and update the entry of (u, c) in a_v to contain w .

So if we were using fully persistent arrays and a fully persistent data structure for the tree color problem we can construct all data structures mentioned above while doing only $O(m)$ updates to these persistent data structures. Alstrup et al. [25] describe a data structure for the tree color problem where each update takes $O(\log \log m)$ expected time and query time is $O(\log m / \log \log m)$. The space is linear in the sum of the sizes of the color-sets of the vertices. To make it persistent without consuming too much space Alstrup et al. [25] suggest how to modify the data structure so that each update makes $O(1)$ memory modifications in the worst case (while using somewhat more space). Then by applying the technique of Dietz [4] (see also Section 33.3.3) to this data structure we can make it fully persistent. The time bounds for updates and queries increase by a factor of $O(\log \log m)$, and the total space is $O(|C|m)$. Similarly, we can make the associated arrays a_v fully persistent. The resulting solution to the binary dispatching problem takes $O(m(\log \log m)^2)$ time to construct, requires $O(|C|m)$ space and support a query in $O(\log m)$ time. Since the number of memory modifications while constructing the data structure is only $O(m)$ Alstrup et al. also suggest that the space can be further reduced to $O(m)$ by maintaining the entire memory as a dynamic perfect hashing data structure.

Fully persistent lists proved useful in reducing the space requirements of few three dimensional geometric algorithms based on the sweep line technique, where the items on the sweep line have secondary lists associated with them. Kitsios and Tsakalidis [26] considered hidden line elimination and hidden surface removal. The input is a collection of (non intersecting) polygons in three dimensions. The hidden line problem asks for the parts of the edges of the polygons that are visible from a given viewing position. The hidden surface removal problem asks to compute the parts of the polygons that are visible from the viewing position.

An algorithm of Nurmi [27] solves these problems by projecting all polygons into a collection of possible intersecting polygons in the plane and then sweeping this plane, stopping at any vertex of a projected polygon, or crossing point of a pair of projected edges. When the sweep stops at such point, the visibility status of its incident edges is determined. The algorithm maintains a binary balanced tree which stores the edges cut by the sweep line in sorted order along the sweep line. With each such edge it also maintains another balanced binary tree over the faces that cover the interval between the edge and its successor edge on the sweep line. These faces are ordered in increasing depth order along the line of sight. An active edge is visible if the topmost face in its list is different from the topmost face in the list of its predecessor. If n is the number of vertices of the input polygons and I is the number of intersections of edges on the projection plane then the sweep line stops at $n + I$ points. Looking more carefully at the updates one has to perform during the sweep, we observe that a constant number of update operations on balanced binary search trees has to be performed non destructively at each point. Thus, using fully persistent balanced search trees one can implement the algorithm in $O((n + I) \log n)$ time and $O(n + I)$ space. Kitsios and Tsakalidis also show that by rebuilding the data structure from scratch every $O(n)$ updates we can reduce the space requirement to $O(n)$ while retaining the same asymptotic running time.

Similar technique has been used by Bozanis et al. [28] to reduce the space requirement of an algorithm of Gupta et al. [29] for the rectangular enclosure reporting problem. In this problem the input is a set S of n rectangles in the plane whose sides are parallel to the axes. The algorithm has to report all pairs (R, R') of rectangles where $R, R' \in S$ and R encloses R' . The algorithm uses the equivalence between the rectangle enclosure reporting problem and the 4-dimensional dominance problem. In the

* We can compress the sparse arrays using hashing but even if we do that the space requirement may be quadratic in m .

4-dimensional dominance problem the input is a set of n points P in four dimensional space. A point $p \neq (p_1, p_2, p_3, p_4)$ dominates $p' \neq (p'_1, p'_2, p'_3, p'_4)$ if and only if $p_i \geq p'_i$ for $i \neq 1, 2, 3, 4$. We ask for an algorithm to report all *dominating pairs* of points, (p, p') , where $p, p' \in P$, and p dominates p' . The algorithm of Gupta et al. first sorts the points by all coordinates and translates the coordinates to ranks so that they become points in U^4 where $U \neq \{0, 1, 2, \dots, n\}$. It then divides the sets into two equal halves R and B according to the forth coordinate (R contains the points with smaller forth coordinate). Using recurrence on B and on R it finds all dominating pairs (p, p') where p and p' are either both in B or both in R . Finally it finds all dominating pairs (r, b) where $r \in R$ and $b \in B$ by iterating a plane sweeping algorithm on the three dimensional projections of the points in R and B . During the sweep, for each point in B , a list of points that it dominates in R is maintained. The size of these lists may potentially be as large as the output size which in turn may be quadratic. Bozanis et al. suggest to reduce the space by making these lists fully persistent, which are periodically being rebuilt.

33.3 General Techniques for Making Data Structures Persistent

We start in Section 33.3.1 describing the fat node simulation. This simulation allows us to obtain fully persistent data structures and has an optimal space expansion but time slowdown logarithmic in the number of versions. Section 33.3.2 describes the node copying and the node splitting methods that reduce the time slowdown to be constant while increasing the space expansion only by a constant factor. In Section 33.3.3 we address the question of making arrays persistent. Finally in Section 33.3.4 we describe simulation that makes data structures confluently persistent.

33.3.1 The Fat Node Method

DSST first considered the *fat node method*. The fat node method works by allowing a field in a node of the data structure to contain a list of values. In a partial persistent setting we associate field value x with version number i , if x was assigned to the field in the update operation that created version i .^{*} We keep this list of values sorted by increasing version number in a search tree. In this method simulating an assignment takes $O(1)$ space, and $O(1)$ time if we maintain a pointer to the end of the list. An access step takes $O(\log m)$ time where m is the number of versions.

The difficulty with making the fat node method work in a fully persistent setting is the lack of total order on the versions. To eliminate this difficulty, DSST impose a total order on the versions consistent with the partial order defined by the version tree. They call this total order the *version list*. When a version i is created it is inserted into the version list immediately after its parent (in the version tree). This implies that the version list defines a preorder on the version tree where for any version i , the descendants of i in the version tree occur consecutively in the version list, starting with i .

The version list is maintained in a data structure that given two versions x and y allows to determine efficiently whether x precedes y . Such a data structure has been suggested by Dietz and Sleator [30]. (See also a simpler related data structure by [31].) The main idea underlying these data structures is to assign an integer label to each version so that these labels monotonically increase as we go along the list. Some difficulty arises since in order to use integers from a polynomial range we occasionally have to relabel some versions. For efficient implementation we need to control the amount of relabeling being done. We denote such a data structure that maintains a linear order subject to the operation $\text{insert}(x, y)$ which inserts x after y , and $\text{order}(x, y)$ which returns “yes” if x precedes y , an *Order Maintenance* (OM) data structure.

As in the partial persistence case we keep a list of version-value pairs in each field. This list contains a pair for each value assigned to the field in any version. These pairs are ordered according to the total order imposed on the versions as described above. We maintain these lists such that the value corresponding to field f in version i is the value associated with the largest version in the list of f that is not larger than i . We can find this version by carrying out a binary search on the list associated with the field using the OM data structure to do comparisons.

To maintain these lists such that the value corresponding to field f in version i is the value associated with the largest version in the list of f that is not larger than i , the simulation of an update in the fully persistent setting differ slightly from what happens in the partially persistent case. Assume we assign a value x to field f in an update that creates version i . (Assume for simplicity that this is the only assignment to f during this update.) First we add the pair (i, x) to the list of pairs associated with field f . Let i' be the version following i in the version list (i.e., in the total order of all versions) and let i'' be the version following i in the list associated with f . (If there is no version following i in one of these lists we are done.) If $i'' > i'$ then the addition of the pair (i, x) to the list of pairs associated with f may change the value of f in all versions between i' and the version preceding i'' in the version list, to be x . To fix that we add another pair (i', y) to the list associated with f , where y is the value of f before the assignment of x to f . The overhead of the fat node method in a fully persistent settings is $O(\log m)$ time and $O(1)$ space per assignment, and $O(\log m)$ time per access step, where m is the number of versions. Next, DSST suggested two methods to reduce the logarithmic

^{*} If the update operation that created version i assigned to a particular field more than once we keep only the value that was assigned last.

time overhead of the fat node method. The simpler one obtains a partially persistent data structure and is called *node copying*. To obtain a fully persistent data structure DSST suggested the *node splitting* method.

33.3.2 Node Copying and Node Splitting

The node-copying and the node splitting methods simulate the fat node method using nodes of constant size. Here we assume that the data structure is a pointer based data structure where each node contains a constant number of fields. For reasons that will become clear shortly we also assume that the nodes are of constant bounded in-degree, that is, the number of pointer fields that contains the address of any particular node is bounded by a constant.

In the node copying method we allow nodes in the persistent data structure to hold only a fixed number of field values. When we run out of space in a node, we create a new copy of the node, containing only the newest value of each field. Let d be the number of pointer fields in an ephemeral node and let p be the maximum in-degree of an ephemeral node. Each persistent node contains d fields which corresponds to the fields in the ephemeral node, p predecessor fields, e extra fields, where e is a sufficiently large constant that we specify later, and one field for a *copy pointer*.

All persistent nodes which correspond to the same ephemeral node are linked together in a single linked list using the copy pointer. Each field in a persistent node has a version stamp associated with it. As we go along the chain of persistent nodes corresponding to one ephemeral node then the version stamps of the fields in one node are no smaller than version stamps of the fields in the preceding nodes. The last persistent node in the chain is called *live*. This is the persistent node representing the ephemeral node in the most recent version which we can still update. In each live node we maintain *predecessor pointers*. If x is a live node and node z points to x then we maintain in x a pointer to z .

We update field f in node v , while simulating the update operation creating version i , as follows.* Let x be the *live* persistent node corresponding to v in the data structure. If there is an empty extra field in x then we assign the new value to this extra field, stamp it with version i , and mark it as a value associated with original field f . If f is a pointer field which now points to a node z , we update the corresponding predecessor pointer in z to point to x . In case all extra fields in x are used (and none of them is stamped with version i) we copy x as follows.

We create a new persistent node y , make the copy pointer of x point to y , store in each original field in y the most recent value assigned to it, and stamp these values with version stamp i . In particular, field f in node y stores its new value marked with version i . For each pointer field in y we also update the corresponding predecessor pointer to point to y rather than to x .

Then we have to update each field pointing to x in version $i - 1$ to point to y in version i . We follow, in turn, each predecessor pointer in x . Let z be a node pointed to by such a predecessor pointer. We identify the field pointing to x in z and update its value in version i to be y . We also update a predecessor pointer in y to point to z . If the old value of the pointer to x in z is not tagged with version i (in particular this means that z has not been copied) then we try to use an extra field to store the new version-value pair. If there is no free extra pointer in z we copy z as above. Then we update the field that points to x to point to y in the new copy of z . This sequence of node copying may cascade, but since each node is copied at most once, the simulation of the update step must terminate. In version i , y is the *live* node corresponding to v .

A simple analysis shows that if we use at least as many extra fields as predecessor fields at each node (i.e., $e \geq p$) then the amortized number of nodes that are copied due to a single update is constant. Intuitively, each time we copy a node we gain e empty extra fields in the live version that “pay” for the assignments that had to be made to redirect pointers to the new copy.

A similar simulation called the *node splitting method* makes a data structure fully persistent with $O(1)$ amortized overhead in time and space. The details however are somewhat more involved so we only sketch the main ideas. Here, since we need predecessor pointers for any version[†] it is convenient to think of the predecessor pointers as part of the ephemeral data structure, and to apply the simulation to the so called *augmented* ephemeral data structure.

We represent each fat node by a list of persistent nodes each of constant size, with twice as many extra pointers as original fields in the corresponding node of the augmented ephemeral data structure. The values in the fields of the persistent nodes are ordered by the version list. Thus each persistent node x is associated with an interval of versions in the version lists, called the *valid interval* of x , and it stores all values of its fields that fall within this interval. The first among these values is stored in an original field and the following ones occupy extra fields.

The key idea underlying this simulation is to maintain the pointers in the persistent structure *consistent* such that when we traverse a pointer valid in version i we arrive at a persistent node whose valid interval contains version i . More precisely, a value c of a pointer field must indicate a persistent node whose valid interval contains the valid interval of c .

* We assume that each field has only one value in any particular version. When we update a field in version i that already has a value stamped with version i then we overwrite its previous value.

† So we cannot simply overwrite a value in a predecessor pointer.

We simulate an update step to field f , while creating version i from version $p(i)$, as follows. If there is already a persistent node x containing f stamped with version i then we merely change the value of f in x . Otherwise, let x be the persistent node whose valid interval contains version i . Let $i+$ be the version following i in the version list. Assume the node following x does not have version stamp of $i+$. We create two new persistent node x' , and x'' , and insert them into the list of persistent nodes of x , such that x' follows x , and x'' follows x' . We give node x' version stamp of i and fill all its original fields with their values at version i . The extra fields in x' are left empty. We give x'' version stamp of $i+$. We fill the original fields of x'' with their values at version $i+$. We move from the extra fields of x all values with version stamps following $i+$ in the version list to x'' . In case the node which follows x in its list has version stamp $i+$ then x'' is not needed.

