The operation $\text{find}(x)$ operates as described above. We now mention the main upper bounds that are known for the classical version of the problem:

Theorem 34.6

A sequence of $m - 1$ dunion and f find operations can be processed as follows:

- i. in $O(m + f\alpha(f + m, m))$ time;
- ii. for any parameter $k > 1$, each find takes $O(\log m / (\log k + \log \log m))$ worst-case time and each dunion takes $O(k)$ worst-case time;
- iii. the i th find operation takes $O(\alpha(i, m))$ worst-case time, and the entire sequence takes $O(m + f\alpha(f + m, m))$ time;
- iv. for any parameter $k > 0$, the entire sequence takes $O(m\alpha(k, m) + kf)$ time;
- v. for any parameter $k > 1$, dunion takes $O(k)$ worst-case time, find takes $t_q = O(\log m / \log k)$ worst-case time, and the entire sequence takes time $O((m + f)(\alpha(m + f, m) + a(t_q, m)))$ time.

We begin by remarking that the bounds (i) and (ii) are in fact implied by Theorem 34.5, but are included here for completeness (see [27] for a more complete history). The upper bound of Theorem 34.5(i) is due to Tarjan [31] (with many interesting

refinements due to [32]). Note that since $\alpha(f + m, m)$ is essentially constant, the running time is linear for all practical purposes. In (i), each dunion takes $O(1)$ worst-case time, but a single find may take $\Omega(\log m)$ time. Result (iii) allows us to process each find quickly, in essentially constant time, but an individual dunion could be quite slow and may in fact take $\Omega(m)$ time. The overall cost of the sequence remains as in (i), though. This was explicitly proved in [33], but the main ideas were already present in [34]. In (iv), the time for a dunion is traded off for find, and the overall running time remains essentially linear (at least for $k \geq 2$) [35].

In either (i) or (iii), although the overall cost of the operation sequence is very low, an individual operation could take $\Omega(\log m)$ or $\Omega(m)$ time respectively. If we wish to minimise the maximum cost of a single operation over the sequence, then choosing (say) $k = \Theta(\sqrt{\log m})$ in (ii), we get that no operation takes more than $O(\log m / \log \log m)$ time. However, the cost of the entire sequence increases to $\Omega(f \log m / \log \log m)$. This result is due to [36].

In [37], the authors ask the question whether one can combine the best features of the results (i) (or (iii)) and (ii). Except possibly for a few extreme cases, this is achieved in [37, Theorem 11]. The result presented there has some technical restrictions (e.g., the algorithm needs to know the value of m in advance), but the authors claim that these are not essential.

We now come to lower bounds for this problem, which are either proved in the pointer machine model or the cell probe model. In general the cell probe model is more powerful (since there are no restrictions on the way that memory is accessed), but the lower bounds are proven assuming that all memory locations can store only numbers of $O(\log m)$ bits. By contrast, the pointer machine model does not place any restrictions on the size of the numbers that can be stored at each node. In the pointer machine model, however, the algorithm is required to maintain the name of each set in distinct nodes, and an operation such as $\text{find}(x)$ must traverse the graph of nodes from the node for x to the node that contains the name of the set that x is in. Lower bounds for the pointer machine model sometimes make the following *separability* assumption [3]:

At any time during the computation, the contents of the memory can be partitioned into collections of records such that each collection corresponds to a currently existing set, and no record in one collection contains a pointer to a record in another collection.

We now give some of the known lower bounds:

Theorem 34.7

- i. Any algorithm that processes a sequence of $m - 1$ dunion and f find operations must take $\Omega(m + f\alpha(f + m, m))$ steps on either the pointer machine model or the cell probe model with a word size of $O(\log m)$ bits.
- ii. Any algorithm that processes a sequence of $m - 1$ dunion and f find operations must take $\Omega(\log m / \log \log m)$ steps for some operation, on either the separable pointer machine model or the cell probe model with a word size of $O(\log m)$ bits.

The lower bound (i) for the pointer machine model is due to [38]; this generalizes an earlier lower bound for separable pointer machine algorithms due to [3] (see also the result due to [39]). The lower bound (ii) is due to [36], while both cell probe lower bounds are due to [40]. Additional lower bounds may be found in [37].

We refer the reader to [27] for variations of the classical union-find problem, including union-find with backtracking and persistent union-find (for the latter, see also [41,42]). Another important variant, which has a similar complexity to that of the union-find problem, is the *split-find* problem. Here we are given an ordered universe U and start with \mathcal{F} containing a single set which contains all of U . We perform an intermixed series of operations $S, T \leftarrow \text{split}(S, x)$ for some $x \in S$, which removes from S all elements $> x$ and places them in a new set T , and $\text{find}(x)$, which as before returns the name of the set containing x . Upper and lower bounds of the form given in Theorems 34.6(i) or 34.7(i) have been proven by [33,34,38]. Finally, we mention the very interesting *Union-copy* problem studied in [43]. In addition to the classical union-find operations, they support an additional operation *copy*, which takes one set as its argument, and adds an exact copy of it to \mathcal{F} . Although it is obviously no longer true that all sets in \mathcal{F} are disjoint, they require that two sets that are to be united must be disjoint. In addition, they want the data structure to support *dual* operations, in the sense that the roles of sets and elements are reversed. For example, the operation *element-union*(x, y) takes two elements x and y that do not both belong to any set in \mathcal{F} , and turns them into a single element that is member of all the sets to which x or y previously belonged. Duals of *copy* and *find* are also supported. They show applications of this data structure to the (geometric) dynamic segment tree data structure.

34.6 Partition Maintenance Algorithms

A partition P of a given universe $U = \{1, 2, \dots, m\}$ is a collection of $\#P$ disjoint subsets (*parts*), $P^{(1)}, P^{(2)}, \dots, P^{(\#P)}$, of U such that $\cup_i P_i = U$. A case of special interest is that of *bipartitions*, which is a partition with two parts. A partition P is an equivalence relation

on U , which we denote as \equiv_P . Given two partitions P and Q , the *induced* partition of P and Q is the partition that represents the equivalence relation $x \equiv y \iff ((x \equiv_P y) \vee (x \equiv_Q y))$ (in words, two elements belong to the same part of the induced partition iff they belong to the same part in both P and Q). The problem we consider is the following. Given a collection \mathcal{F} of partitions (initially empty), to support the following operations:

$$\left. \begin{array}{ll} \text{report}(\mathcal{F}) & \text{Report the partition induced by the members of } \mathcal{F}. \\ \text{insert}(P) & \text{Add partition } P \text{ to } \mathcal{F}. \\ \text{delete}(P) & \text{Remove partition } P \text{ from } \mathcal{F}. \end{array} \right\} \quad (34.7)$$

We assume here that each new partition P is given by an array $A[1..m]$ containing integers from 0 to $\#P - 1$. Other operations include asking if two elements belong to the same partition of the global induced partition, reporting the set of elements that belong to the same part of the global induced partition, or, for any two elements, reporting the number of partitions in which these two elements are in different parts.

As noted by Bender et al. [44] and Calinescu [45], this problem has a number of applications. The general issue is supporting a *classification system* that attempts to categorize objects based on a number of tests, where each test realizes a partition of the objects (a bipartition, for instance, could model the outcome of a boolean test). The above data structure would be useful in the pre-processing phase of such a classification system, where, for example, an algorithm may repeatedly insert and delete partitions (tests) until it finds a small set of tests that distinguish all items of the universe. Examples in optical character recognition (OCR) and VLSI are given by the above authors.

We now discuss some solutions to these problems. The model used is the word RAM model with word size $\Theta(\log n)$, where we take $k = |\mathcal{F}|$ and $n = km$. We first consider the case of general partitions, and then that of bipartitions. A simple data structure for general partitions was given by Bender et al. [44], and resembles the partition tree of Section 34.3. A key fact they use is (apply radix sorting on triples of the form $(P[i], Q[i], i)$):

Proposition 34.1

Given two partitions P and Q of $U = \{1, \dots, m\}$ we can calculate the induced partition of P and Q in $O(m)$ time.

This immediately implies that we can maintain the induced partition of \mathcal{F} under inserts alone in $O(m)$ time and also support report in $O(m)$ time—we simply maintain the global induced partition and update it with each insert. Deletes are not so easy, however.

We place the partitions at the leaves of a full binary tree with k leaves. At each internal node v of this binary tree we store the partition induced by all the partitions descended from v . Clearly, the root contains the global induced partition. Inserting a partition P involves replacing a leaf containing a partition Q by an internal node that has P and Q as children, and updating the partitions stored at this internal node and all its ancestors. Deleting a partition involves deleting the appropriate leaf, and maintaining fullness by possibly swapping a “rightmost” leaf with the deleted leaf. In either case, we update partitions from at most two leaves up to the root. This gives a data structure that supports insert and delete in $O(m \log k)$ time and report in $O(m)$ time. The space used is $O(mn)$ words of memory.

The time for insert can be improved to amortised $O(m)$, while leaving the time complexity of all other operations the same. The idea is to group all partitions into disjoint groups of $t = \lceil \log k \rceil$ each, leaving perhaps one incomplete group of size smaller than t . For each group we store its induced partition, and also store the induced partitions of all groups, except the incomplete group, at the leaves of a tree T (which may now have $O(k/\log k)$ leaves) as before. In addition, we explicitly store the global induced partition G .