After this first stage of the update step, values of pointer fields previously indicating x may be inconsistent. The simulation then continues to restore consistency. We locate all nodes containing inconsistent values and insert them into a set S . Then we pull out one node at the time from S and fix its values. To fix a value we may have to replace it with two or more values each valid in a subinterval of the valid interval of the original value. This increases the number of values that has to be stored at the node so we may have to split the node. This splitting may cause more values to become inconsistent. So node splitting and consistency fixing cascades until consistency is completely restored. The analysis is based on the fact that each node splitting produce a node with sufficiently many empty extra fields. For further details see [1].

33.3.3 Handling Arrays

Dietz [4] describes a general technique for making arrays persistent. In his method, it takes $O(\log \log m)$ time to access the array and $O(\log \log m)$ expected amortized time to change the content of an entry, where m is the total number of updates. The space is linear in m . We denote the size of the array by n and assume that $n < m$.

Dietz essentially suggests to think of the array as one big fat node with n fields. The list of versions-values pairs describing the assignments to each entry of the array is represented in a data structure of van Emde Boas et al. [5,6]. This data structure is made to consume space linear in the number of items using dynamic perfect hashing [32]. Each version is encoded in this data structure by its label in the associated Order Maintenance (OM) data structure. (See Section 33.3.1.)

A problem arises with the solution above since we refer to the labels not solely via order queries on pairs of versions. Therefore when a label of a version changes by the OM data structure the old label has to be deleted from the corresponding van Emde Boaz data structure and the new label has to be inserted instead. We recall that any one of the known OM data structures consists of two levels. The versions are partitioned into sublists of size $O(\log m)$. Each sublist gets a label and each version within a sublist gets a label. The final label of a version is the concatenation of these two labels. Now this data structure supports an insertion in $O(1)$ time. However, this insertion may change the labels of a constant number of sublists and thereby implicitly change the labels of $O(\log m)$ versions. Reinserting all these labels into the van Emde Boaz structures containing them may take $\Omega(\log m \log \log m)$ time.

Dietz suggests to solve this problem by bucketizing the van Emde Boaz data structure. Consider a list of versions stored in such a data structure. We split the list into buckets of size $O(\log m)$. We maintain the versions in each bucket in a regular balanced search tree and we maintain the smallest version from each bucket in a van Emde Boaz data structure. This way we need to delete and reinsert a label of a version into the van Emde Boaz data structure only when the minimum label in a bucket gets relabeled.

Although there are only $O(m/\log m)$ elements now in the van Emde Boaz data structures, it could still be the case that we relabel these particular elements too often. This can happen if sublists that get split in the OM data structure contains a particular large number of buckets' minima. To prevent that from happening we modify slightly the OM data structure as follows.

We associate a potential to each version which equals 1 if the version is currently not a minimum in its bucket of its van Emde Boaz data structure and equals $\log \log m$ if it is a minimum in its bucket. Notice that since there are only $O(m/\log m)$ buckets' minima the total potential assigned to all versions throughout the process is $O(m)$. We partition the versions into sublists according to their potentials where the sum of the potentials of the elements in each sublist is $O(\log m)$. We assign labels to the sublists and within each sublists as in the original OM data structure. When we have to split a sublist the work associated with the split, including the required updates on the associated van Emde Boaz data structures, is proportional to the increase in the potential of this sublist since it had last split.

Since we can model the memory of a Random Access Machine (RAM) as a large array. This technique of Dietz is in fact general enough to make any data structure on a RAM persistent with double logarithmic overhead on each access or update to memory.

33.3.4 Making Data Structures Confluently Persistent

Finding a general simulation to make a pointer based data structure confluently persistent is a considerably harder task. In a fully persistent setting we can construct any version by carrying out a particular sequence of updates ephemerally. This seemingly innocent fact is already problematic in a confluently persistent setting. In a confluently persistent setting when an update applies

to two versions, one has to produce these two versions to perform the update. Note that these two versions may originate from the same ancestral version so we need some form of persistence even to produce a single version. In particular, methods that achieve persistence typically create versions that share nodes. Semantically however, when an update applied to versions that share nodes we would like the result to be as if we perform the update on two completely independent copies of the input versions.

In a fully persistent setting if each operation takes time polynomial in the number of versions then the size of each version is also polynomial in the number of versions. This breaks down in a confluently persistent setting where even when each operation takes constant time the size of a single version could be exponential in the number of versions. Recall the example of the linked list mentioned in Section 33.1. It is initialized to contain a single node and then concatenated with itself n time. The size of the last versions is 2^n . It follows that any polynomial simulation of a data structure to make it confluently persistent must in some cases represent versions as a compressed form.

Consider the naive scheme to make a data structure persistent which copies the input versions before each update. This method is polynomial in a fully persistent setting when we know that each update operation allocates a polynomial (in the number of versions) number of new nodes. This is not true in a confluently persistent setting as the linked list example given above shows. Thus there is no easy polynomial method to obtain confluently persistence at all.

What precisely causes this difficulty in obtaining a confluently persistent simulation? Lets assume first a fully persistent setting and the naive scheme mentioned above. Consider a single node x created during the update that constructed version v . Node x exists in version v and copies of it may also exist in descendant versions of v . Notice however that each version derived from v contains only a *single* node which is either x or a copy of it. In contrast if we are in a confluently persistent setting a descendant version of v may contain more than a single copy of x . For example, consider the linked list being concatenated to itself as described above. Let x be the node allocated when creating the first version. Then after one catenation we obtain a version which contains two copies of x , after 2 catenations we obtain a version containing 4 copies of x , and in version n we have 2^n copies of x .

Now, if we get back to the fat node method, then we can observe that it identifies a node in a specific version using a pointer to a fat node and a version number. This works since in each version there is only one copy of any node, and thus breaks down in the confluently persistent setting. In a confluently persistent setting we need more than a version number and an address of a fat node to identify a particular node in a particular version.

To address this identification problem Fiat and Kaplan [7] used the notion of *pedigree*. To define pedigree we need the following notation. We denote the version DAG by D , and the version corresponding to vertex $v \in D$ by D_v . Consider the naive scheme defined above. Let w be some node in the data structure D_v . We say that node w in version v was *derived from* node y in version u if version u was one of the versions on which the update producing v had been performed, and furthermore node $w \in D_v$ was formed by a (possibly empty) set of assignments to a copy of node $y \in D_u$.

Let w be a node in some version D_u where D_u is produced by the naive scheme. We associate a *pedigree* with w , and denote it by $p(w)$. The pedigree, $p(w)$, is a path $p \neq \langle v_0, v_1, \dots, v_k \neq u \rangle$ in the version DAG such that there exist nodes $w_0, w_1, \dots, w_{k-1}, w_k \neq w$, where w_i is a node of D_{v_i} , w_0 was allocated in v_0 , and w_i is derived from w_{i-1} for $1 \leq i \leq k$. We also call w_0 the *seminal node* of w , and denote it by $s(w)$. Note that $p(w)$ and $s(w)$ uniquely identify w among all nodes of the naive scheme.

As an example consider Figure 33.1. We see that version v_4 has three nodes (the 1st, 3rd, and 5th nodes of the linked list) with the same seminal node w_0' . The pedigree of the 1st node in D_{v_4} is $\langle v_0, v_1, v_3, v_4 \rangle$. The pedigree of the 2nd node in D_{v_4} is also $\langle v_0, v_1, v_3, v_4 \rangle$ but its seminal node is w_0 . Similarly, we can see that the pedigrees of the 3rd, and the 5th nodes of D_{v_4} are $\langle v_0, v_2, v_3, v_4 \rangle$ and $\langle v_0, v_2, v_4 \rangle$, respectively.

The basic simulation of Fiat and Kaplan is called the *full path method* and it works as follows. The data structure consists of a collection of *fat nodes*. Each fat node corresponds to an explicit allocation of a node by an update operation or in another words, to some seminal node of the naive scheme. For example, the update operations of Figure 33.1 performs 3 allocations (3 seminal nodes) labeled w_0 , w_0' , and w_0'' , so our data structure will have 3 fat nodes, $f(w_0)$, $f(w_0')$ and $f(w_0'')$. The full path method represents a node w of the naive scheme by a pointer to the fat node representing $s(w)$, together with the pedigree $p(w)$. Thus a single fat node f represents all nodes sharing the same seminal node. We denote this set of nodes by $N(f)$. Note that $N(f)$ may contain nodes that co-exist within the same version and nodes that exist in different versions. A *fat node* contains the same fields as the corresponding seminal node. Each of these fields, however, rather than storing a single value as in the original node stores a dynamic table of field values in the fat node. The simulation will be able to find the correct value in node $w \in N(f)$ using $p(w)$. To specify the representation of a set of values we need the following definition of an *assignment pedigree*.

Let $p \neq \langle v_0, \dots, v_k \neq u \rangle$ be the pedigree of a node $w \in D_u$. Let $w_k \neq w, w_{k-1}, \dots, w_1, w_i \in D_{v_i}$ be the sequence of nodes such that $w_i \in D_{v_i}$ is derived from $w_{i-1} \in D_{v_{i-1}}$. This sequence exists by the definition of node's pedigree. Let A be a field in w and let j be the maximum such that there has been an assignment to field A in w_j during the update that created v_j . We define the *assignment pedigree of a field A* in node w , denoted by $p(A, w)$, to be the pedigree of w_j , that is, $p(A, w) = \langle v_0, v_1, \dots, v_j \rangle$.

In the example of Figure 33.1 the nodes contain one pointer field (named *next*) and one data field (named *x*). The assignment pedigree of *x* in the 1st node of D_{v_4} is simply $\langle v_0 \rangle$, the assignment pedigree of *x* in the 2nd node of D_{v_4} is likewise $\langle v_0 \rangle$, the assignment pedigree of *x* in the 3rd node of D_{v_4} is $\langle v_0, v_2, v_3 \rangle$. Pointer fields also have assignment pedigrees. The assignment

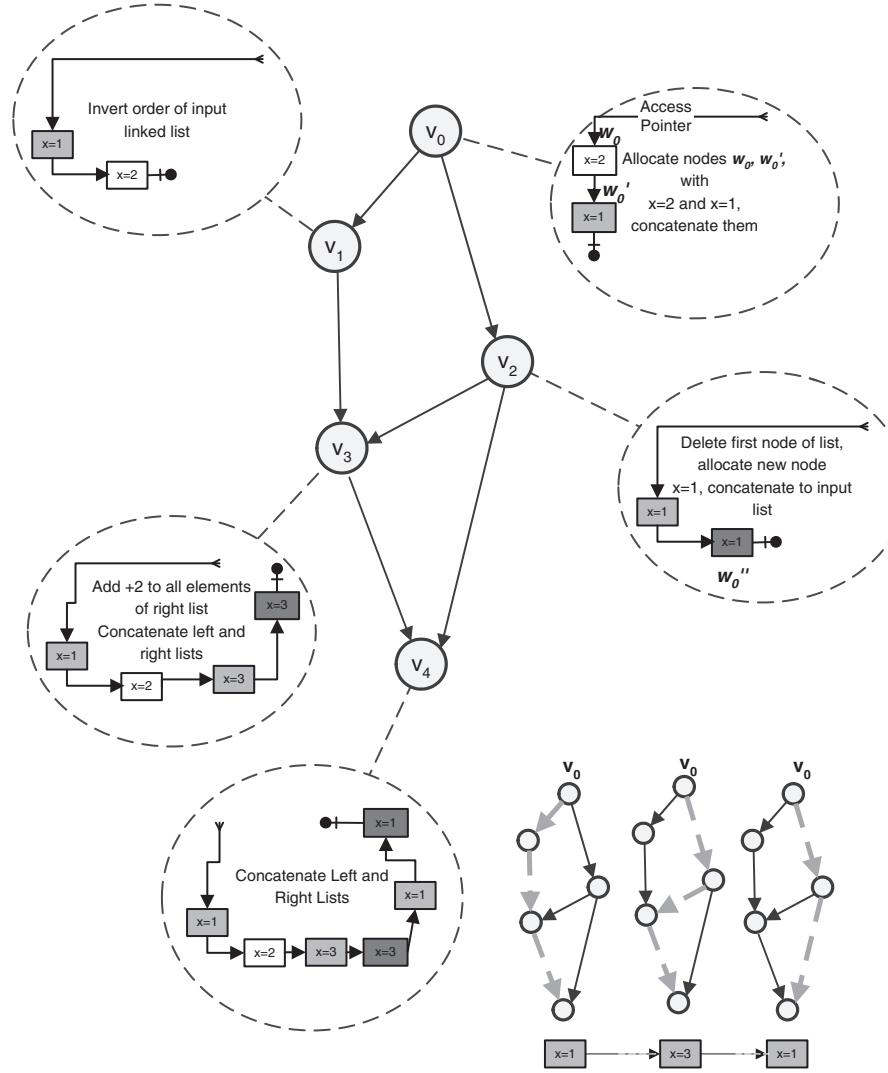

FIGURE 33.1 A DAG of five versions. In each circle we show the corresponding update operation and the resulting version. Nodes with the same color originate from the same seminal node. The three gray nodes in version D_{v_4} all have the same seminal node (w_0'), and are distinguished by their pedigrees $\langle v_0, v_1, v_3, v_4 \rangle$, $\langle v_0, v_1, v_2, v_3, v_4 \rangle$, and $\langle v_0, v_1, v_2, v_4 \rangle$.

pedigree of the pointer field in the 1st node of D_{v_4} is $\langle v_0, v_1 \rangle$, the assignment pedigree of the pointer field in the 2nd node of D_{v_4} is $\langle v_0, v_1, v_3 \rangle$, the assignment pedigree of the pointer field of the 3rd node of D_{v_4} is $\langle v_0, v_2 \rangle$, finally, the assignment pedigree of the pointer field of the 4th node of D_{v_4} is $\langle v_2, v_3, v_4 \rangle$.

We call the set $\{p(A, w) | w \in N(f)\}$ the set of all assignment pedigrees for field A in a fat note f , and denote it by $P(A, f)$. The table that represents field A in fat node f contains an entry for each assignment pedigree in $P(A, f)$. The value of a table entry, indexed by an assignment pedigree $p \neq \langle v_0, v_1, \dots, v_j \rangle$, depends on the type of the field as follows. If A is a data field then the value stored is the value assigned to A in the node $w_j \in D_{v_j}$ whose pedigree is p . If A is a pointer field then let w be the node pointed to by field A after the assignment to A in w_j . We store the pedigree of w and the address of the fat node that represents the seminal node of w .

An access pointer to a node w in version v is represented by a pointer to the fat node representing the seminal node of w and the pedigree of w .

In Figure 33.2 we give the fat nodes of the persistent data structure given in Figure 33.1. For example, the field next has three assignments in nodes of $N(f(w_0'))$. Thus, there are three assignment pedigrees in $P(\text{next}, f(w_0'))$:

1. $\langle v_0 \rangle$ —allocation of w_0' in version D_{v_0} and default assignment of null to next.
2. $\langle v_0, v_1 \rangle$ —inverting the order of the linked list in version D_{v_1} and thus assigning next a new value. The pointer is to a node whose pedigree is $\langle v_0, v_1 \rangle$ and whose seminal node is w_0 . So we associate the value $(\langle v_0, v_1 \rangle, f(w_0))$ with $\langle v_0, v_1 \rangle$.

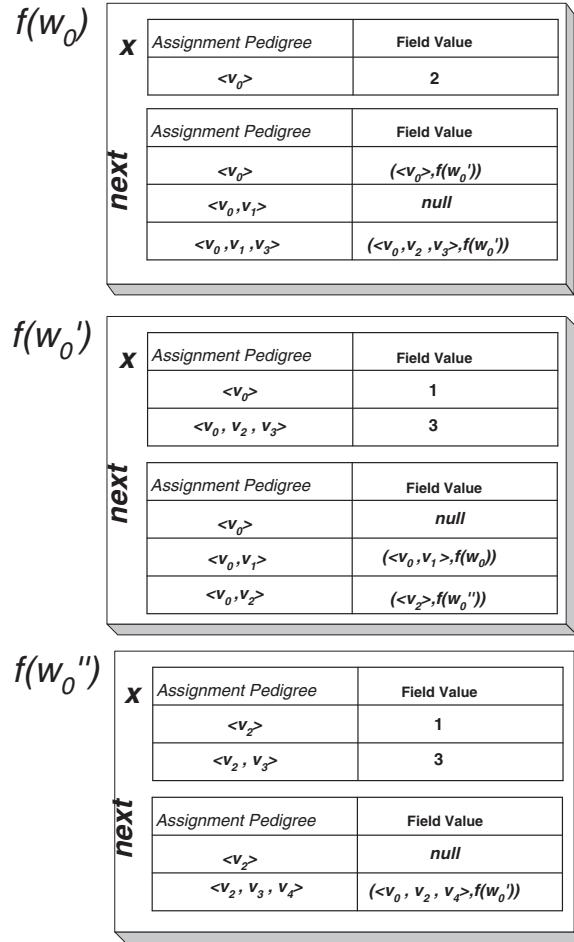

FIGURE 33.2 The fat nodes for the example of Figure 33.1.

3. $\langle v_0, v_2 \rangle$ —allocating a new node, w_0'' , in version D_{v_2} , and assigning next to point to this new node. The pedigree of w_0'' is $\langle v_2 \rangle$ so we associate the value $(\langle v_2 \rangle, f(w_0''))$ with $\langle v_0, v_2 \rangle$.

You can see all three entries in the table for next in the fat node $f(w_0')$ (Figure 33.2). Similarly, we give the table for field x in $f(w_0')$ as well as the tables for both fields in fat nodes $f(w_0)$ and $f(w_0'')$.

When we traverse the data structure we are pointing to some fat node f and hold a pedigree q of some node w whose seminal node corresponds to f and we would like to retrieve the value of field A in node w from the table representing field A in f . We do that as follows. First we identify the assignment pedigree $p(A, w)$ of field A in node w . This is the longest pedigree which is a prefix of q and has an entry in this table. In case A is a data field, the value we are after is simply the value associated with $p(A, w)$. However if A is a pointer field then the value stored with $p(A, w)$ may not be the value of A in w . This value identifies a node in the version where the assignment occurred, whereas we are interested in a node in the version of w that this pointer field points to.

Let $q \neq \langle q_0, \dots, q_k \rangle$ and let $p(A, w) \neq \langle q_0, q_1, \dots, q_j \rangle$. Let the value of $p(A, w)$ be (t, f) , where t is the pedigree of the target node in D_{q_j} and f is the fat node representing the seminal node of this target node. The nodes identified by the pedigrees $p(A, w)$ and t were copied in versions q_{j+1}, \dots, q_k without any assignment made to field A in the nodes derived from the node whose pedigree is $p(A, w)$. Thus the pedigree of the target node of field A of node w in D_{q_k} is $t \parallel \langle q_{j+1}, \dots, q_k \rangle$, where \parallel represents concatenation.

It follows that we need representations for pedigrees and the tables representing field values that support an efficient implementation of the followings.

1. Given a pedigree q find the longest prefix of q stored in a table.
2. Given a pedigree q , replace a prefix of q with another pedigree p .
3. To facilitate updates we also need to be able to add a pedigree to a table representing some field with a corresponding value.

In their simplest simulation Fiat and Kaplan suggested to represent pedigrees as linked lists of version numbers, and to represent tables with field values as tries. Each assignment pedigree contained in the table is represented by a path in the corresponding trie. The last node of the path stores the associated value. Nodes in the trie can have large degrees so for efficiency we represent the children of each node in a trie by a splay tree.

Let U be the total number of assignments the simulation performs and consider the update creating version v . Then with this implementation each assignment performed during this update requires $O(d(v))$ words of size $O(\log U)$ bits, and takes $O(d(v) + \log U)$ time, where $d(v)$ is the depth of v in the DAG. Field retrieval also takes $O(d(v) + \log U)$ time.

The second method suggested by Fiat and Kaplan is the *compressed path method*. The essence of the compressed path method is a particular partition of our DAG into disjoint trees. This partition is defined such that every path enters and leaves any specific tree at most once. The compressed path method encodes paths in the DAG as a sequence of pairs of versions. Each such pair contains a version where the path enters a tree T and the version where the path leaves the tree T . The length of each such representation is $O(e(D))$.^{*} Each value of a field in a fat node is now associated with the compressed representation of the path of the node in $N(f)$ in which the corresponding assignment occurred. A key property of these compressed path representations is that they allow easy implementation of the operations we need to perform on pedigree, like replacing a prefix of a pedigree with another pedigree when traversing a pointer. With the compressed path method each assignment requires up to $O(e(D))$ words each of $O(\log U)$ bits. Searching or updating the trie representing all values of a field in a fat node requires $O(e(D) + \log U)$ time. For the case where the DAG is a tree this method degenerates to the fat node simulation of [1].

Fiat and Kaplan also suggested how to use randomization to speed up their two basic methods at the expense of (slightly) larger space expansion and polynomially small error probability. The basic idea is encode each path (or compressed path) in the DAG by an integer. We assign to each version a random integer, and the encoding of a path p is simply the sum of the integers that correspond to the versions on p . Each value of a field in a fat node is now associated with the integer encoding the path of the node in $N(f)$ in which the corresponding assignment occurred. To index the values of each field we use a hash table storing all the integers corresponding to these values.

To deal with values of pointer fields we have to combine this encoding with a representation of paths in the DAG (or compressed paths) as balanced search trees, whose leaves (in left to right order) contain the random integers associated with the vertices along the path (or compressed path). This representation allows us to perform certain operations on these paths in logarithmic (or poly-logarithmic) time whereas the same operations required linear time using the simpler representation of paths in the non-randomized methods.

33.4 Making Specific Data Structures More Efficient

The purely functional deques of Kaplan and Tarjan [11], the confluently persistent deques of Kaplan, Okasaki, and Tarjan [14], the purely functional heaps of Brodal and Okasaki [33], and the purely functional finger search trees of Kaplan and Tarjan [19], are all based on a simple and useful mechanism called redundant counters, which to the best of our knowledge first appeared in lecture notes by Clancy and Knuth [15]. In this section we describe what redundant counters are, and demonstrate how they are used in simple persistent deques data structure.

A persistent implementation of deques support the following operations: $q' \neq \text{push}(x, q)$: Inserts an element x to the beginning of the deque q returning a new deque q' in which x is the first element followed by the elements of q . $(x, q') \neq \text{pop}(q)$: Returns a pair where x is the first element of q and q' is a deque containing all elements of q but x . $q' \neq \text{Inject}(x, q)$: Inserts an element x to the end of the deque q returning a new deque q' in which x is the last element preceded by the elements of q . $(x, q') \neq \text{eject}(q)$: Returns a pair where x is the last element of q and q' is a deque containing all elements of q but x . A *stack* supports only push and pop, a *queue* supports only push and eject. Catenable deques also support the operation $q \neq \text{catenate}(q_1, q_2)$: Returns a queue q containing all the elements of q_1 followed by the elements of q_2 .

Although queues, and in particular catenable queues, are not trivial to make persistent, stacks are easy. The regular representation of a stack by a singly linked list of nodes, each containing an element, ordered from first to last, is in fact purely functional. To push an element onto a stack, we create a new node containing the new element and a pointer to the node containing the previously first element on the stack. To pop a stack, we retrieve the first element and a pointer to the node containing the previously second element.

Direct ways to make queues persistent simulate queues by stacks. One stack holds elements from the beginning of the queue and the other holds elements from its end. If we are interested in fully persistence this simulation should be real time and its details are not trivial. For a detailed discussion see Kaplan and Tarjan [11] and the references there.

^{*} Recall that $e(D)$ is the logarithm of the maximum number of different paths from the root of the DAG to any particular version.

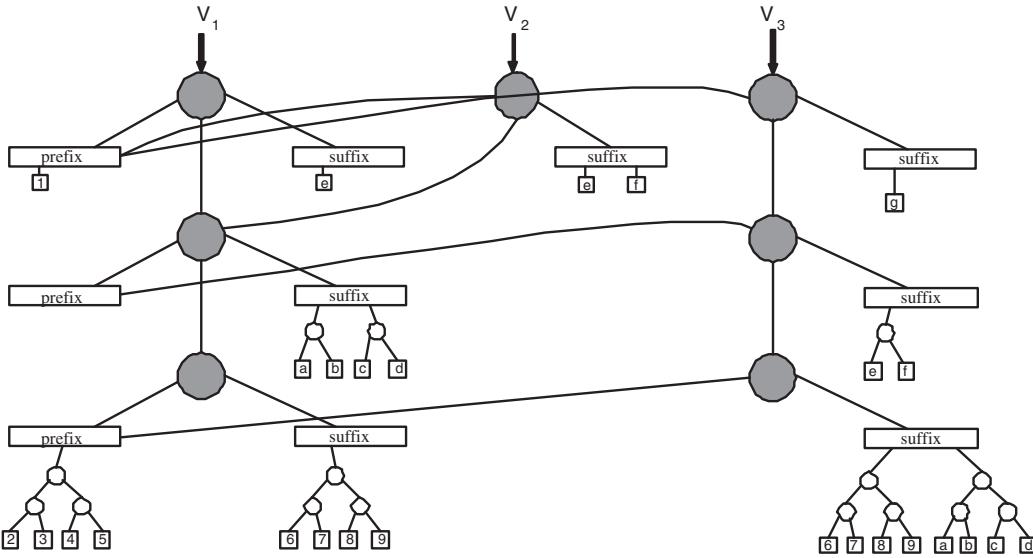

FIGURE 33.3 Representation of a deque of elements over A . Each circle denotes a deque and each rectangle denotes a buffer. Squares correspond to elements from A which we denote by numbers and letters. Each buffer contains 0, 1, or 2 elements. Three versions are shown V_1 , V_2 , and V_3 . Version V_2 was obtained from V_1 by injecting the element f . Version V_3 obtained from version V_2 by injecting the element g . The latter inject triggered two recursive injects into the child and grandchild deques of V_2 . Note that identical binary trees and elements are represented only once but we draw them multiple times to avoid cluttering of the figure.