When performing $\text{insert}(P)$ we add P to the incomplete group and in $O(m)$ time, update the global partition G . If the incomplete group reaches size t , in addition, we calculate the group’s induced partition in $O(mt) = O(m \log k)$ time and insert this induced partition into T , also taking $O(m \log k)$ time, and start a new empty incomplete group. Deleting a partition P is done as follows. We delete P from its group. If P is in the incomplete group we recompute the G in $O(mt)$ time. If P ’s group is stored in T , we recompute the new partition induced by P ’s group in $O(mt)$ time and update T in $O(m \log k)$ time (if P is the last remaining partition in its group we delete the corresponding leaf, as before). We then recompute G in $O(mt) = O(m \log k)$ time as well. Note that the amortised cost of an insertion is now $O(m)$, since we spend $O(m \log k)$ time every $\log k$ insertions. Finally, Bender et al. note that a signature-based scheme gives a Monte-Carlo method that performs all operations in $O(m)$ time, but has a small chance of outputting an incorrect result (the algorithm runs correctly with probability $1 - O(m^{-c})$ on all inputs).

We now consider the important special case of bi-partitions, and give a sketch of Calinescu’s [45] algorithm for solving this problem in optimal amortised time. Again letting $k = |\mathcal{F}|$, one can associate a k -bit binary string σ_x with each $x \in U = \{1, \dots, m\}$, which specifies in which part of each of the k partitions x lies. Let π denote a permutation such that $\sigma_{\pi^{-1}(i)} \leq \sigma_{\pi^{-1}(i+1)}$, for $i = 1, \dots, m-1$; that is, π represents a sorted order on the (multi-set) of strings $\{\sigma_x | x \in U\}$. Furthermore, let lcp_i denote the most

significant position where $\sigma_{\pi^{-1}(i)}$ and $\sigma_{\pi^{-1}(i+1)}$ differ, for $i = 1, \dots, m - 1$ ($lcp_i = k + 1$ if $\sigma_{\pi^{-1}(i)} = \sigma_{\pi^{-1}(i+1)}$). We can now clearly support report in $O(m)$ time, as elements in the same part of the global induced partition will be consecutive in sorted order, and the lcp values allow us to determine the boundaries of parts of the global induced partition without inspecting the strings. An insert of a partition is also easily supported, as only local re-arrangements of elements lying within the same part of the previous global induced partition are required.

Deleting a partition is a little harder, and requires a few observations. Suppose that we delete the partition that gives the t th most significant bit of $\sigma_1, \dots, \sigma_m$. Suppose that for two indices $i, j, j > i$, $lcp_i < t$ and $lcp_j < t$, but all lcp 's in between are at least t . Then we can conclude that the strings in positions 1 to $i - 1$ of the sorted order continue to appear in (possibly a different order in) positions 1 to $i - 1$ after the deletion of this partition, and likewise the strings in positions $j + 1$ to m also do not “move” except internally. Let Σ denote the strings that appear in positions i through j in sorted order, that is, $\Sigma = \{\sigma_l \mid l \in \{\pi^{-1}(i), \pi^{-1}(i+1), \dots, \pi^{-1}(j)\}\}$. We now show how to sort Σ , and repeated application of this procedure suffices to re-sort the array. Note that all the strings in Σ that have 0 in the t th position maintain their relative order after the deletion, and likewise those strings with 1 in the t th position. Thus, re-sorting Σ is simply a matter of merging these two sets of strings. At a high level, the merging procedure proceeds like the (standard, trivial) algorithm. However, a naive approach would require $\Theta(k)$ time per comparison, which is excessive. Instead, we note that at each step of the merging, the next candidate can either be determined in $O(1)$ time (when the relative order of the two candidates is implicit from the lcp data) or a number, c , of comparisons need to be made. However, if c comparisons are made, then there is at least one lcp value in the new array that is c more than its counterpart in the old array. Since lcp values are bounded by $O(k)$, no string will be involved in more than $O(k)$ comparisons during its lifetime, and the cost of these comparisons can be charged to the insertions of the partitions. This intuition can be formalized by a potential function argument to show that the amortised cost of a deletion is indeed $O(n)$, thus giving an optimal (amortised) algorithm for this problem.

34.7 Conclusions

We have presented a number of algorithms and data structures for supporting (largely) basic set-theoretic operations. Aside from the union-find problem, which has been extensively studied, relatively little research has been done into these problems. For instance, even the most basic problem, that of finding a general-purpose data structure that supports basic set operations, is not yet satisfactorily solved. The problem becomes more acute if one is concerned about the space usage of the data structures—for example, it is not known whether one can solve set equality testing efficiently in linear space.

Due to the proliferation of unstructured data, set operations are increasingly important. For instance, many search engines return a set of documents that match a given boolean keyword query by means of set operations on the sets of documents that contain each of the keywords in the query. The characteristics of this kind of application also suggest directions for research. For example, given the large data-sets that could be involved, it is a little surprising that work on external-memory algorithms for these problems is somewhat limited. Another issue is that these sets usually have patterns (e.g., the number of sets that contain a given keyword may satisfy a power law; certain sets of keywords may be more likely to be queried together etc.), which should be exploited by efficient algorithms.

With the latter motivation in mind, Demaine et al. [46] have considered the *adaptive* complexity of these problems. They assume that they are given a collection of sorted lists that comprise the sets, and need to compute unions, intersections and differences of these sets. If one is only interested in worst-case complexity (across all instances) then this problem is uninteresting (it essentially boils down to merging). However, some instances can be harder than others: for instance, computing the intersection of two sets when all elements in one set are smaller than the other is much easier than for sets that interleave substantially. Building on this idea, they develop a notion of the complexity of a given instance of a problem and develop algorithms that, for each particular instance, are efficient with respect to the difficulty of that instance.

35.1 The Cache-Oblivious Model

The memory system of most modern computers consists of a hierarchy of memory levels, with each level acting as a cache for the next; for a typical desktop computer the hierarchy consists of registers, level 1 cache, level 2 cache, level 3 cache, main memory, and disk. One of the essential characteristics of the hierarchy is that the memory levels get larger and slower the further they get from the processor, with the access time increasing most dramatically between main memory and disk. Another characteristic is that data is moved between levels in large blocks. As a consequence of this, the memory access pattern of an algorithm has a major influence on its practical running time. Unfortunately, the RAM model (Figure 35.1) traditionally used to design and analyze algorithms is not capable of capturing this, since it assumes that all memory accesses take equal time.

Because of the shortcomings of the RAM model, a number of more realistic models have been proposed in recent years. The most successful of these models is the simple two-level I/O-model introduced by Aggarwal and Vitter [1] (Figure 35.2). In this model the memory hierarchy is assumed to consist of a fast memory of size M and a slower infinite memory, and data is transferred between the levels in blocks of B consecutive elements. Computation can only be performed on data in the fast memory, and it is assumed that algorithms have complete control over transfers of blocks between the two levels. We denote such a transfer a *memory transfer*. The complexity measure is the number of memory transfers needed to solve a problem. The strength of the I/O model is that it captures part of the memory hierarchy, while being sufficiently simple to make design and analysis of algorithms feasible. In particular, it adequately models the situation where the memory transfers between two levels of the memory hierarchy dominate the running time, which is often the case when the size of the data exceeds the size of main memory. Agarwal and Vitter showed that comparison based sorting and searching require $\Theta(\text{Sort}_{M,B}(N)) = \Theta\left(\frac{N}{B} \log_{M/B} \frac{N}{B}\right)$ and $\Theta(\log_B N)$ memory transfers in the I/O-model, respectively [1]. Subsequently a large number of other results have been obtained in the model; see the surveys by Arge [2] and Vitter [3] for references. Also see Chapter 28.

More elaborate models of multi-level memory than the I/O-model have been proposed (see, e.g., [3] for an overview) but these models have been less successful, mainly because of their complexity. A major shortcoming of the proposed models, including the I/O-model, have also been that they assume that the characteristics of the memory hierarchy (the level and block sizes) are known. Very recently however, the *cache-oblivious* model, which assumes no knowledge about the hierarchy, was introduced by Frigo et al. [4]. In essence, a cache-oblivious algorithm is an algorithm formulated in the RAM model but analyzed in the I/O model, with the analysis required to hold for any B and M . Memory transfers are assumed to be performed by an off-line

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

optimal replacement strategy. The beauty of the cache-oblivious model is that since the I/O-model analysis holds for any block and memory size, it holds for *all* levels of a multi-level memory hierarchy (see [4] for details). In other words, by optimizing an algorithm to one unknown level of the memory hierarchy, it is optimized on all levels simultaneously. Thus the cache-oblivious model is effectively a way of modeling a complicated multi-level memory hierarchy using the simple two-level I/O-model.

Frigo et al. [4] described optimal $\Theta(\text{Sort}_{M,B}(N))$ memory transfer cache-oblivious algorithms for matrix transposition, fast Fourier transform, and sorting; Prokop also described a static search tree obtaining the optimal $O(\log_B N)$ transfer search bound [5]. Subsequently, Bender et al. [6] described a cache-oblivious dynamic search trees with the same search cost, and simpler and improved cache-oblivious dynamic search trees were then developed by several authors [7–10]. Cache-oblivious algorithms have also been developed for, for example, problems in computational geometry [7,11,12], for scanning dynamic sets [7], for layout of static trees [13], for partial persistence [7], and for a number of fundamental graph problems [14] using cache-oblivious priority queues [14,15]. Most of these results make the so-called *tall cache assumption*, that is, they assume that $M > \Omega(B^2)$; we make the same assumption throughout this chapter.