Kaplan and Tarjan [11] described a new way to do a simulation of a deque with stacks. They suggest to represent a deque by a recursive structure that is built from bounded-size deques called *buffers*. Buffers are of two kinds: *prefixes* and *suffixes*. A non-empty deque q over a set A is represented by an ordered triple consisting of a *prefix*, $\text{prefix}(q)$, of elements of A , a *child deque*, $\text{child}(q)$, whose elements are ordered pairs of elements of A , and a *suffix*, $\text{suffix}(q)$, of elements of A . The order of elements within q is the one consistent with the orders of all of its component parts. The *child* deque $\text{child}(q)$, if non-empty, is represented in the same way. Thus the structure is recursive and unwinds linearly. We define the descendants $\{\text{child}^i(q)\}$ of deque d in the standard way, namely $\text{child}^0(q) = q$ and $\text{child}^{i+1}(q) = \text{child}(\text{child}^i(q))$ for $i \geq 0$ if $\text{child}^i(q)$ is non-empty.

Observe that the elements of q are just elements of A , the elements of $\text{child}(q)$ are pairs of elements of A , the elements of $\text{child}(\text{child}(q))$ are pairs of pairs of elements of A , and so on. One can think of each element of $\text{child}^i(q)$ as being a complete binary tree of depth i , with elements of A at its 2^i leaves. One can also think of the entire structure representing q as a stack (of q and its descendants), each element of which is prefix-suffix pair. All the elements of q are stored in the prefixes and suffixes at the various levels of this structure, grouped into binary trees of the appropriate depths: level i contains the prefix and suffix of $\text{child}^i(q)$. See Figure 33.3.

Because of the pairing, we can bring *two* elements up to level i by doing *one pop* or *eject* at level $i + 1$. Similarly, we can move *two* elements down from level i by doing *one push* or *inject* at level $i + 1$. This two-for-one payoff leads to real-time performance.

Assume that each prefix or suffix is allowed to hold 0, 1, or 2 elements, from the beginning or end of the queue, respectively. We can implement $q' = \text{push}(x, q)$ as follows. If the prefix of q contains 0 or 1 elements we allocate a new node to represent q' , make its child deque and its suffix identical to the child and suffix of q , respectively. The prefix of q' is a newly allocated prefix containing x and the element in the prefix of q , if the prefix of q contained one element. We return a pointer to the new node which represents q' . For an example consider version V_2 shown in Figure 33.3 that was obtained from version V_1 by a case of inject symmetric to the case of the push just described.

The hard case of the push is when the prefix of q already contains two elements. In this case we make a pair containing these two elements and push this pair recursively into $\text{child}(q)$. Then we allocate a new node to represent q' , make its suffix identical to the suffix of q , make the deque returned by the recursive push to $\text{child}(q)$ the child of q' , and make the prefix of q' be a newly allocated prefix containing x . For an example consider version V_3 shown in Figure 33.3 that was obtained from version V_2 by a recursive case of inject symmetric to the recursive case of the push just described. The implementations of pop and eject is symmetric.

This implementation is clearly purely functional and therefore fully persistent. However the time and space bounds per operation are $O(\log n)$. The same bounds as one gets by using search trees to represent the deques with the path copying technique. These logarithmic time bounds are by far off from the ephemeral $O(1)$ time and space bounds.

Notice that there is a clear correspondence between this data structure and binary counters. If we think of a buffer with two elements as the digit 1, and of any other buffer as the digit 0, then the implementation of $push(q)$ is similar to adding one to the binary number defined by the prefixes of the queues $child^i(q)$. It follows that if we are only interested in partially persistent deques then this implementation has $O(1)$ amortized time bound per operation (see the discussion of binary counters in the next section). To make this simulation efficient in a fully persistent setting and even in the worst case, Kaplan and Tarjan suggested to use redundant counters.

33.4.1 Redundant Binary Counters

To simplify the presentation we describe redundant binary counters, but the ideas carry over to any basis. Consider first the regular binary representation of an integer i . To obtain from this representation the representation of $i + 1$ we first flip the rightmost digit. If we flipped a 1 to 0 then we repeat the process on the next digit to the left. Obviously, this process can be long for some integers. But it is straightforward to show that if we carry out a sequence of such increments starting from zero then on average only a constant number of digits change per increment.* Redundant binary representations (or counters as we will call them) address the problem of how to represent i so we can obtain a representation of $i + 1$ while changing only a constant number of digits in the worst case.

A *redundant binary representation*, d , of a non-negative integer x is a sequence of digits d_n, \dots, d_0 , with $d_i \in \{0, 1, \dots, 2\}$, such that $x = \sum_{i=0}^n d_i 2^i$. We call d *regular* if, between any two digits equal to 2, there is a 0, and there is a 0 between the rightmost 2 and the least significant digit. Notice that the traditional binary representation of each integer (which does not use the digit 2) is *regular*. In the sequel when we refer to a regular representation we mean a regular redundant binary representation, unless we explicitly state otherwise.

Suppose we have a regular representation of i . We can obtain a regular representation of $i + 1$ as follows. First we increment the rightmost digit. Note that since the representation of i is regular, its rightmost digit is either 0 or 1. So after the increment the rightmost digit is either 1 or 2 and we still have a redundant binary representation for $i + 1$. Our concern is that this representation of $i + 1$ may not be regular. However, since the representation of i we started out with was regular the only violation to regularity that we may have in the representation of $i + 1$ is lacking a 0 between the rightmost 2 and the least significant digit. It is easy to check that between any two digits equal to 2, there still is a 0, by the regularity of i .

We can change the representation of $i + 1$ to a representation which is guaranteed to be regular by a simple *fix* operation. A *fix* operation on a digit $d_i \neq 2$ increments d_{i+1} by 1 and sets d_i to 0, producing a new regular representation d' representing the same number as d .† If after incrementing the rightmost digit we perform a fix on the rightmost 2 then we switch to another representation of $i + 1$ that must be regular. We omit the proof here which is straightforward.

It is clear that the increment together with the fix that may follow change at most three digits. Therefore redundant binary representations allow to perform an increment while changing constantly many digits. However notice that in any application of this numbering system we will also need a representation that allows to get to the digits which we need to fix efficiently. We show one such representation in the next section.

These redundant representations can be extended so we can also decrement it while changing only a constant number of digits, or even more generally so that we can increment or decrement any digit (add or subtract 2^i) while changing a constant number of other digits. These additional properties of the counters were exploited by other applications (see, e.g., [19,34]).

33.4.2 Persistent Deques

Kaplan and Tarjan use this redundant binary system to improve the deque implementation we described above as follows. We allow each of the prefixes and suffixes to contain between 0 and 5 elements. We label each buffer, and each deque, by one of the digits 0, 1, and 2. We label a buffer 0 if it has two or three elements, we label it 1 if it has one or four elements, and we label it 2 if it has zero or five elements. Observe that we can add one element to or delete one element from a buffer labeled 0 or 1 without violating its size constraint: A buffer labeled 0 may change its label to 1, and a buffer labeled 1 may change its label to 2. (In fact a 1 can also be changed to 0 but this may not violate regularity.) The label of a deque is the larger among the labels of its buffers, unless its child and one of its buffers are empty, in which case the label of the deque is identical to the label of its nonempty buffer.

This coloring of the deques maps each deque to a redundant binary representation. The least significant digit of this representation is the digit of q , the next significant digit is the digit of $child(q)$, and, in general, the i th significant digit is the digit corresponding to $child^i(q)$ if the latter is not empty. We impose an additional constraint on the deques and require that the redundant binary representation of any top-level deque is regular.

* The rightmost digit changes every increment, the digit to it left changes every other operation, and so on.

† We use the *fix* only when we know that d_{i+1} is either 0 or 1.

A regular top-level deque is labeled 0 or 1 which implies that both its prefix and its suffix are labeled 0 or 1. This means that any deque operation can be performed by operating on the appropriate top-level buffer. Suppose that the operation is either a push or a pop, the case of inject and eject is symmetric. We can construct the resulting queue q' by setting $\text{child}(q') \neq \text{child}(q)$ and $\text{suffix}(q') \neq \text{suffix}(q)$. The prefix of q' is a newly allocated buffer that contains the elements in $\text{prefix}(q)$ together with the new element in case of push or without the first element in case of pop. Clearly all these manipulations take constant time.

The label of q' , however, may be one larger than the label of q . So the redundant binary representation corresponding to q' is either the same as the redundant binary representation of q in which case it is regular, or it is obtained from the redundant binary representation of q by incrementing the least significant digit. (The least significant digit can also decrease in which case regularity is also preserved.) This corresponds to the first step in the increment procedure for redundant regular representations described in the previous section.

To make the redundant binary representation of q' regular we may have to apply a fix operation. Let i be the minimum such that $\text{child}^i(q')$ is labeled 2. If for all $j < i$, $\text{child}^j(q')$ is labeled 1 then the fix has to change the label of $\text{child}^i(q')$ to 0 and increment the label of $\text{child}^{i+1}(q')$.

Fortunately, we have an appropriate interpretation for such a fix. Assume $\text{child}^{i+1}(q')$ have a non-empty child. (We omit the discussion of the case where $\text{child}^{i+1}(q')$ have an empty child which is similar.) We know that the label of $\text{child}^{i+1}(q')$ is either 0 or 1 so neither of its buffers is empty or full. If the prefix of $\text{child}^i(q')$ has at least four elements we eject 2 of these elements and push them as a single pair to the prefix of $\text{child}^{i+1}(q')$. If the prefix of $\text{child}^i(q')$ has at most one element we pop a pair from the prefix of $\text{child}^{i+1}(q')$ and inject the components of the pair into the prefix of $\text{child}^i(q')$. This makes the prefix of $\text{child}^i(q')$ containing either two or three elements. Similarly by popping a pair from or pushing a pair to the suffix of $\text{child}^i(q')$, and injecting a pair to or ejecting a pair from the suffix of $\text{child}^{i+1}(q')$ we make the suffix of $\text{child}^i(q')$ containing two or three elements. As a result the label of $\text{child}^i(q')$ and its two buffers becomes 0 while possibly increasing the label of one or both buffers of $\text{child}^{i+1}(q')$ and thereby the label of $\text{child}^{i+1}(q')$ as well.

There is one missing piece for this simulation to work efficiently. The topmost deque labeled 2 may be arbitrarily deep in the recursive structure of q' , since it can be separated from the top level by many deques labeled 1. To implement the fix efficiently we have to be able to find this deque fast and change it in a purely functional way by copying the deques that change without having to copy all their ancestors deques.

For this reason we do not represent a deque in the obvious way, as a stack of prefix-suffix pairs. Instead, we break this stack up into substacks. There is one substack for the top-level deque and one for each descendant deque labeled 0 or 2 not at the top level. Each substack consists of a top-level, or a deque labeled 0, or a deque labeled 2 and all consecutive proper descendant deques labeled 1. We represent the entire deque by a stack of substacks of prefix-suffix pairs using this partition into substacks. This can be realized with four pointers per each node representing a deque at some level. Two of the pointers are to the prefix and suffix of the deque. One pointer is to the node for the child deque if this deque is non-empty and labeled 1. One pointer is to the node of the nearest proper descendant deque not labeled 1, if such a deque exists and q itself is not labeled 1 or top-level. See [Figure 4.2](#).

A single deque operation will require access to at most the top three substacks, and to at most the top two elements in any such substack. The label changes caused by a deque operation produce only minor changes to the stack partition into substacks, changes that can be made in constant time. In particular, changing the label of the top-level deque does not affect the partition into substacks. Changing the label of the topmost deque which is labeled 2 to 0 and the label of its child from 1 to 2 splits one substack into its first element, now a new substack, and the rest. This is just a substack pop operation. Changing the label of the topmost deque which is labeled 2 to 0 and the label of its child from 0 to 1 merges a singleton substack with the substack under it. This is just a substack push operation.

To add catenation, Kaplan and Tarjan had to change the definition of the data structure and allow deques to be stored as components of elements of recursive deques. The redundant binary numbering system, however, still plays a key role. To represent a catenable deque, Kaplan and Tarjan use noncatenable deques as the basic building blocks. They define a *triple* over a set A recursively as a prefix of elements of A , a possibly empty deque of triples over A , and a suffix of elements of A , where each prefix or suffix is a noncatenable deque. Then, they represent a catenable deque of elements from A by either one or two triples over A . The underlying skeleton of this structure is a binary tree (or two binary trees) of triples. The redundant binary number system is extended so that it can distribute work along these trees by adding an extra digit.

Kaplan, Okasaki, and Tarjan [14] simplified these data structures at the expense of making the time bounds amortized rather than worst case and using assignment, thus obtaining a confluently persistent data structure which is not purely functional. The key idea underlying their data structure is to relax the rigid constraint of maintaining regularity. Instead, we “improve” the representation of a deque q with full or empty prefix when we try to push or pop an element from it. Similarly, with full or empty suffix. This improvement in the representation of q is visible to all deques that contain q as a subdeque at some level and prevents from pushing into deques with full prefixes or popping from deques with empty prefixes from happening too often.

More specifically, assume that we push into a deque q with full prefix. First, we eject two elements from this prefix, make a pair containing them, and push the pair recursively into $\text{child}(q)$. Let the result of the recursive push be $\text{child}'(q)$. Then we change the

representation of q so that it has a new prefix which contains all the elements in the prefix of q but the two which we ejected, and its child deque is $\text{child}'(q)$. The suffix of q does not change. Finally we perform the push into q by creating a new queue q' that has the same suffix and child deque as q , but has a new prefix that contains the elements in the prefix of q together with the new element. A careful but simple analysis shows that each operation in this implementation takes $O(1)$ amortized time. By extending this idea, Kaplan, Okasaki, and Tarjan managed to construct catenable deques using only constant size buffers as the basic building blocks.

33.5 Concluding Remarks and Open Questions

Much progress has been made on persistent data structures since the seminal paper of Driscoll et al. [1]. This progress has three folds: In developing general techniques to make any data structure persistent, in making specific data structures persistent, and in emerging algorithmic applications. Techniques developed to address these challenges sometimes proved useful for other applications as well.

This algorithmic field still comprise intriguing challenges. In developing general techniques to make data structures persistent, a notable challenge is to find a way to make the time slowdown of the node splitting method worst case. Another interesting research track is how to restrict the operations that combine versions in a confluently persistent setting so that better time bounds, or simpler simulations, are possible. We also believe that the techniques and data structures developed in this field would prove useful for numerous forthcoming applications.

34.1 Introduction

Sets are a fundamental concept in computer science: the study of algorithms and data structures for maintaining them were among the earliest developments in data structures. Our focus will be on problems that involve maintaining a family \mathcal{F} of sets, where all sets are drawn from a *universe* U of elements. We do not assume that there is a particular natural order among the elements of U , and in particular do not focus on data structuring problems on sets where the operations explicitly assume such an order (e.g., priority queues). A *base* repertoire of actions is as follows:

<code>create()</code>	Create a new empty set, add it to \mathcal{F} and return the name of the set.	(34.1)
<code>destroy(A)</code>	If $A = \emptyset$ then remove A from \mathcal{F} . If $A \neq \emptyset$, flag an error.	
<code>insert(x, A)</code>	Set $A \leftarrow A \cup \{x\}$.	
<code>delete(x, A)</code>	Set $A \leftarrow A - \{x\}$.	

The following operation is fundamental for data structuring problems involving sets in general, but plays only an auxiliary role in this chapter:

$$\text{member}(\mathbf{x}, \mathbf{A}) \text{ Returns ‘true’ if } \mathbf{x} \in \mathbf{A} \text{ and ‘false’ otherwise.} \quad (34.2)$$

If we take only `insert`, `delete` and `member`, we get the *dictionary* problem, covered in Part III. The base repertoire plus `member` is essentially no more difficult, as it represents the problem of maintaining a collection of independent dictionaries over a common universe. In this chapter, we focus on adding operations to this base repertoire that take two or more sets as arguments. For example, we could consider the standard set-theoretic operations on two sets A and B :

$$A \text{ op } B, \text{op} \in \{\cup, \cap, -\}.$$

A data structure may support only an *enumerative* form of these operations, whereby the result of $A \text{ op } B$ is, in essence, some kind of enumeration of the set $A \text{ op } B$. This result may not be in the same representation as A or B , and so one may not be able to operate on it (e.g., $((A \text{ op } B) \text{ op } C)$ may not involve just two executions of `op`). The complexity of the algorithms will generally

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

be measured in terms of the following parameters:

$$\begin{aligned} n &= \sum_{A \in \mathcal{F}} |A| \text{ (the total size of all sets in the family)} \\ m &= |U| \text{ (the size of the universe)} \\ k &= |\mathcal{F}| \text{ (the number of sets in the family)} \end{aligned} \tag{34.3}$$

34.1.1 Models of Computation

The problems that we consider in this chapter have been studied on a variety of different computation models. The primary models for proving upper bounds are the *pointer machine* model and the *random-access machine (RAM)* model. The pointer machine [1–3] postulates a storage consisting of an unbounded collection of registers (or records) connected by pointers. Each register can contain an arbitrary amount of additional information, and no arithmetic is allowed to compute the address of a register. The processor has a constant number of (data and pointer) registers that it can manipulate directly, but all other temporary results must be held in the storage records. In particular, this means that to answer a query, the processor must either start from a pointer p into the data structure provided by the “user” or from one of the constant number of pointers it itself holds, and explore the data structure by following pointers starting from p .

The RAM model we use is a standard variant of the original RAM model [4], the *word RAM* model [5]. Briefly, the word RAM model uses the unit-cost criterion, and a word size of $\Theta(\log n)$ bits, where $n = \sum_{S \in \mathcal{F}} |S|$.[†] Clearly the word size should be at least $\log n + O(1)$ bits—otherwise one could not even address the amount of memory required to store \mathcal{F} . Nevertheless, there are instances where the solutions that result from the use of this model could be viewed as “cheating.” For example, we could have $n = 2^{\Theta(|U|)}$, in which case the word size would be $\Theta(|U|)$ bits, which would allow most set operations to be done in $O(1)$ time by bitwise operations on a single word. The solutions that we discuss, however, do not exploit this fact. In the related *cell probe* model, the storage of the computer is modeled by cells numbered $0, 1, 2, \dots$, each of which can store a number of $O(\log n)$ bits. The running time of an algorithm in this model is measured as just the number of words (cells) accessed during an operation. All other computations are free.

The *arithmetic* model, used primarily for proving lower bounds, was proposed by Fredman [6] and Yao [7]. We now give a somewhat simplified description of this model which conveys the essential aspects: the interested reader is referred to [8, section 7.2.3] for further details. In many cases of interest, it is useful to assume that the data structure operates on values from a set \mathcal{M} , which is a *monoid*. This means that $\mathcal{M} = (\mathcal{M}, +, 0)$ is augmented with an associative and commutative operator $+$ such that \mathcal{M} is closed under $+$ and 0 is the identity element for $+$. The data structure is modeled as an collection of variables v_0, v_1, \dots , each of which can hold a value from \mathcal{M} and initially contains 0 . After receiving the input to each operation, the algorithm executes a sequence of operations of the form $v_i \leftarrow \text{INPUT}$, $v_i \leftarrow v_j + v_k$ or $\text{OUTPUT} \leftarrow v_i$. The algorithm must be correct for all choices of \mathcal{M} , thus in particular it cannot assume that the operator $+$ is invertible. The cost of an algorithm in processing a sequence of operations is the total number of such instructions executed by it. The restriction that \mathcal{M} is a monoid (rather than say, a group) is partly for ease of proving lower bounds. However, known algorithms in this framework do not gain significant asymptotic speedups by exploiting stronger models (e.g., by using the fact that $+$ is invertible in groups).

34.2 Simple Randomized Set Representations

In this section we cover a simple, but general-purpose set representation due to [9,10]. In addition to the base repertoire (34.1), we wish to support:

$$A \text{ op } B, \text{ op } \in \{\cup, \cap, -\},$$

as well as the following boolean operations:

$$\text{equal}(A, B) \quad \text{Returns ‘true’ if } A = B \text{ and ‘false’ otherwise.} \tag{34.4}$$

$$\text{subset}(A, B) \quad \text{Returns ‘true’ if } A \subseteq B \text{ and ‘false’ otherwise.} \tag{34.5}$$

This representation touches upon a topic of interest in its own right, that of the *unique* representation of sets, which can be defined as follows. We consider a class of representations that suffice to represent all subsets of a given universe U . However, we require that each set should have a unique representation within that class. In particular the representation should be independent of the sequence of operations that created the set (e.g., a red-black tree representation is not unique). Unique representations have the

[†] To some readers, the idea that the wordsize of a machine can change as we update the data structure may appear a little strange, but it is merely a formal device to ensure reasonable usage.

desirable property that it is then possible to ensure that all instances of the same set within a family (including sets that are created as intermediate results in a computation) are represented by the same object within the data structure. This allows constant-time equality tests of two sets: just check if they are the same object! The difficulty, of course, is to combine unique representations with rapid updates.

This definition also applies to *randomized* algorithms, which may access a source of random bits while executing a query or update, and the uniqueness requirement here means that the choice of representation for a set depends solely upon the sequence of random bits that are output by the source. (If, as in practice, one uses a pseudo-random generator, then the representation for a given set depends only upon the seed used by the pseudo-random number generator.)

34.2.1 The Hash Trie

We first weaken the notion of a unique representation, and speak about the unique representation of sets from a *labeled* universe. Here, we assume that the elements of the universe U are labeled with (not necessarily unique) b -bit strings, and for $x \in U$ we denote its label by $\ell(x)$. In addition, we also have the notion of a *labeled set* A_y , where y is a sequence of $\leq b$ bits. Any labeled set A_y satisfies the property that for all $x \in A_y$, y is a prefix of $\ell(x)$.

Given a set from a labeled universe, one can of course use the well-known binary trie [11] to represent it. For the sake of precision we now define the binary trie, when used to represent a (labeled) set S_y :

- If $|S_y| = 0$ then the trie is empty.
- If $|y| = b$ then the trie is a leaf node that contains a pointer to a linked list containing all elements of S_y .
- Otherwise, the trie comprises an internal node with an edge labeled 0 pointing to a binary trie for the set

$$S_{y0} = \{x \in S_y \mid y0 \text{ is a prefix of } \ell(x)\}$$

and an edge labeled 1 pointing to a binary trie for the labeled set

$$S_{y1} = \{x \in S_y \mid y1 \text{ is a prefix of } \ell(x)\}$$

A set $S \subseteq U$ is represented as the labeled set S_Λ , where Λ denotes the empty string.

Consider a family \mathcal{F} of sets from a universe U and let each node in the resulting collection of tries represent a labeled set in the natural way. Then if two nodes represent labeled sets A_z and B_z , such that $A_z = B_z$ (note that the label is the same) then the subtrees rooted at these nodes have an identical structure. One can then save space by ensuring that all sets in \mathcal{F} whose representations have instances of the set A_z point to a single instance of A_z . By consistently applying this principle, we will ensure that two sets $S, T, S = T$ point to a single instance of S_Λ .

We now give an example. Let $U = \{a, b, c, d, e, f\}$ and \mathcal{F} contain the sets $X = \{a, c, f\}$, $Y = \{c, d, e\}$ and $Z = \{a, b, c, f\}$. Suppose that the elements of U are labeled as follows:

$$\ell(a) = 001, \ell(b) = 011, \ell(c) = 010, \ell(d) = 101, \ell(e) = 110, \ell(f) = 010$$

Without exploiting the unique representation property, we would get the representation in Figure 34.1(i), and by exploiting it and storing subtrees uniquely it we get the representation in Figure 34.1(ii). Updates now need to be done with a little care: one cannot, for example, add a new child to a node, as the subtree in which the node lies may be shared among a number of sets. The solution is to use *nondestructive* updates, namely, implementing updates by making a *copy* of the path from the leaf to be added/deleted to the name of the sets (cf. *persistent* data structures). Figure 34.1(iii) shows the state of the data structure after executing the commands `insert(a, Y)` and `insert(b, X)`, which we now explain.

First, let us consider the operation `insert(a, Y)`. We need to insert a as a sibling of c in the trie for Y . Since the path from c up to the root of Y could potentially be shared by other sets, we do not modify the node that is the parent of c , instead making a copy of the entire path from c to the node that is the root of the representation of Y , as shown in the figure. The pointer for Y is then appropriately modified. The nodes that were previously part of the representation of Y (shown in dotted outline) are, in this example, not reachable as part of any set and may be cleared as part of a garbage-collection phase (they are not explicitly freed during the insertion). Now coming to `insert(b, X)`, we proceed as before, and do not insert b directly as a sibling of (c, f) under X . However, before creating a new node with the leaves b and (c, f) as children, we check the data structure to see if such a node exists and find one (this is the node representing the set Z_{01}). Therefore, we avoid creating this node. Continuing, we discover that all the nodes that we would have tried to create as part of this insertion already exist and therefore conclude that the sets X and Z are now the same (and hence their tries should be represented by the same node).