Empirical investigations of the practical efficiency of cache-oblivious algorithms for sorting [16], searching [9,10,17] and matrix problems [4] have also been performed. The overall conclusion of these investigations is that cache-oblivious methods often outperform RAM algorithms, but not always as much as algorithms tuned to the specific memory hierarchy and problem size. On the other hand, cache-oblivious algorithms perform well on all levels of the memory hierarchy, and seem to be more robust to changing problem sizes than cache-aware algorithms.

In the rest of this chapter we describe some of the most fundamental and representative cache-oblivious data structure results. In Section 35.2 we discuss two fundamental primitives used to design cache-oblivious data structures. In Section 35.3 we describe two cache-oblivious dynamic search trees, and in Section 35.4 two priority queues. Finally, in Section 35.5 we discuss structures for 2-dimensional orthogonal range searching.

35.2 Fundamental Primitives

The most fundamental cache-oblivious primitive is scanning—scanning an array with N elements incurs $\Theta\left(\frac{N}{B}\right)$ memory transfers for any value of B . Thus algorithms such as median finding and data structures such as stacks and queues that only rely on scanning are automatically cache-oblivious. In fact, the examples above are optimal in the cache-oblivious model. Other examples of algorithms that only rely on scanning include Quicksort and Mergesort. However, they are not asymptotically optimal in the cache-oblivious model since they use $O\left(\frac{N}{B} \log \frac{N}{M}\right)$ memory transfers rather than $\Theta(\text{Sort}_{M,B}(N))$.

Apart from algorithms and data structures that only utilize scanning, most cache-oblivious results use recursion to obtain efficiency; in almost all cases, the sizes of the recursive problems decrease double-exponentially. In this section we describe two of the most fundamental such recursive schemes, namely the *van Emde Boas layout* and the *k-merger*.

35.2.1 Van Emde Boas Layout

One of the most fundamental data structures in the I/O-model is the B-tree [18]. A B-tree is basically a fanout $\Theta(B)$ tree with all leaves on the same level. Since it has height $O(\log_B N)$ and each node can be accessed in $O(1)$ memory transfers, it supports

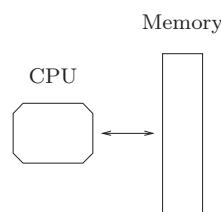

FIGURE 35.1 The RAM model.

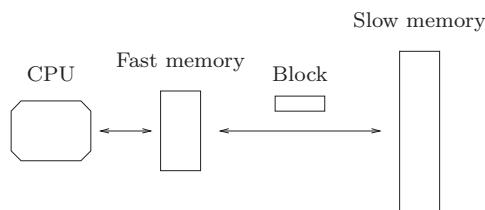

FIGURE 35.2 The I/O model.

searches in $O(\log_B N)$ memory transfers. It also supports range queries, that is, the reporting of all K elements in a given query range, in $O(\log_B N + \frac{K}{B})$ memory transfers. Since B is an integral part of the definition of the structure, it seems challenging to develop a cache-oblivious B-tree structure. However, Prokop [5] showed how a binary tree can be laid out in memory in order to obtain a (static) cache-oblivious version of a B-tree. The main idea is to use a recursively defined layout called the *van Emde Boas layout* closely related to the definition of a van Emde Boas tree [19]. The layout has been used as a basic building block of most cache-oblivious search structures (e.g., in [6–11,13]).

35.2.1.1 Layout

For simplicity, we only consider complete binary trees. A binary tree is complete if it has $N = 2^h - 1$ nodes and height h for some integer h . The basic idea in the van Emde Boas layout of a complete binary tree \mathcal{T} with N leaves is to divide \mathcal{T} at the middle level and lay out the pieces recursively (Figure 35.3). More precisely, if \mathcal{T} only has one node it is simply laid out as a single node in memory. Otherwise, we define the *top tree* \mathcal{T}_0 to be the subtree consisting of the nodes in the topmost $\lfloor h/2 \rfloor$ levels of \mathcal{T} , and the *bottom trees* $\mathcal{T}_1, \dots, \mathcal{T}_k$ to be the $\Theta(\sqrt{N})$ subtrees rooted in the nodes on level $\lceil h/2 \rceil$ of \mathcal{T} ; note that all the subtrees have size $\Theta(\sqrt{N})$. The van Emde Boas layout of \mathcal{T} consists of the van Emde Boas layout of \mathcal{T}_0 followed by the van Emde Boas layouts of $\mathcal{T}_1, \dots, \mathcal{T}_k$.

35.2.1.2 Search

To analyze the number of memory transfers needed to perform a search in \mathcal{T} , that is, traverse a root-leaf path, we consider the first recursive level of the van Emde Boas layout where the subtrees are smaller than B . As this level \mathcal{T} is divided into a set of *base trees* of size between $\Theta(\sqrt{B})$ and $\Theta(B)$, that is, of height $\Omega(\log B)$ (Figure 35.4). By the definition of the layout, each base tree is stored in $O(B)$ contiguous memory locations and can thus be accessed in $O(1)$ memory transfers. That the search is performed in $O(\log_B N)$ memory transfers then follows since the search path traverses $O((\log N)/\log B) = O(\log_B N)$ different base trees.

35.2.1.3 Range query

To analyze the number of memory transfers needed to answer a range query $[x_1, x_2]$ on \mathcal{T} using the standard recursive algorithm that traverses the relevant parts of \mathcal{T} (starting at the root), we first note that the two paths to x_1 and x_2 are traversed in $O(\log_B N)$

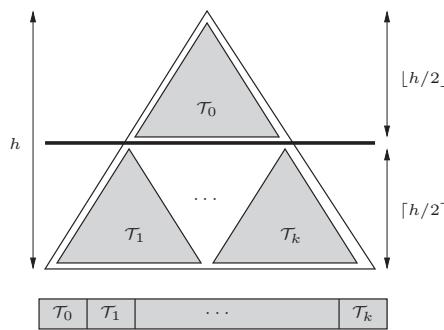

FIGURE 35.3 The van Emde Boas layout.

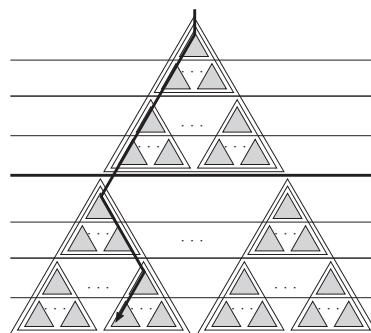

FIGURE 35.4 A search path.

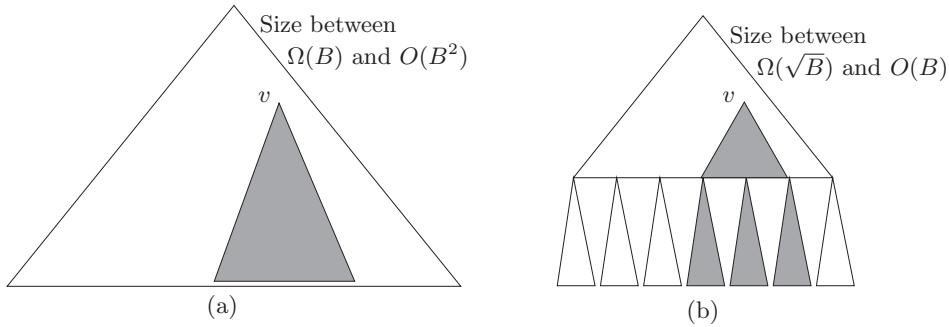

FIGURE 35.5 Traversing tree T_v with $O(B)$ leaves; (a) smallest recursive van Emde Boas level containing T_v has size between $\Omega(B)$ and $O(B^2)$; (b) next level in recursive subdivision.

memory transfers. Next we consider traversed nodes v that are not on the two paths to x_1 and x_2 . Since all elements in the subtree T_v rooted at such a node v are reported, and since a subtree of height $\log B$ stores $\Theta(B)$ elements, $O(\frac{K}{B})$ subtrees T_v of height $\log B$ are visited. This in turn means that the number of visited nodes above the last $\log B$ levels of \mathcal{T} is also $O(\frac{K}{B})$; thus they can all be accessed in $O(\frac{K}{B})$ memory transfers. Consider the smallest recursive level of the van Emde Boas layout that completely contain T_v . This level is of size between $\Omega(B)$ and $O(B^2)$ (Figure 35.5a). On the next level of recursion T_v is broken into a top part and $O(\sqrt{B})$ bottom parts of size between $\Omega(\sqrt{B})$ and $O(B)$ each (Figure 35.5b). The top part is contained in a recursive level of size $O(B)$ and is thus stored within $O(B)$ consecutive memory locations; therefore it can be accessed in $O(1)$ memory accesses. Similarly, the $O(B)$ nodes in the $O(\sqrt{B})$ bottom parts are stored consecutively in memory; therefore they can all be accessed in a total of $O(1)$ memory transfers. Therefore, the optimal paging strategy can ensure that any traversal of T_v is performed in $O(1)$ memory transfers, simply by accessing the relevant $O(1)$ blocks. Thus overall a range query is performed in $O(\log_B N + \frac{K}{B})$ memory transfers.

Theorem 35.1

Let \mathcal{T} be a complete binary tree with N leaves laid out using the van Emde Boas layout. The number of memory transfers needed to perform a search (traverse a root-to-leaf path) and a range query in \mathcal{T} is $O(\log_B N)$ and $O(\log_B N + \frac{K}{B})$, respectively.

Note that the navigation from node to node in the van Emde Boas layout is straight-forward if the tree is implemented using pointers. However, navigation using arithmetic on array indexes is also possible [9]. This avoids the use of pointers and hence saves space.

The constant in the $O(\log_B N)$ bound for searching in Theorem 35.1 can be seen to be four. Further investigations of which constants are possible for cache-oblivious comparison based searching appear in [20].

35.2.2 k -Merger

In the I/O-model the two basic optimal sorting algorithms are multi-way versions of Mergesort and distribution sorting (Quicksort) [1]. Similarly, Frigo et al. [4] showed how both merge based and distribution based optimal cache-oblivious sorting algorithms can be developed. The merging based algorithm, *Funnelsort*, is based on a so-called *k-merger*. This structure has been used as a basic building block in several cache-oblivious algorithms. Here we describe a simplified version of the *k-merger* due to Brodal and Fagerberg [12].

35.2.2.1 Binary mergers and merge trees

A *binary merger* merges two sorted input streams into a sorted output stream: In one merge step an element is moved from the head of one of the input streams to the tail of the output stream; the heads of the input streams, as well as the tail of the output stream, reside in *buffers* of a limited capacity.

Binary mergers can be combined to form *binary merge trees* by letting the output buffer of one merger be the input buffer of another—in other words, a binary merge tree is a binary tree with mergers at the nodes and buffers at the edges, and it is used to merge a set of sorted input streams (at the leaves) into one sorted output stream (at the root). Refer to Figure 35.6 for an example.

An *invocation* of a binary merger in a binary merge tree is a recursive procedure that performs merge steps until the output buffer is full (or both input streams are exhausted); if an input buffer becomes empty during the invocation (and the corresponding stream is not exhausted), the input buffer is recursively filled by an invocation of the merger having this buffer as output buffer.

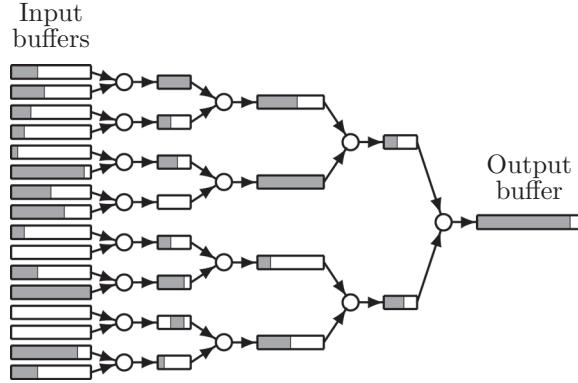

FIGURE 35.6 A 16-merger consisting of 15 binary mergers. Shaded parts represent elements in buffers.

```

Procedure FILL( $v$ )
  while  $v$ 's output buffer is not full
    if left input buffer empty
      FILL(left child of  $v$ )
    if right input buffer empty
      FILL(right child of  $v$ )
    perform one merge step
  
```

FIGURE 35.7 Invocation of binary merger v .

If both input streams of a merger get exhausted, the corresponding output stream is marked as exhausted. A procedure $\text{FILL}(v)$ performing an invocation of a binary merger v is shown in Figure 35.7 (ignoring exhaustion issues). A single invocation $\text{FILL}(r)$ on the root r of a merge tree will merge the streams at the leaves of the tree.

35.2.2.2 k -merger

A k -merger is a binary merge tree with specific buffer sizes. For simplicity, we assume that k is a power of two, in which case a k -merger is a complete binary tree of $k - 1$ binary mergers. The output buffer at the root has size k^3 , and the sizes of the rest of the buffers are defined recursively in a manner resembling the definition of the van Emde Boas layout: Let $i = \log k$ be the height of the k -merger. We define the *top tree* to be the subtree consisting of all mergers of depth at most $\lceil i/2 \rceil$, and the *bottom trees* to be the subtrees rooted in nodes at depth $\lceil i/2 \rceil + 1$. We let the edges between the top and bottom trees have buffers of size $k^{3/2}$, and define the sizes of the remaining buffers by recursion on the top and bottom trees. The input buffers at the leaves hold the input streams and are not part of the k -merger definition. The space required by a k -merger, excluding the output buffer at the root, is given by $S(k) = k^{1/2} \cdot k^{3/2} + (k^{1/2} + 1) \cdot S(k^{1/2})$, which has the solution $S(k) = \Theta(k^2)$.

We now analyze the number of memory transfers needed to fill the output buffer of size k^3 at the root of a k -merger. In the recursive definition of the buffer sizes in the k -merger, consider the first level where the subtrees (excluding output buffers) have size less than $M/3$; if \bar{k} is the number of leaves of one such subtree, we by the space usage of k -mergers have $\bar{k}^2 \leq M/3$ and $(\bar{k}^2)^2 = \bar{k}^4 = \Omega(M)$. We call these subtrees of the k -merger *base trees* and the buffers between the base trees *large buffers*. Assuming $B^2 \leq M/3$, a base tree T_v rooted in v together with one block from each of the large buffers surrounding it (i.e., its single output buffer and \bar{k} input buffers) can be contained in fast memory, since $M/3 + B + \bar{k} \cdot B \leq M/3 + B + (M/3)^{1/2} \cdot (M/3)^{1/2} \leq M$. If the k -merger consists of a single base tree, the number of memory transfers used to fill its output buffer with k^3 elements during an invocation is trivially $O(k^3/B + k)$. Otherwise, consider an invocation of the root v of a base tree T_v , which will fill up the size $\Omega(\bar{k}^3)$ output buffer of v . Loading T_v and one block for each of the \bar{k} buffers just below it into fast memory will incur $O(\bar{k}^2/B + \bar{k})$ memory transfers. This is $O(1/B)$ memory transfer for each of the $\Omega(\bar{k}^3)$ elements output, since $\bar{k}^4 = \Omega(M)$ implies $\bar{k}^2 = \Omega(M^{1/2}) = \Omega(B)$, from which $\bar{k} = O(\bar{k}^3/B)$ follows. Provided that none of the input buffers just below T_v become empty, the output buffer can then be filled in $O(\bar{k}^3/B)$ memory transfers since elements can be read from the input buffers in $O(1/B)$ transfers amortized. If a buffer below T_v becomes empty, a recursive invocation is needed. This invocation may evict T_v from memory, leading to its reloading when the invocation finishes. We charge this cost to the $\Omega(\bar{k}^3)$ elements in the filled buffer, or $O(1/B)$ memory transfers per

element. Finally, the last time an invocation is used to fill a particular buffer, the buffer may not be completely filled (due to exhaustion). However, this happens only once for each buffer, so we can pay the cost by charging $O(1/B)$ memory transfers to each position in each buffer in the k -merger. As the entire k -merger uses $O(k^2)$ space and merges k^3 elements, these charges add up to $O(1/B)$ memory transfers per element.

We charge an element $O(1/B)$ memory transfers each time it is inserted into a large buffer. Since $\bar{k} = \Omega(M^{1/4})$, each element is inserted in $O(\log_{\bar{k}} k) = O(\log_M k^3)$ large buffers. Thus we have the following.

Theorem 35.2

Excluding the output buffers, the size of a k -merger is $O(k^2)$ and it performs $O\left(\frac{k^3}{B} \log_M k^3 + k\right)$ memory transfers during an invocation to fill up its output buffer of size k^3 .

35.2.2.3 Funnelsort

The cache-oblivious sorting algorithm Funnelsort is easily obtained once the k -merger structure is defined: Funnelsort breaks the N input elements into $N^{1/3}$ groups of size $N^{2/3}$, sorts them recursively, and then merges the sorted groups using an $N^{1/3}$ -merger.

Funnelsort can be analyzed as follows: Since the space usage of a k -merger is sub-linear in its output, the elements in a recursive sort of size $M/3$ only need to be loaded into memory once during the entire following recursive sort. For k -mergers at the remaining higher levels in the recursion tree, we have $k^3 \geq M/3 \geq B^2$, which implies $k^2 \geq B^{4/3} > B$ and hence $k^3/B > k$. By Theorem 35.2, the number of memory transfers during a merge involving N' elements is then $O(\log_M(N')/B)$ per element. Hence, the total number of memory transfers per element is

$$O\left(\frac{1}{B} \left(1 + \sum_{i=0}^{\infty} \log_M N^{(2/3)^i}\right)\right) = O((\log_M N)/B).$$

Since $\log_M x = \Theta(\log_{M/B} x)$ when $B^2 \leq M/3$, we have the following theorem.

Theorem 35.3

Funnelsort sorts N element using $O(\text{Sort}_{M,B}(N))$ memory transfers.