To support the reuse of existing nodes, a dictionary data structure that stores all nodes currently in the data structure is maintained. A node x with left child y and right child z is stored in this dictionary with the key $\langle y, z \rangle$ (either of y or z could be nil).

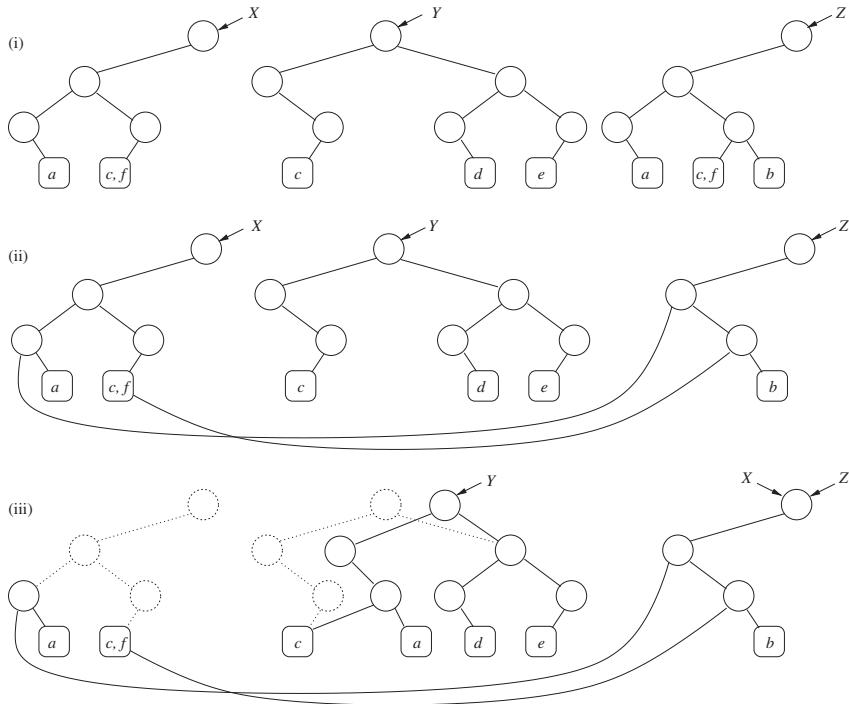

FIGURE 34.1 Unique set representations.

Each insertion requires $\Theta(b)$ lookups or insertions into this dictionary. Avoiding this overhead is important, but in a randomized setting the dictionary can be implemented using dynamic perfect hashing, giving $O(1)$ overhead. This idea is also used in practical implementations of functional programming languages such as LISP, and is referred to as *hashed consing* in that context.[‡]

In a randomized setting, the other problem, that of obtaining suitable labels, can also be solved easily. We simply let ℓ be a function chosen at random from a universal class of hash functions (cf. [Chapter 9](#)). By choosing $\ell : U \rightarrow \{1, \dots, n^3\}$ (e.g.) we can ensure that the number of *collisions*, or pairs of distinct elements x, y in U with $\ell(x) = \ell(y)$ is $O(1)$ with a probability that tends to 1 as $n \rightarrow \infty$. This means that we can essentially ignore the possibility that there are more than a constant number of elements at the leaf of any trie. Clearly, labels are $O(\log n)$ bits long.

Note that we can ensure that both the lengths of the labels and the number of collisions stays under control as n changes, by simply rehashing whenever the value of n doubles or halves since the last rehash. We now analyze some parameters of this data structure. Clearly, equality testing takes $O(1)$ time. Each insertion or deletion takes time and space proportional to the depth of the tries, which is $O(\log n)$. Both insertions and deletions may cause some nodes to become “garbage” (i.e., unreachable from any set)—these need to be compacted periodically, for example, when a rehash occurs. It is easy to verify that the amortized cost of rehashing and garbage collection is negligible. This gives parts (i) and (ii) of the following theorem; for part (iii) we refer the reader to [[9, Chapter 8](#)]:

Theorem 34.1

There is a data structure for a family of sets that:

- Supports `insert` and `delete` in $O(\log n)$ amortized expected time and equality-testing in $O(1)$ worst-case time;
- Uses $O(n \log n)$ space, and
- Given two sets A and B , supports the constructive version of $A \text{ op } B$ for $\text{op} \in \{\cup, \cap, -, \subseteq\}$ in $O(|S_2|(1 + \log(S_3/S_2))$ amortized expected time, where S_2 and S_3 are the middle and largest sets of $A - B$, $B - A$ and $A \cap B$.

[‡] The operation for creating a new node is called a Cons.

Remark 34.1

Note that a fairly naive bound for an operation $A \text{ op } B$, for $\text{op} \in \{\cap, \cup, -, \subseteq\}$ is $O(|A| \log |B|)$, implemented by storing each tree in the family in a binary-tree based dictionary. Thus, Theorem 34.1 is not, in the worst case, a lot better. On the other hand, if we have two large sets S and T that differ in only a constant number k of elements then the expected running time of the above algorithm is $O(k \log \max\{|S|, |T|\})$.

34.2.2 Some Remarks on Unique Representations

There are interesting issues regarding the unique representation problem, in particular for unlabeled universes. We first mention here that both the *randomized search tree* and the *skip list* (cf. Chapter 14) satisfy the unique representation described above, even for unlabeled universes, and support the dictionary operations (insert, delete and member) in $O(\log n)$ expected time. In each of these cases, the algorithm described there should be modified so that instead of choosing a random height for a node in a skip list, or a random priority for a node in a randomized search tree, we should choose a function $U \rightarrow [0, 1]$ that behaves “randomly” (we refer the reader to [12] for a precise theoretical statement).

By representing each set in a family using either one of these representations we get alternatives to parts (i) and (ii) for Theorem 34.1. However, one may ask about deterministic unique representations that support rapid updates. The reader is directed to [13, 14] and the references therein for pointers to the literature on this fascinating area. We only note here that [14] show a $\Theta(n^{1/3})$ time bound for supporting the above dictionary operations, provided that the class of representations is restricted to “graph-like” representations (including, of course, trees). This shows an exponential separation between randomized uniquely represented dictionaries and deterministic (non-unique) dictionaries on the other hand, and deterministic uniquely represented dictionaries on the other. This result is not entirely conclusive, however: by labeling elements in U with integers from $\{0, \dots, m - 1\}$, as observed in [13, Section 2.3], the above trie-based approach gives uniquely represented dictionaries that support all operations in $O(\log m)$ time, where $m = |U|$. Thus, there is a “dichotomy” depending upon whether we are interested in bounds that depend on m alone or n alone (cf. Chapter 40). It is not known how the complexity of unique representation depends on the relationship between m and n . Indeed, the gap in knowledge is quite large, as the $\Omega(n^{1/3})$ applies when $n \sim \log^* |U|$, while the $O(\log m)$ algorithm is optimal only when $n \sim |U|^\epsilon$ for some constant $\epsilon > 0$.

34.3 Equality Testing

We now consider representations that only support the base repertoire (34.1) and the equal operation (34.4). Clearly we would like solutions that are better (at least in some respects) than those given by Theorem 34.1, and we begin by considering deterministic data structures. We first discuss one due to [13], which is based on binary tries (cf. Section 34.2).

The operations applied to our data structure are divided into *epochs*. At the start of an epoch the data structure is rebuilt “from scratch.” Without loss of generality we can consider U to consist of all the elements that were present in \mathcal{F} at the start of an epoch, plus all the elements that have appeared as the argument to an insert or delete operation since then (note that U may contain elements no longer present in \mathcal{F}). We can then label elements in U with values from $\{0, \dots, |U| - 1\}$, using $\lceil \log m \rceil$ -bit integers, where $m = |U|$. Whenever we insert an element that is not in U , we give it the next higher integer. If $\sum_{A \in \mathcal{F}} |A| = n_0$ at the start of an epoch, we start the next epoch after $n_0/2$ updates (inserts or deletes). Rebuilding from scratch involves resetting U to be only those elements that are currently present in \mathcal{F} , relabeling all elements with integers from $\{0, \dots, |U| - 1\}$, and recreating the data structure with these labels, as well as any auxiliary data structures. It will be easy to see that the amortized cost of rebuilding is negligible, and that $|U| = O(n)$ at all times.

Each set is represented as a binary trie, with shared subtrees as in the previous section. Updates are also done non-destructively. A key difference is the method used to avoid creating nodes that already exist. Nodes are numbered serially in order of creation. If node p points to node v , we say that p is one of (possibly many) parents of v . Each node v , maintains a set $\text{parents}(v)$ of all its parents. Each parent $p \in \text{parents}(v)$ is assigned a key equal to $(\text{node-number}(w), b)$, where w is the other node (besides v) pointed to by p , and b equals 0 or 1 depending on whether v is a left child of p or not. When doing an update, before creating a new node with left child x and right child y , we search set $\text{parents}(x)$ for the key $(\text{node-number}(y), 0)$. If such a key is found, we return the matching parent, which is precisely a node with left child x and right child y . Otherwise, create a new node p with pointers to v and w , set $\text{parents}(p)$ to empty, insert p into $\text{parents}(v)$ and $\text{parents}(w)$, and return p . The issue is how to represent the sets $\text{parents}(v)$ (cf. the dictionary in the previous section).

Each set $\text{parents}(v)$ is represented by a binary search tree and a variation of the splay algorithm is used to perform searches. The splay algorithm is especially appropriate as it can be used to exploit patterns in the sequence of accesses. Although a detailed consideration of splay trees is beyond the scope of this chapter, the necessary facts are, roughly, that (a) insertion of a key that is larger than the maximum key currently in the tree (a *passive* insertion) has constant amortized cost while an insertion that is

not passive (an *active*) insertion has logarithmic amortized cost (b) if the frequency of search for an item i is $0 < \alpha_i < 1$ then the amortized cost of all searches for item i is essentially $O(1 + \log(1/\alpha_i))$. This is summarized in the lemma below:

Lemma 34.1

Consider a sequence of insertions and searches performed on an (initially empty) binary search tree using splays. Let:

- s_i = the number of searches of item i
- s = the total number of searches,
- a = the number of active insertions, and
- p = the number of passive insertions.

The cost of this sequence is $O((p + a) + s + a \log a + \sum_{s_i \geq 1} s_i \log(s/s_i))$.

Remark 34.2

Insertions into an initially non-empty tree are easily handled: pretend to start with an empty tree and initialize the tree with a sequence of passive insertions. By the above lemma, the additional cost is linear in the size of the initial tree.

We now argue that although an update (`insert` or `delete`) may result in $\Theta(\log m)$ node creations, and hence as many insertions into the *parents* dictionaries, most of the insertions are passive. Specifically, let $x(y, z)$ denote the creation of a node x with children y and z . Then, an update may result in a sequence of node creations: $y_1(x_0, x_1), y_2(y_1, x_2), \dots, y_l(y_{l-1}, x_l)$, where y_1, \dots, y_l are “new” nodes and x_0, \dots, x_l are nodes that existed previously in the data structure. Note that because the y_i ’s are new nodes, they have higher *node-numbers* than the x_i ’s. As a result, of the $2l$ insertions into *parents* dictionaries caused by this update, all but two—the insertion of y_i with key $\langle \text{node-number}(x_0), b \rangle$ ($\langle \text{node-number}(x_1), 1 - b \rangle$) into *parents*(x_1) (*parents*(x_0))—are passive.

We now need to bound the time to perform searches on the *parents* dictionary. For this, we consider a single epoch, and let $G = (V, E)$ be directed acyclic graph formed by the nodes at the end of the epoch. The sources (nodes of zero in degree) are the roots of (current and past) sets and the sinks (nodes of zero outdegree) are the elements of U . Note that all nodes have outdegree at most 2.