In the above analysis, the exact (tall cache) assumption on the size of the fast memory is $B^2 \leq M/3$. In [12] it is shown how to generalize Funnelsort such that it works under the weaker assumption $B^{1+\varepsilon} \leq M$, for fixed $\varepsilon > 0$. The resulting algorithm incurs the optimal $O(\text{Sort}_{M,B}(N))$ memory transfers when $B^{1+\varepsilon} = M$, at the price of incurring $O(1/\varepsilon \cdot \text{Sort}_{M,B}(N))$ memory transfers when $B^2 \leq M$. It is shown in [21] that this trade-off is the best possible for comparison based cache-oblivious sorting.

35.3 Dynamic B-Trees

The van Emde Boas layout of a binary tree provides a static cache-oblivious version of B -trees. The first dynamic solution was given Bender et al. [6], and later several simplified structures were developed [7–10]. In this section, we describe two of these structures [7,9].

35.3.1 Density Based

In this section we describe the dynamic cache-oblivious search tree structure of Brodal et al. [9]. A similar proposal was given independently by Bender et al. [8].

The basic idea in the structure is to embed a dynamic binary tree of height $\log N + O(1)$ into a static complete binary tree, that is, in a tree with $2^h - 1$ nodes and height h , which in turn is embedded into an array using the van Emde Boas layout. Refer to Figure 35.8.

To maintain the dynamic tree we use techniques for maintaining small height in a binary tree developed by Andersson and Lai [22]; in a different setting, similar techniques has also been given by Itai et al. [23]. These techniques give an algorithm for maintaining height $\log N + O(1)$ using amortized $O(\log^2 N)$ time per update. If the height bound is violated after performing an update in a leaf l , this algorithm performs rebalancing by rebuilding the subtree rooted at a specific node v on the search path from the root to l . The subtree is rebuilt to perfect balance in time linear in the size of the subtree. In a binary tree of perfect balance the element in any node v is the median of all the elements stored in the subtree T_v rooted in v . This implies that only the lowest level in T_v is not completely filled and the empty positions appearing at this level are evenly distributed across the level. Hence,

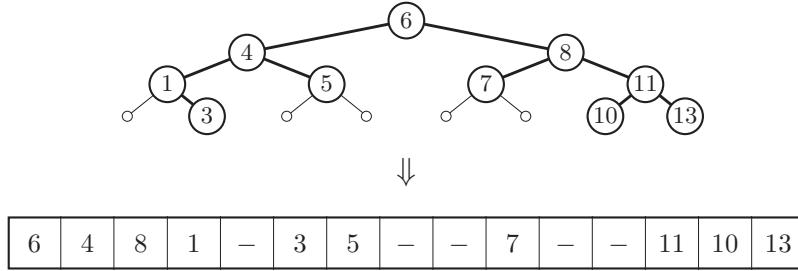

FIGURE 35.8 Illustration of embedding a height H tree into a complete static tree of height H , and the van Emde Boas layout of this tree.

the net effect of the rebuilding is to redistribute the empty positions in \mathcal{T}_v . Note that this can lower the cost of future insertions in \mathcal{T}_v , and consequently it may in the long run be better to rebuild a subtree larger than strictly necessary for reestablishment of the height bound. The criterion for choosing how large a subtree to rebuild, that is, for choosing the node v , is the crucial part of the algorithms by Andersson and Lai [22] and Itai et al. [23]. Below we give the details of how they can be used in the cache-oblivious setting.

35.3.1.1 Structure

As mentioned, the data structure consists of a dynamic binary tree \mathcal{T} embedded into a static complete binary tree \mathcal{T}' of height H , which in turn is embedded into an array using the van Emde Boas layout.

In order to present the update and query algorithms, we define the *density* $\rho(u)$ of a node u as $|T_u|/|T'_u|$, where $|T_u|$ and $|T'_u|$ are the number of nodes in the trees rooted in u in \mathcal{T} and \mathcal{T}' , respectively. In Figure 35.8, the node containing the element 4 has balance $4/7$. We also define two *density thresholds* τ_i and γ_i for the nodes on each level $i = 1, 2, \dots, H$ (where the root is at level 1). The upper density thresholds τ_i are evenly spaced values between $3/4$ and 1 , and the lower density thresholds γ_i are evenly spaced values between $1/4$ and $1/8$. More precisely, $\tau_i = 3/4 + (i-1)/(4(H-1))$ and $\gamma_i = 1/4 - (i-1)/(8(H-1))$.

35.3.1.2 Updates

To insert a new element into the structure we first locate the position in \mathcal{T} of the new node w . If the insertion of w violates the height bound H , we rebalance \mathcal{T} as follows: First we find the lowest ancestor v of w satisfying $\gamma_i \leq \rho(v) \leq \tau_i$, where i is the level of v . If no ancestor v satisfies the requirement, we rebuild the entire structure, that is, \mathcal{T} , \mathcal{T}' and the layout of \mathcal{T}' : For k the integer such that $2^k \leq N < 2^{k+1}$ we choose the new height H of the tree \mathcal{T}' as $k+1$ if $N \leq 5/4 \cdot 2^k$; otherwise we choose $H = k+2$. On the other hand, if the ancestor v exists we rebuild \mathcal{T}_v : We first create a sorted list of all elements in \mathcal{T}_v by an in-order traversal of \mathcal{T}_v . The $\lceil |T_v|/2 \rceil$ th element becomes the element stored at v , the smallest $\lfloor (|T_v|-1)/2 \rfloor$ elements are recursively distributed in the left subtree of v , and the largest $\lceil (|T_v|-1)/2 \rceil$ elements are recursively distributed in the right subtree of v .

We can delete an element from the structure in a similar way: We first locate the node w in \mathcal{T} containing the element e to be deleted. If w is not a leaf and has a right subtree, we then locate the node w' containing the immediate successor of e (the node reached by following left children in the right subtree of w), swap the elements in w and w' , and let $w = w'$. We repeat this until w is a leaf. If on the other hand w is not a leaf but only has a left subtree, we instead repeatedly swap w with the node containing the predecessor of e . Finally, we delete the leaf w from \mathcal{T} , and rebalance the tree by rebuilding the subtree rooted at the lowest ancestor v of w satisfying $\gamma_i \leq \rho(v) \leq \tau_i$, where i is the level of v ; if no such node exists we rebuild the entire structure completely.

Similar to the proof of Andersson and Lai [22] and Itai et al. [23] that updates are performed in $O(\log^2 N)$ time, Brodal et al. [9] showed that using the above algorithms, updates can be performed in amortized $O(\log_B N + (\log^2 N)/B)$ memory transfers.

35.3.1.3 Range queries

In Section 35.2, we discussed how a range query can be answered in $O(\log_B N + \frac{K}{B})$ memory transfers on a complete tree \mathcal{T}' laid out using the van Emde Boas layout. Since it can be shown that the above update algorithm maintains a lower density threshold of $1/8$ for all nodes, we can also perform range queries in \mathcal{T} efficiently: To answer a range query $[x_1, x_2]$ we traverse the two paths to x_1 and x_2 in \mathcal{T} , as well as $O(\log N)$ subtrees rooted in children of nodes on these paths. Traversing one subtree \mathcal{T}_v in \mathcal{T} incurs at most the number of memory transfers needed to traverse the corresponding (full) subtree \mathcal{T}'_v in \mathcal{T}' . By the lower density threshold of $1/8$ we know that the size of \mathcal{T}'_v is at most a factor of eight larger than the size of \mathcal{T}_v . Thus a range query is answered in $O(\log_B N + \frac{K}{B})$ memory transfers.

Theorem 35.4

There exists a linear size cache-oblivious data structure for storing N elements, such that updates can be performed in amortized $O(\log_B N + (\log^2 N)/B)$ memory transfers and range queries in $O(\log_B N + \frac{K}{B})$ memory transfers.

Using the method for moving between nodes in a van Emde Boas layout using arithmetic on the node indices rather than pointers, the above data structure can be implemented as a single size $O(N)$ array of data elements. The amortized complexity of updates can also be lowered to $O(\log_B N)$ by changing leaves into pointers to buckets containing $\Theta(\log N)$ elements each. With this modification a search can still be performed in $O(\log_B N)$ memory transfers. However, then range queries cannot be answered efficiently, since the $O\left(\frac{K}{\log N}\right)$ buckets can reside in arbitrary positions in memory.

35.3.2 Exponential Tree Based

The second dynamic cache-oblivious search tree we consider is based on the so-called *exponential layout* of Bender et al. [7]. For simplicity, we here describe the structure slightly differently than in [7].

35.3.2.1 Structure

Consider a complete balanced binary tree \mathcal{T} with N leaves. Intuitively, the idea in an exponential layout of \mathcal{T} is to recursively decompose \mathcal{T} into a set of *components*, which are each laid out using the van Emde Boas layout. More precisely, we define component \mathcal{C}_0 to consist of the first $\frac{1}{2} \log N$ levels of \mathcal{T} . The component \mathcal{C}_0 contains \sqrt{N} nodes and is called an N -component because its root is the root of a tree with N leaves (that is, \mathcal{T}). To obtain the exponential layout of \mathcal{T} , we first store \mathcal{C}_0 using the van Emde Boas layout, followed immediately by the recursive layout of the \sqrt{N} subtrees, $\mathcal{T}_1, \mathcal{T}_2, \dots, \mathcal{T}_{\sqrt{N}}$, of size \sqrt{N} , beneath \mathcal{C}_0 in \mathcal{T} , ordered from left to right. Note how the definition of the exponential layout naturally defines a decomposition of \mathcal{T} into $\log \log N + O(1)$ layers, with layer i consisting of a number of $N^{1/2^{i-1}}$ -components. An X -component is of size $\Theta(\sqrt{X})$ and its $\Theta(\sqrt{X})$ leaves are connected to \sqrt{X} -components. Thus the root of an X -component is the root of a tree containing X elements. Refer to Figure 35.9. Since the described layout of \mathcal{T} is really identical to the van Emde Boas layout, it follows immediately that it uses linear space and that a root-to-leaf path can be traversed in $O(\log_B N)$ memory transfers.

By slightly relaxing the requirements on the layout described above, we are able to maintain it dynamically: We define an *exponential layout* of a balanced binary tree \mathcal{T} with N leaves to consist of a composition of \mathcal{T} into $\log \log N + O(1)$ layers, with layer i consisting of a number of $N^{1/2^{i-1}}$ -components, each laid out using the van Emde Boas layout (Figure 35.9). An X -component has size $\Theta(\sqrt{X})$ but unlike above we allow its root to be root in a tree containing between X and $2X$ elements. Note how this means that an X -component has between $X/2\sqrt{X} = \frac{1}{2}\sqrt{X}$ and $2X/\sqrt{X} = 2\sqrt{X}$ leaves. We store the layout of \mathcal{T} in memory almost as previously: If the root of \mathcal{T} is root in an X -component \mathcal{C}_0 , we store \mathcal{C}_0 first in $2 \cdot 2\sqrt{X} - 1$ memory locations (the maximal size of an X -component), followed immediately by the layouts of the subtrees (\sqrt{X} -components) rooted in the leaves of \mathcal{C}_0 (in no particular order). We make room in the layout for the at most $2\sqrt{X}$ such subtrees. This exponential layout for \mathcal{T} uses $S(N) = \Theta(\sqrt{N}) + 2\sqrt{N} \cdot S(\sqrt{N})$ space, which is $\Theta(N \log N)$.

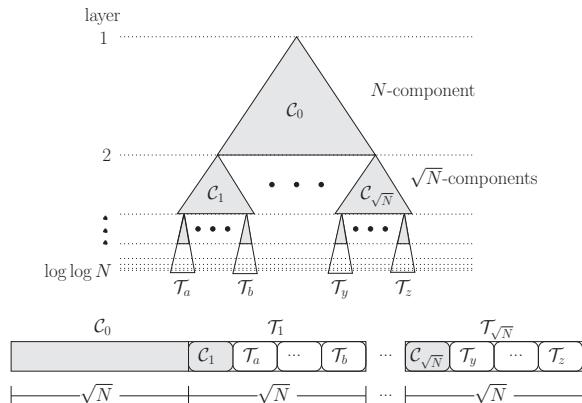

FIGURE 35.9 Components and exponential layout.

35.3.2.2 Search

Even with the modified definition of the exponential layout, we can traverse any root-to-leaf path in \mathcal{T} in $O(\log_B N)$ memory transfers: The path passes through exactly one $N^{1/2^{i-1}}$ -component for $1 \leq i \leq \log \log N + O(1)$. Each X -component is stored in a van Emde Boas layout of size $\Theta(\sqrt{X})$ and can therefore be traversed in $\Theta(\log_B \sqrt{X})$ memory transfers (Theorem 35.1). Thus, if we use at least one memory transfer in each component, we perform a search in $O(\log_B N) + \log \log N$ memory accesses. However, we do not actually use a memory transfer for each of the $\log \log N + O(1)$ components: Consider the traversed X -component with $\sqrt{B} \leq X \leq B$. This component is of size $O(\sqrt{B})$ and can therefore be loaded in $O(1)$ memory transfers. All smaller traversed components are of total size $O(\sqrt{B} \log \sqrt{B}) = O(B)$, and since they are stored in consecutively memory locations they can also be traversed in $O(1)$ memory transfers. Therefore only $O(1)$ memory transfers are used to traverse the last $\log \log B - O(1)$ components. Thus, the total cost of traversing a root-to-leaf path is $O(\log_B N + \log \log N - \log \log B) = O(\log_B N)$.

35.3.2.3 Updates

To perform an insertion in \mathcal{T} we first search for the leaf l where we want to perform the insertion; inserting the new element below l will increase the number of elements stored below each of the $\log \log N + O(1)$ components on the path to the root, and may thus result in several components needing *rebalancing* (an X -component with $2X$ elements stored below it). We perform the insertion and rebalance the tree in a simple way as follows: We find the topmost X -component C_j on the path to the root with $2X$ elements below it. Then we divide these elements into two groups of X elements and store them separately in the exponential layout (effectively we *split* C_j with $2X$ elements below it into two X -components with X elements each). This can easily be done in $O(X)$ memory transfers. Finally, we update a leaf and insert a new leaf in the X^2 -component above C_j (corresponding to the two new X -components); we can easily do so in $O(X)$ memory transfers by rebuilding it. Thus overall we have performed the insertion and rebalancing in $O(X)$ memory transfers. The rebuilding guarantees that after rebuilding an X -component, X inserts have to be performed below it before it needs rebalancing again. Therefore we can charge the $O(X)$ cost to the X insertions that occurred below C_j since it was last rebuilt, and argue that each insertion is charged $O(1)$ memory accesses on each of the $\log \log N + O(1)$ levels. In fact, using the same argument as above for the searching cost, we can argue that we only need to charge an insertion $O(1)$ transfers on the last $\log \log B - O(1)$ levels of \mathcal{T} , since rebalancing on any of these levels can always be performed in $O(1)$ memory transfers. Thus overall we perform an insertion in $O(\log_B N)$ memory transfers amortized.

Deletions can easily be handled in $O(\log_B N)$ memory transfers using global rebuilding: To delete the element in a leaf l of \mathcal{T} we simply mark l as deleted. If l 's sibling is also marked as deleted, we mark their parent deleted too; we continue this process along one path to the root of \mathcal{T} . This way we can still perform searches in $O(\log_B N)$ memory transfers, as long as we have only deleted a fraction of the elements in the tree. After $\frac{N}{2}$ deletes we therefore rebuild the entire structure in $O(N \log_B N)$ memory accesses, or $O(\log_B N)$ accesses per delete operation.

Bender et al. [7] showed how to modify the update algorithms to perform updates “lazily” and obtain worst case $O(\log_B N)$ bounds.

35.3.2.4 Reducing space usage

To reduce the space of the layout of a tree \mathcal{T} to linear we simply make room for $2 \log N$ elements in each leaf, and maintain that a leaf contains between $\log N$ and $2 \log N$ elements. This does not increase the $O(\log_B N)$ search and update costs since the $O(\log N)$ elements in a leaf can be scanned in $O((\log N)/B) = O(\log_B N)$ memory accesses. However, it reduces the number of elements stored in the exponential layout to $O(N/\log N)$.

Theorem 35.5

The exponential layout of a search tree \mathcal{T} on N elements uses linear space and supports updates in $O(\log_B N)$ memory accesses and searches in $O(\log_B N)$ memory accesses.

Note that the analogue of Theorem 35.1 does not hold for the exponential layout, that is, it does not support efficient range queries. The reason is partly that the \sqrt{X} -components below an X -component are not located in (sorted) order in memory because components are rebalanced by splitting, and partly because of the leaves containing $\Theta(\log N)$ elements. However, Bender et al. [7] showed how the exponential layout can be used to obtain a number of other important results: The structure as described above can easily be extended such that if two subsequent searched are separated by d elements, then the second search can be performed in $O(\log^* d + \log_B d)$ memory transfers. It can also be extended such that R queries (*batched searching*) can be answered simultaneously in $O(R \log_B \frac{N}{R} + \text{Sort}_{M,B}(R))$ memory transfers. The exponential layout can also be used to develop a *persistent B-tree*, where updates can be performed in the current version of the structure and queries can be performed in the

current as well as all previous versions, with both operations incurring $O(\log_B N)$ memory transfers. It can also be used as a basic building block in a linear space *planar point location* structure that answers queries in $O(\log_B N)$ memory transfers.

35.4 Priority Queues

A priority queue maintains a set of elements with a priority (or key) each under the operations `INSERT` and `DELETEMIN`, where an `INSERT` operation inserts a new element in the queue, and a `DELETEMIN` operation finds and deletes the element with the minimum key in the queue. Frequently we also consider a `DELETE` operation, which deletes an element with a given key from the priority queue. This operation can easily be supported using `INSERT` and `DELETEMIN`: To perform a `DELETE` we insert a special delete-element in the queue with the relevant key, such that we can detect if an element returned by a `DELETEMIN` has really been deleted by performing another `DELETEMIN`.

A balanced search tree can be used to implement a priority queue. Thus the existence of a dynamic cache-oblivious B-tree immediately implies the existence of a cache-oblivious priority queue where all operations can be performed in $O(\log_B N)$ memory transfers, where N is the total number of elements inserted. However, it turns out that one can design a priority queue where all operations can be performed in $\Theta(\text{Sort}_{M,B}(N)/N) = O\left(\frac{1}{B} \log_{M/B} \frac{N}{B}\right)$ memory transfers; for most realistic values of N, M , and B , this bound is less than 1 and we can, therefore, only obtain it in an amortized sense. In this section we describe two different structures that obtain these bounds [14,15].