An update to sets in \mathcal{F} results searches in the the *parents* dictionary of nodes that lie along a path π from a source to a sink in G . It should be noted that the path is traversed in reverse, from a sink to a source. Note that each time that a search traverses an edge (v, w) , where w is a parent of v , the key that is searched for in *parents*(v) is the same. Thus we can identify the traversal of an edge in G with a search of a particular key in a particular dictionary. Let a_e denote the number of times an edge $e \in E$ is traversed, and note that we can delete from G all edges with $a_e = 0$. Letting $A_v = \sum_{(w,v) \in E} a_{(w,v)}$, the cost of searches in *parents*(v) for any vertex $v \in V$, denoted $\text{cost}(v)$, is given by $\sum_{(w,v) \in E} a_{(w,v)} \log A_v / a_{w,v}$, by Lemma 34.1. Let V' denote the set of nodes that are neither sinks nor sources, and note that for any $v \in V'$, $\sum_{(w,v) \in E} a_{(w,v)} = \sum_{(v,w) \in E} a_{(v,w)}$. Thus, we have:

$$\begin{aligned} \sum_{v \in V} \text{cost}(v) &= \sum_{(w,v) \in E} a_{(w,v)} \log A_v / a_{w,v} \\ &= \sum_{v \in V'} \sum_{(w,v) \in E} a_{(w,v)} \log A_v + \sum_{v \in V - V'} \sum_{(w,v) \in E} a_{(w,v)} \log A_v + \sum_{e \in E} a_e \log 1/a_e \\ &= \sum_{v \in V'} \sum_{(v,w) \in E} a_{(v,w)} \log A_v + \sum_{v \in V - V'} \sum_{(w,v) \in E} a_{(w,v)} \log A_v + \sum_{e \in E} a_e \log 1/a_e \\ &\leq \sum_{v \in V'} \sum_{(v,w) \in E} a_{(v,w)} \log A_v / a_{(v,w)} + \sum_{v \in V - V'} \sum_{(w,v) \in E} a_{(w,v)} \log A_v \\ &\leq \sum_{v \in V'} \log \text{out}(v) + \sum_{v \in V - V'} \sum_{(w,v) \in E} a_{(w,v)} \log A_v \end{aligned}$$

where $\text{out}(v)$ denotes the out-degree of v . The last step uses the fact that for all $\alpha_1, \dots, \alpha_d$, $\alpha_i \in [0,1]$ and $\sum_i \alpha_i = 1$, $\sum_{i=1}^d \alpha_i \log(1/\alpha_i) \leq \log d$ (the “entropy” inequality).

Note that $\sum_{v \in V - V'} \sum_{(w,v) \in E} a_{(w,v)}$ is just the number of updates in this epoch and is therefore $\Theta(n)$. Since $A_v = O(n)$ we can bound the latter term by $O(n \log n)$. Since the outdegree of each node is 2, the former term is $O(V)$, which is also $O(n \log n)$. We thus find that all dictionary operations in the sets *parents*(v) take $O(n \log n)$ time, and so the amortized cost of an update is $O(\log n)$. To conclude:

Theorem 34.2

There is a data structure for a family of sets that supports insert, delete and member in $O(\log n)$ amortized time, equal in $O(1)$ worst-case time, and uses $O(n \log n)$ words of space, where n is the current size of the family of sets.

We now describe the *partition tree* data structure for this problem [15,16]. Since the partition tree is closely related to the above data structure, results based on the partition tree are not significantly different from those of Theorem 34.2. We describe a slightly simplified version of the partition tree by assuming that U is fixed. The partition tree is a *full* binary tree T with $|U|$ leaves, that is, a tree where the leaves are all at depth $\lfloor \log |U| \rfloor$ or $\lceil \log |U| \rceil$, and all nodes have either two or zero children. At the leaves of this tree we place the elements of U (in any order). For each internal node v of T , we let $D(v)$ denote the elements of U that are at leaves descended from v . A set $A \in \mathcal{F}$ is stored at an internal node v if $D(v) \cap A \neq \emptyset$. Furthermore, all sets that are stored at an internal node v are grouped into equivalence classes, where the equivalence relation is given by $A \equiv B \iff (A \cup D(v) = B \cup D(v))$. Clearly, two sets are equal iff they belong to the same equivalence class at the root of the tree and so this representation supports constant-time equality testing. Note that if n_v is the number of sets stored at an internal node v of T , then $\sum_v n_v = O(n \log |U|)$. This is because each set containing x appears once on each node from the path leading from x to the root (and hence $O(\log |U|)$ times in all), and $\sum_{x \in U} |\{A \in \mathcal{F} \mid x \in A\}| = n$. The key issue, of course, is how to update the partition tree when executing $\text{insert}(x, A)$ ($\text{delete}(x, A)$). We traverse T from x to the root, storing (or removing) A from all the nodes along the path. We now show how to maintain the equivalence classes at these nodes.

At the leaf, there is only one equivalence class, consisting of all sets that contain x . We merely need to add (delete) A to (from) this equivalence class. In general, however, at each node we need to determine whether adding/deleting x to/from A causes A to move into a new equivalence class of its own or into an existing equivalence class. This can be done as follows. Suppose γ is a (non-empty) equivalence class at a (non-leaf) node u in T and suppose that v, w are u 's children. A little thought shows that must be (non-empty) equivalence classes α, β at v, w respectively such that $\gamma = \alpha \cap \beta$. A global dictionary stores the name of γ with the key $\langle \alpha, \beta \rangle$. Inductively assume that following an operation $\text{insert}(x, A)$ (or $\text{delete}(x, A)$) we have updated the equivalence class of A at all ancestors of x up to and including a node v , and suppose that A is in the equivalence class α at v . Next we determine the equivalence class β of A in v 's sibling (this would not have changed by the update). We then look up the dictionary with the key $\langle \alpha, \beta \rangle$; if we find an equivalence class γ stored with this key then A belongs to γ in v 's parent u , otherwise we create a new equivalence class in u and update the dictionary.

Lam and Lee [16] asked whether a solution could be found that performed all operations in good single-operation worst-case time. The main obstacles to achieving this are the amortization in the splay tree and the periodic rebuilding of the partition tree. Again dividing the operation sequence into *epochs*, Lam and Lee noted that at the end of an epoch, the partition tree could be copied and rebuilt incrementally whilst allowing the old partition tree to continue to answer queries for a while (this is an implementation of the *global rebuilding* approach of Overmars [17]). By “naming” the equivalence classes using integers from an appropriate range, they note that the dictionary may be implemented using a two-dimensional array of size $O(n^2 \log n)$ words, which supports dictionary operations in $O(1)$ worst-case time. Alternatively, using standard balanced binary trees or Willard's q -fast tries [18], or the more complex data structure of Beame and Fich [19] gives a worst-case complexity of $O(\log n)$, $O(\sqrt{\log n})$ and $O((\log \log n)^2)$ for the dictionary lookup, respectively. Using these data structures for the dictionary we get:

Theorem 34.3

There is a data structure for a family of sets that supports equal in $O(1)$ worst-case time, and insert and delete in either (i) $O(\log n (\log \log n)^2)$ worst-case time and $O(n \log n)$ space or (ii) $O(\log n)$ worst-case time and $O(n^2 \log n)$ space.

Remark 34.3

The reader may have noticed the similarities between the lookups in partition trees and the lookup needed to avoid creating existing nodes in the solutions of Theorems 34.1 and 34.2; indeed the examples in Figure 34.2 should make it clear that, at least in the case that $|U|$ is a power of 2, there is a mapping from nodes in the DAG of Theorem 34.2 and partitions in the partition tree. The figure illustrates the following example: $U = \{a, b, c, d\}$, $\mathcal{F} = \{A, B, C, D\}$, $A = \{a, c, d\} = C$, $B = \{a, b, d\}$, $D = \{c, d\}$, and an assumed labeling function that labels a, b, c and d with 00, 01, 10 and 11 respectively. The partitions in (ii) shown circled with a dashed/dotted line correspond to the nodes circled with a dashed/dotted line in (i).

34.4 Extremal Sets and Subset Testing

This section deals with testing sets in \mathcal{F} for the subset containment relationship. We first survey a static version of this problem, and then consider a dynamisation.

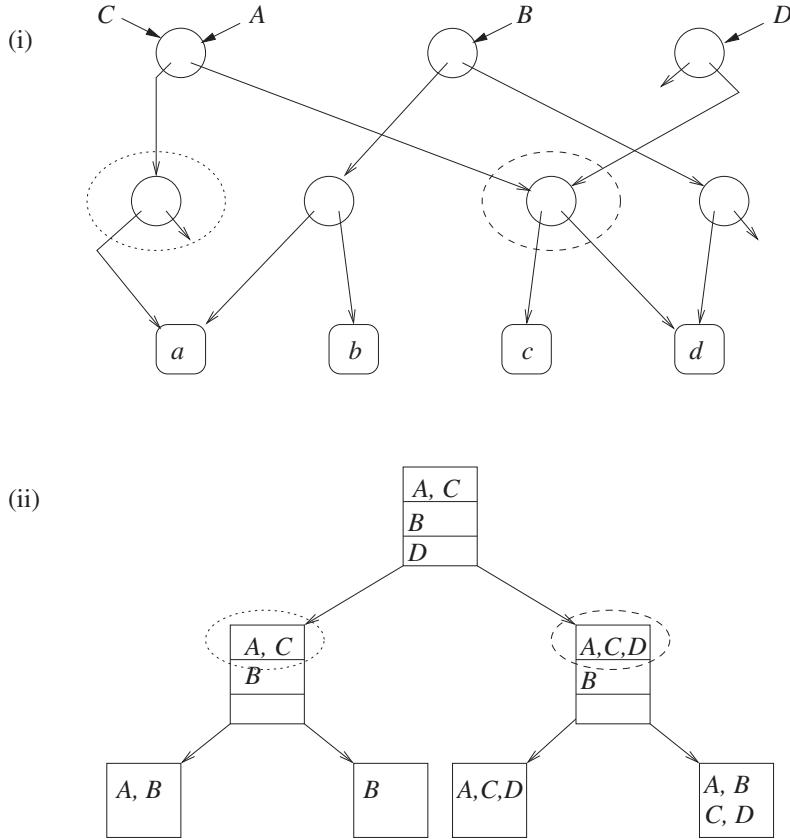

FIGURE 34.2 The partition tree (ii) and its relation to the DAG created by the binary trie representation with shared subtrees.

34.4.1 Static Extremal Sets

Here we assume that we are given a family \mathcal{F} of sets from a common universe as input. A set S is *maximal* in \mathcal{F} if there is no set $T \in \mathcal{F}$ such that $S \subset T$. A set S is *minimal* in \mathcal{F} if there is no set $T \in \mathcal{F}$ such that $S \supset T$. The *extremal sets* problem is that of finding all the maximal (or all the minimal) sets in \mathcal{F} . A closely related problem is the computation of the *complete subset graph*, which represents all edges in the partial order induced among members of \mathcal{F} by the subset relation. Specifically, the complete subset graph is a directed graph whose vertices are the members of \mathcal{F} and there is an edge from x to y iff $x \subset y$. This is a problem that arises in a number of practical contexts, for example, it can be used to maximally simplify formulae in restricted conjunctive normal form [20].

This problem has been considered in a number of papers including [20–24]. We now summarize the results in these papers. As before, we let $k = |\mathcal{F}|$ denote the size of the family, and $n = \sum_{S \in \mathcal{F}} |S|$ be the total cardinality of all sets. A number of straightforward approaches can be found with a worst-case complexity of $O(n^2)$. It can be shown that the subset graph has $\Omega(n^2 / (\log n)^2)$ edges [21], which gives a lower bound for any algorithm that explicitly lists the complete subset graph. An aim, therefore, is to bridge the gap between these bounds; all results below are in the word RAM model.

Yellin and Jutla gave an algorithm that computes the subset graph using $O(n^2 / \log n)$ dictionary operations. Using hashing, all dictionary operations take $O(1)$ expected time, and we get an $O(n^2 / \log n)$ expected running time. Using Willard's q -fast tries [18], or the more complex data structure of Beame and Fich [19] gives running times of $O(n^2 / \sqrt{\log n})$ or $O((n \log \log n)^2 / \log n)$ respectively. Pritchard [22] gave a simple algorithm that ran in $O(n^2 / \log n)$ time. In [23] he re-analyzed an earlier algorithm [20] to show that this algorithm, too, ran in $O(n^2 / \log n)$ time (the algorithm of [20,23] uses RAM operations less extensively and is a good candidate for porting to the pointer machine model). Finally, Pritchard [24] gave an algorithm that uses the bit-parallelism of the word RAM extensively to achieve an $O(n \log \log n / (\log n)^2)$ running time.

All of the above are static problems—it is very natural to ask about the complexity of this problem when updates may change the sets in \mathcal{F} . Again, if one wishes explicitly to maintain the entire subset graph, it is easy to see that $\Omega(n)$ edges may change as the result of a single update. Take $U = \{1, \dots, u\}$ and $\mathcal{F} = \{A, B_2, \dots, B_u\}$, where $A = U$ and $B_i = \{1, i\}$ for $i = 2, \dots, u$. The sum of the sizes of the sets in \mathcal{F} is $2u - 2$, but deleting the element 1 from A removes all $u - 1$ edges from the complete subset

graph. It is not very hard to come up with algorithms that can achieve an $O(n)$ running time (see, e.g., [21]). To obtain a better complexity, therefore, we must consider algorithms that do not explicitly store this graph. One way of doing this is to consider the *dynamic subset testing* problem, defined as the problem of supporting the base repertoire (34.1) and the subset operation (34.5). Since the query $\text{subset}(A, B)$ tests if there is an edge between A and B in the complete subset graph, this problem seems to be an appropriate dynamisation of the extremal sets problem, and it is dealt with in the next section.

34.4.2 Dynamic Set Intersections and Subset Testing

Rather than consider the dynamic subset testing problem directly, we consider a related problem, the *dynamic set intersection* problem. In addition to the base repertoire (34.1) of actions above, we consider an enumerative version of the following:

$$\text{intersect}(A, B) \quad \text{Report the intersection of sets } A \text{ and } B. \quad (34.6)$$

Other variations could include returning the size of the intersection, or retrieving some values associated with the elements in the intersection. A unifying way to study these problems is as follows: we are given a set \mathcal{M} of *information* items that will be associated with elements of U , a function $I : U \rightarrow \mathcal{M}$ that associates values from M with keys in U . We assume that $\mathcal{M} = (\mathcal{M}, +, 0)$ is a monoid. The query $\text{intersect}(A, B)$ then returns $\sum_{x \in A \cap B} I(x)$, where the sum is taken with respect to $+$. It is easy to cast the intersection problem and its variants in this framework. The basic problem defined above can be obtained by letting $\mathcal{M} = (2^U, \cup, \{\})$ and $I(x) = \{x\}$ for all x , and the problem where one merely has to report the size of the intersection can be obtained by setting $\mathcal{M} = (\mathbb{N}, +, 0)$ and $I(x) = 1$ for all x , where $+$ here is normal (arithmetic) addition. Note that dynamic subset testing, defined in the previous section, easily reduces to the intersection problem: $A \subseteq B$ iff $|A| = |A \cap B|$.

We now survey the results in this area. It is useful to use the notation $\tilde{O}(f(n)) = \bigcup_{c=0}^{\infty} O(f(n) \log^c n)$, which ignores polylogarithmic factors are ignored (a similar convention is used for the Ω notation, with inverse polylogarithmic factors being ignored).

For this problem, Yellin [25] gave an algorithm that processed a sequence of n insertions and deletions and q intersect operations in time $\tilde{O}(n \cdot n^{1/k} + q n^{(1-1/k)})$ time for any fixed k . The intuition behind this result is as follows. Take $t = n^{1-1/k}$ and say that a set $S \in \mathcal{F}$ is *large* if $|S| \geq t$ and *small* otherwise. All sets are represented as dictionaries (allowing membership testing in logarithmic time). Intersections between two small sets, or between a small set and a large one, are handled by testing each element of one set for membership in the other. Clearly this takes $\tilde{O}(t)$ time, and insertion into and deletion from a small set takes $\tilde{O}(1)$ time. For every pair of large sets S, T , the algorithm keeps track of $I(S \cap T)$ explicitly, by storing the elements of $S \cap T$ in a balanced binary search tree, and storing at any internal node x the monoid sums of all the elements under x .[§] Since there are at most $n/t = n^{1/k}$ large sets, an insertion into, or a deletion from, a large set requires updating at most $n^{1/k}$ of the pairwise intersections with other sets, and takes $\tilde{O}(n^{1/k})$ time. This proves the time bound, modulo some details such as dealing with changes in the value of t caused by changes in n and so on.

Dietz et al. [26] noticed that if one were to process a sequence of n updates and q queries, where n and q are known in advance, then the overall cost of Yellin's algorithm for processing the sequence is minimized by taking $n^{1/k} = \min\{n, \sqrt{q}\}$, giving an overall time bound of $\tilde{O}(q + n\sqrt{q})$. They gave an algorithm that achieves this bound even when n and q are not known in advance.

We now show that this bound is essentially tight in the arithmetic model, by giving a lower bound of $\tilde{\Omega}(q + n\sqrt{q})$. For simplicity, consider the problem where the elements in the intersection are to be reported, that is, take $\mathcal{M} = (2^U, \cup, \{\})$ and $I(x) = \{x\}$. Starting from an empty family \mathcal{F} , we build it up by insertions so that the (sums of) sizes of the pairwise intersections of sets in \mathcal{F} are large, and query all possible intersections of the sets. If the answers to all the queries were to be obtained by adding (unioning) together singleton sets, then the lower bound would follow. Unfortunately, this is too simplistic: subsets obtained as temporary values during the computation of one answer may be re-used to answer another query. To get around this, we note that a subset that is used to compute the answer to several intersection queries must lie in the common intersection of all the sets involved, and construct \mathcal{F} so that the common intersection of any of a sufficiently large (yet small) number of sets in \mathcal{F} is small. This means that no large subset can be reused very often.

We assume that $q \leq n^2$ (otherwise the lower bound is trivial). Starting with an empty family, we perform a sequence of $n = \Theta(N)$ insert operations and q queries. We choose $U = \{1, \dots, 2N/\sqrt{q}\}$ and $k = |\mathcal{F}| = \sqrt{q}$; we let $m = |U|$ and let $\ell = c \log N$ for some sufficiently large constant $c > 0$. We assume the existence of a family $\mathcal{F} = \{S_1, \dots, S_k\}$ with the following properties:

- a. $|S_i \cap S_j| = \Omega(m)$ for all i, j with $1 \leq i < j \leq k$.
- b. for any pairwise distinct indices i_1, \dots, i_ℓ , $|\bigcap_{j=1}^\ell S_{i_j}| < \ell$.

The existence of such a family is easily shown by a probabilistic argument (a collection of random sets of the appropriate size suffices). We now represent \mathcal{F} in the data structure by executing the appropriate insertions. Note that this requires at most

[§] If the monoid is $\mathcal{M} = (2^U, \cup, \{\})$, we do not store the monoid sum explicitly, but instead take the monoid sum at an internal node to be implicitly represented by the subtree rooted at it.

$km = N = \Theta(n)$ update operations, since $|S_i| \leq m$ for all i . We then query the pairwise intersections of all the sets; there are $(k/2) = \Theta(q)$ queries in all.

Firstly, note that the sizes of all the output sets sum to $\Omega(mk^2)$ by (a) above. The output to each query is conceptually obtained by a binary *union tree* in which each internal node combines the answers from its children; the external nodes represent singleton sets. Each node can be labeled with a set in the obvious way. Consider the entire forest; we wish to count the number of distinct nodes in the forest (that is, nodes labeled with distinct sets). Since each distinct set corresponds to at least one instruction that is not counted elsewhere, counting the number of distinct sets is a lower bound on the number of instructions executed.

We consider only nodes that correspond to sets of size ℓ or larger. Clearly, the number of such sets is $\Omega(mk^2/\ell)$. Furthermore, no such set can be used to answer more than $(\ell/2)$ different queries by (b). It follows that there are $\Omega(mk^2/\ell^3) = \tilde{\Omega}(n\sqrt{q})$ distinct sets, giving us a lower bound of this magnitude (as mentioned above, a lower bound of $\Omega(q)$ is trivial whenever $q = \tilde{\Omega}(n\sqrt{q})$).

Dietz et al. also considered the relatively high memory usage of the above algorithms. For example, if $q = \Theta(n)$ then both Yellin's algorithm and Dietz et al.'s algorithm use $\Omega(n^{3/2})$ space. Dietz et al. also considered the complexity of the above problem when the algorithms were restricted to use s memory locations, where $n \leq s \leq n^2$, and gave an algorithm that processed n operations (queries and updates) in $\tilde{O}(n/s^{1/3})$ time. Both the upper bound and the lower bound are more complex than those for the unlimited-memory case. We summarize with the main theorems of Dietz et al.:

Theorem 34.4

For the problem of maintaining a family of sets under create, insert, delete and intersect, we have the following results:

- i. Any algorithm requires $\tilde{\Omega}(q + n\sqrt{q})$ time to process a sequence of n updates and q queries in the arithmetic model of computation.
- ii. Any intermixed sequence of n updates and q queries can be processed in $\tilde{O}(n\sqrt{q} + q)$ time using $O(\min\{n\sqrt{q}, n^2\})$ space.
- iii. There is a sequence of $O(n)$ updates and queries that requires $\tilde{\Omega}(n^2s^{-1/3})$ operations in the arithmetic model, if the algorithm is restricted to using s memory locations.
- iv. Any intermixed sequence of $O(n)$ updates and queries can be performed in $\tilde{O}(n^2/s^{1/3})$ time and $O(s)$ space.

As mentioned above, the arithmetic model is a relatively weak one (making it easy to prove lower bounds), but all the algorithms that realise the upper bounds fit into this model. It would be interesting to prove similar lower bounds for stronger models or to design algorithms that improve upon the performance of the above in stronger models. Note also, that the lower bounds are for the intersection problem, not the problem that we originally considered, that of subset testing. Since we get back a boolean answer from a subset testing query, it does not fit into the arithmetic framework.

34.5 The Disjoint Set Union-Find Problem

In this section we cover the best-studied set problem: the *disjoint set union-find* problem. The study of this problem and its variants has generated dozens of papers; indeed, it would not be unreasonable to devote an entire chapter to this problem alone. Fortunately, much of the work on this problem took place from the 1960s through to the early 1990s, and this work is surveyed in an excellent article by Galil and Italiano [27]. In this section, we summarise the main results prior to 1991 but focus on developments since then.

We begin with by formulating the problem in a recent, more general way [28], that fits better in our framework. We start with the base repertoire, but now require that $\text{insert}(x, A)$ is only permitted if $x \notin B$, for all sets $B \in \mathcal{F} - \{A\}$. This ensures that all sets in \mathcal{F} are pairwise disjoint. We now add the following operations:

$\text{dunion}(A, B, C)$ This sets $C \leftarrow A \cup B$, but destroys (removes from \mathcal{F}) A and B .

$\text{find}(x)$ For any $x \in \cup_{A \in \mathcal{F}} A$, returns the name of the set that x is in.

This problem has a number of applications, beginning historically with the efficient implementation of EQUIVALENCE and COMMON statements in early FORTRAN compilers in the 1960s, and continues to find applications in diverse areas such as dynamic graph algorithms, meldable data structures and implementations of unification algorithms.

It is difficult to discuss the disjoint-set union-find problem without reference to *Ackermann's function*, which is defined for integers $i, n \geq 0$ as follows:

$$A(i, n) = \begin{cases} 2n & \text{for } i = 0, n \geq 0 \\ 1 & \text{for } i \geq 1, n = 0 \\ A(i-1, A(i, n-1)) & \text{for } i, n \geq 1 \end{cases}$$

For a fixed i , the *row* inverse of Ackermann's function, denoted by $a(i, n)$, is defined as:

$$a(i, n) = \min\{j \mid A(i, j) \geq n\}.$$

It can be verified that $a(1, n) = \Theta(\log n)$ and $a(2, n) = \Theta(\log^* n)$, where $\log^* n$ is the *iterated logarithm* function. The functional inverse of Ackermann's function is defined for $m, n \geq 1$ by:

$$\alpha(m, n) = \min\{i \geq 1 \mid A(i, 4\lceil m/n \rceil) \geq n\}$$

Since $A(3, 4) = 2^{2^{...^2}} \left\{ \text{65,536 times} \right\}$, for all practical purposes, $\alpha(m, n) \leq 3$ whenever $m, n \geq 1$. Indeed, if m grows sufficiently faster than n (e.g., $m = \Omega(n \log^* n)$) then $\alpha(m, n)$ is indeed a constant.

The union-find problem in the above formalisation was studied by [29], who gave the following results:

Theorem 34.5

- i. An intermixed sequence of f find, m insert, m create, $d \leq m$ delete operations and at most $m - 1$ dunion operations takes $O(m + (f + d)\alpha(f + m, m))$ time. The size of the data structure at any time during the sequence is proportional to the number of live items in it.
- ii. For any parameter $k > 1$, an intermixed sequence of find, dunion, insert, create, and delete operations can be processed in the following worst-case time bounds: find and delete in $O(\log m / \log k)$ time, create and insert in $O(1)$ time and dunion in $O(k)$ time, where m is the current number of elements in the data structure.

In fact, [29] showed that this problem could be reduced to the classical union-find problem (see below). This reduction is such that the time bounds for find and dunion change only by a constant factor, but the time to delete an element x is the same as the time it takes to find the set containing x plus the time it takes to unite a singleton set with this set. The results follow by applying this result, respectively, to the classical union-find data structures given in Theorem 34.6(i) and Theorem 34.6(ii) (in fact they use a variant of the latter result due to Smid [30]).

An interesting variant of the above problem was considered by the same authors in [28]. They replaced the find operation with the seemingly simpler:

$b\text{find}(x, A)$ Return “true” if $x \in A$ and “false” otherwise.

This “boolean” union-find problem was motivated by the problem of implementing *meldable* priority queues. Kaplan et al. showed that the lower bounds established for the classical union-find problem apply to this problem as well (see Theorem 34.7).

34.5.1 The Classical Union-Find Problem and Variants

In the classical version of this problem, we have $U = \{1, \dots, m\}$ and \mathcal{F} initially equals $\{\{1\}, \{2\}, \dots, \{m\}\}$; we assume that the name of the set $\{i\}$ is simply i . The operation dunion is modified as follows:

$dunion(A, B)$ This sets $A \leftarrow A \cup B$, but destroys (removes from \mathcal{F}) B .