35.4.1 Merge Based Priority Queue: Funnel Heap

The cache-oblivious priority queue *Funnel Heap* due to Brodal and Fagerberg [15] is inspired by the sorting algorithm Funnel-sort [4,12]. The structure only uses binary merging; essentially it is a heap-ordered binary tree with mergers in the nodes and buffers on the edges.

35.4.1.1 Structure

The main part of the Funnel Heap structure is a sequence of k -mergers (Section 35.2.2) with double-exponentially increasing k , linked together in a list using binary mergers; refer to Figure 35.10. This part of the structure constitutes a single binary merge tree. Additionally, there is a single insertion buffer I .

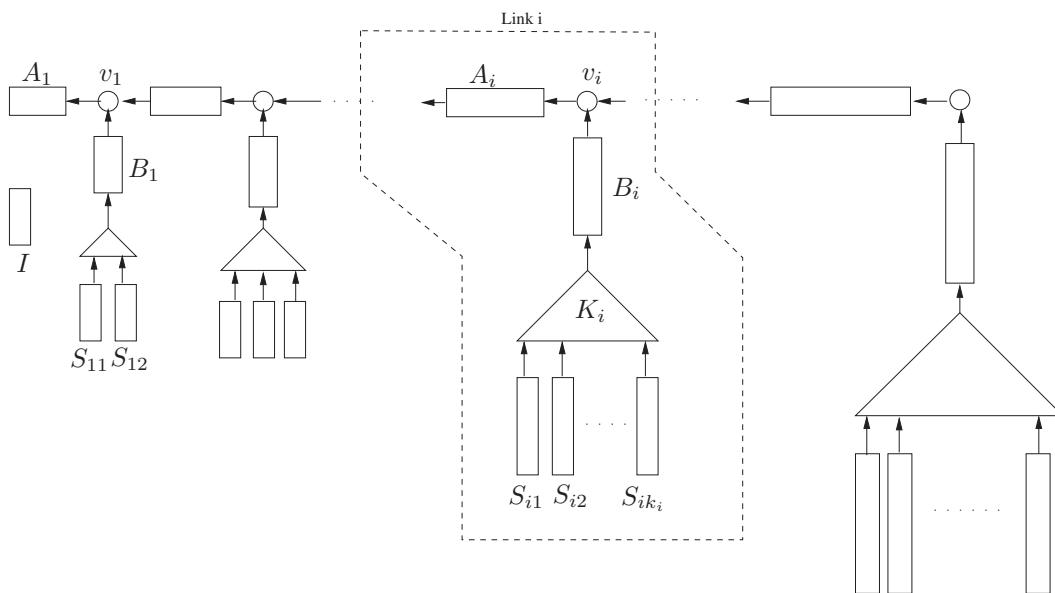

FIGURE 35.10 Funnel Heap: Sequence of k -mergers (triangles) linked together using buffers (rectangles) and binary mergers (circles).

More precisely, let k_i and s_i be values defined inductively by

$$\begin{aligned} (k_1, s_1) &= (2, 8), \\ s_{i+1} &= s_i(k_i + 1), \\ k_{i+1} &= \lceil \lceil s_{i+1}^{1/3} \rceil \rceil, \end{aligned} \tag{35.1}$$

where $\lceil \lceil x \rceil \rceil$ denotes the smallest power of two above x , that is, $\lceil \lceil x \rceil \rceil = 2^{\lceil \log x \rceil}$. We note that $s_i^{1/3} \leq k_i < 2s_i^{1/3}$, from which $s_i^{4/3} < s_{i+1} < 3s_i^{4/3}$ follows, so both s_i and k_i grow double-exponentially: $s_{i+1} = \Theta(s_i^{4/3})$ and $k_{i+1} = \Theta(k_i^{4/3})$. We also note that by induction on i we have $s_i = s_1 + \sum_{j=1}^{i-1} k_j s_j$ for all i .

A Funnel Heap consists of a linked list with *link* i containing a binary merger v_i , two buffers A_i and B_i , and a k_i -merger K_i having k_i input buffers S_{i1}, \dots, S_{ik_i} . We refer to B_i, K_i , and S_{i1}, \dots, S_{ik_i} as the *lower part* of the link. The size of both A_i and B_i is k_i^3 , and the size of each S_{ij} is s_i . Link i has an associated counter c_i for which $1 \leq c_i \leq k_i + 1$. The initial value of c_i is one for all i . The structure also has one insertion buffer I of size s_1 . We maintain the following invariants:

Invariant 35.1

For link i , $S_{ic_i}, \dots, S_{ik_i}$ are empty.

Invariant 35.2

On any path in the merge tree from some buffer to the root buffer A_1 , elements appear in decreasing order.

Invariant 35.3

Elements in buffer I appear in sorted order.

Invariant 35.2 can be rephrased as the entire merge tree being in heap order. It implies that in all buffers in the merge tree, the elements appear in sorted order, and that the minimum element in the queue will be in A_1 or I , if buffer A_1 is non-empty. Note that an invocation (Figure 35.7) of any binary merger in the tree maintains the invariants.

35.4.1.2 Layout

The Funnel Heap is laid out in consecutive memory locations in the order I , link 1, link 2, \dots , with link i being laid out in the order $c_i, A_i, v_i, B_i, K_i, S_{i1}, S_{i2}, \dots, S_{ik_i}$.

35.4.1.3 Operations

To perform a `DELETEMIN` operation we compare the smallest element in I with the smallest element in A_1 and remove the smallest of these; if A_1 is empty we first perform an invocation of v_1 . The correctness of this procedure follows immediately from Invariant 35.2.

To perform an `INSERT` operation we insert the new element among the (constant number of) elements in I , maintaining Invariant 35.3. If the number of elements in I is now s_1 , we examine the links in order to find the lowest index i for which $c_i \leq k_i$. Then we perform the following `SWEEEP(i)` operation.

In `SWEEEP(i)`, we first traverse the path p from A_1 to S_{ic_i} and record how many elements are contained in each encountered buffer. Then we traverse the part of p going from A_i to S_{ic_i} , remove the elements in the encountered buffers, and form a sorted stream σ_1 of the removed elements. Next we form another sorted stream σ_2 of all elements in links 1, $\dots, i-1$ and in buffer I ; we do so by marking A_i temporarily as exhausted and calling `DELETEMIN` repeatedly. We then merge σ_1 and σ_2 into a single stream σ , and traverse p again while inserting the front (smallest) elements of σ in the buffers on p such that they contain the same numbers of elements as before we emptied them. Finally, we insert the remaining elements from σ into S_{ic_i} , reset c_l to one for $l = 1, 2, \dots, i-1$, and increment c_i .

To see that `SWEEEP(i)` does not insert more than the allowed s_i elements into S_{ic_i} , first note that the lower part of link i is emptied each time c_i is reset to one. This implies that the lower part of link i never contains more than the number of elements inserted into $S_{i1}, S_{i2}, \dots, S_{ik_i}$ by the at most k_i `SWEEEP(i)` operations occurring since last time c_i was reset. Since $s_i = s_1 + \sum_{j=1}^{i-1} k_j s_j$ for all i , it follows by induction on time that no instance of `SWEEEP(i)` inserts more than s_i elements into S_{ic_i} .

Clearly, `SWEEEP(i)` maintains Invariants 35.1 and 35.3, since I and the lower parts of links 1, $\dots, i-1$ are empty afterwards. Invariant 35.2 is also maintained, since the new elements in the buffers on p are the smallest elements in σ , distributed such that each buffer contains exactly the same number of elements as before the `SWEEEP(i)` operation. After the operation, an element on

this path can only be smaller than the element occupying the same location before the operation, and therefore the merge tree is in heap order.

35.4.1.4 Analysis

To analyze the amortized cost of an `INSERT` or `DELETEMIN` operation, we first consider the number of memory transfers used to move elements upwards (towards A_1) by invocations of binary mergers in the merge tree. For now we assume that all invocations result in full buffers, that is, that no exhaustions occur. We imagine charging the cost of filling a particular buffer evenly to the elements being brought into the buffer, and will show that this way an element from an input buffer of K_i is charged $O\left(\frac{1}{B} \log_{M/B} s_i\right)$ memory transfers during its ascent to A_1 .

Our proof rely on the optimal replacement strategy keeping as many as possible of the first links of the Funnel Heap in fast memory at all times. To analyze the number of links that fit in fast memory, we define Δ_i to be the sum of the space used by links 1 to i and define i_M to be the largest i for which $\Delta_i \leq M$. By the space bound for k -mergers in Theorem 35.2 we see that the space used by link i is dominated by the $\Theta(s_i k_i) = \Theta(k_i^4)$ space use of S_{i1}, \dots, S_{ik_i} . Since $k_{i+1} = \Theta(k_i^{4/3})$, the space used by link i grows double-exponentially with i . Hence, Δ_i is a sum of double-exponentially increasing terms and is therefore dominated by its last term. In other words, $\Delta_i = \Theta(k_i^4) = \Theta(s_i^{4/3})$. By the definition of i_M we have $\Delta_{i_M} \leq M < \Delta_{i_M+1}$. Using $s_{i+1} = \Theta(s_i^{4/3})$ we see that $\log_M(s_{i_M}) = \Theta(1)$.

Now consider an element in an input buffer of K_i . If $i \leq i_M$ the element will not get charged at all in our charging scheme, since no memory transfers are used to fill buffers in the links that fit in fast memory. So assume $i > i_M$. In that case the element will get charged for the ascent through K_i to B_i and then through v_j to A_j for $j = i, i-1, \dots, i_M$. First consider the cost of ascending through K_i : By Theorem 35.2, an invocation of the root of K_i to fill B_i with k_i^3 elements incurs $O\left(k_i + \frac{k_i^3}{B} \log_{M/B} k_i^3\right)$ memory transfers altogether. Since $M < \Delta_{i_M+1} = \Theta(k_{i_M+1}^4)$ we have $M = O(k_i^4)$. By the tall cache assumption $M = \Omega(B^2)$ we get $B = O(k_i^2)$, which implies $k_i = O(k_i^3/B)$. Under the assumption that no exhaustions occur, that is, that buffers are filled completely, it follows that an element is charged $O\left(\frac{1}{B} \log_{M/B} k_i^3\right) = O\left(\frac{1}{B} \log_{M/B} s_i\right)$ memory transfers to ascend through K_i and into B_i . Next consider the cost of ascending through v_j , that is, insertion into A_j , for $j = i, i-1, \dots, i_M$: Filling of A_j incurs $O(1 + |A_j|/B)$ memory transfers. Since $B = O(k_{i_M+1}^2) = O(k_{i_M}^{8/3})$ and $|A_j| = k_j^3$, this is $O(|A_j|/B)$ memory transfers, so an element is charged $O(1/B)$ memory transfers for each A_j (under the assumption of no exhaustions). It only remains to bound the number of such buffers A_j , that is, to bound $i - i_M$. From $s_i^{4/3} < s_{i+1}$ we have $s_{i_M}^{(4/3)^{i-i_M}} < s_i$. Using $\log_M(s_{i_M}) = \Theta(1)$ we get $i - i_M = O(\log \log_M s_i)$. From $\log \log_M s_i = O(\log_M s_i)$ and the tall cache assumption $M = \Omega(B^2)$ we get $i - i_M = O(\log_M s_i) = O(\log_{M/B} s_i)$. In total we have proved our claim that, assuming no exhaustions occur, an element in an input buffer of K_i is charged $O\left(\frac{1}{B} \log_{M/B} s_i\right)$ memory transfers during its ascent to A_1 .

We imagine maintaining the *credit invariant* that each element in a buffer holds enough credits to be able to pay for the ascent from its current position to A_1 , at the cost analyzed above. In particular, an element needs $O\left(\frac{1}{B} \log_{M/B} s_i\right)$ credits when it is inserted in an input buffer of K_i . The cost of these credits we will attribute to the `SWEEP(i)` operation inserting it, effectively making all invocations of mergers be prepaid by `SWEEP(i)` operations.

A `SWEEP(i)` operation also incurs memory transfers by itself; we now bound these. In the `SWEEP(i)` operation we first form σ_1 by traversing the path p from A_1 to S_{ic_i} . Since the links are laid out sequentially in memory, this traversal at most constitutes a linear scan of the consecutive memory locations containing A_1 through K_i . Such a scan takes $O((\Delta_{i-1} + |A_i| + |B_i| + |K_i|)/B) = O(k_i^3/B) = O(s_i/B)$ memory transfers. Next we form σ_2 using `DELETEMIN` operations; the cost of which is paid for by the credits placed on the elements. Finally, we merge of σ_1 and σ_2 into σ , and place some of the elements in buffers on p and some of the elements in S_{ic_i} . The number of memory transfers needed for this is bounded by the $O(s_i/B)$ memory transfers needed to traverse p and S_{ic_i} . Hence, the memory transfers incurred by the `SWEEP(i)` operation itself is $O(s_i/B)$.

After the `SWEEP(i)` operation, the credit invariant must be reestablished. Each of the $O(s_i)$ elements inserted into S_{ic_i} must receive $O\left(\frac{1}{B} \log_{M/B} s_i\right)$ credits. Additionally, the elements inserted into the part of the path p from A_1 through A_{i-1} must receive enough credits to cover their ascent to A_1 , since the credits that resided with elements in the same positions before the operations were used when forming σ_2 by `DELETEMIN` operations. This constitutes $O(\Delta_{i-1}) = o(s_i)$ elements, which by the analysis above, must receive $O\left(\frac{1}{B} \log_{M/B} s_i\right)$ credits each. Altogether $O(s_i/B) + O\left(\frac{s_i}{B} \log_{M/B} s_i\right) = O\left(\frac{s_i}{B} \log_{M/B} s_i\right)$ memory transfers are attributed to a `SWEEP(i)` operation, again under the assumption that no exhaustions occur during invocations.

To actually account for exhaustions, that is, the memory transfers incurred when filling buffers that become exhausted, we note that filling a buffer partly incurs at most the same number of memory transfers as filling it entirely. This number was analyzed above to be $O(|A_i|/B)$ for A_i and $O\left(\frac{|B_i|}{B} \log_{M/B} s_i\right)$ for B_i , when $i > i_M$. If B_i become exhausted, only a `SWEEP(i)` can remove that status. If A_i become exhausted, only a `SWEEP(j)` for $j \geq i$ can remove that status. As at most a single `SWEEP(j)` with $j > i$

can take place between one SWEEP(i) and the next, B_i can only become exhausted once for each SWEEP(i), and A_i can only become exhausted twice for each SWEEP(i). From $|A_i| = |B_i| = k_i^3 = \Theta(s_i)$ it follows that charging SWEEP(i) an additional cost of $O\left(\frac{s_i}{B} \log_{M/B} s_i\right)$ memory transfers will cover all costs of filling buffers when exhaustion occurs.

Overall we have shown that we can account for all memory transfers if we attribute $O\left(\frac{s_i}{B} \log_{M/B} s_i\right)$ memory transfers to each SWEEP(i). By induction on i , we can show that at least s_i insertions have to take place between each SWEEP(i). Thus, if we charge the SWEEP(i) cost to the last s_i insertions preceding the SWEEP(i), each insertion is charged $O\left(\frac{1}{B} \log_{M/B} s_i\right)$ memory transfers. Given a sequence of operation on an initial empty priority queue, let i_{max} be the largest i for which SWEEP(i) takes place. We have $s_{i_{max}} \leq N$, where N is the number of insertions in the sequence. An insertion can be charged by at most one SWEEP(i) for $i = 1, \dots, i_{max}$, so by the double-exponential growth of s_i , the number of memory transfers charged to an insertion is

$$O\left(\sum_{k=0}^{\infty} \frac{1}{B} \log_{M/B} N^{(3/4)^k}\right) = O\left(\frac{1}{B} \log_{M/B} N\right) = O\left(\frac{1}{B} \log_{M/B} \frac{N}{B}\right),$$

where the last equality follows from the tall cache assumption $M = \Omega(B^2)$.

Finally, we bound the space use of the entire structure. To ensure a space usage linear in N , we create a link i when it is first used, that is, when the first SWEEP(i) occurs. At that point in time, c_i, A_i, v_i, B_i, K_i , and S_{i1} are created. These take up $\Theta(s_i)$ space combined. At each subsequent SWEEP(i) operation, we create the next input buffer S_{ic_i} of size s_i . As noted above, each SWEEP(i) is preceded by at least s_i insertions, from which an $O(N)$ space bound follows. To ensure that the entire structure is laid out in consecutive memory locations, the structure is moved to a larger memory area when it has grown by a constant factor. When allocated, the size of the new memory area is chosen such that it will hold the input buffers S_{ij} that will be created before the next move. The amortized cost of this is $O(1/B)$ per insertion.

Theorem 35.6

Using $\Theta(M)$ fast memory, a sequence of N INSERT, DELETEMIN, and DELETE operations can be performed on an initially empty Funnel Heap using $O(N)$ space in $O\left(\frac{1}{B} \log_{M/B} \frac{N}{B}\right)$ amortized memory transfers each.

Brodal and Fagerberg [15] gave a refined analysis for a variant of the Funnel Heap that shows that the structure adapts to different usage profiles. More precisely, they showed that the i th insertion uses amortized $O\left(\frac{1}{B} \log_{M/B} \frac{N_i}{B}\right)$ memory transfers, where N_i can be defined in any of the following three ways: (a) N_i is the number of elements present in the priority queue when the i th insertion is performed, (b) if the i th inserted element is removed by a DELETEMIN operation prior to the j th insertion then $N_i = j - i$, or (c) N_i is the maximum rank of the i th inserted element during its lifetime in the priority queue, where rank denotes the number of smaller elements in the queue.

35.4.2 Exponential Level Based Priority Queue

While the Funnel Heap is inspired by Mergesort and uses k -mergers as the basic building block, the exponential level priority queue of Arge et al. [14] is somewhat inspired by distribution sorting and uses sorting as a basic building block.

35.4.2.1 Structure

The structure consists of $\Theta(\log \log N)$ levels whose sizes vary from N to some small size c below a constant threshold c_t ; the size of a level corresponds (asymptotically) to the number of elements that can be stored within it. The i th level from above has size $N^{(2/3)^{i-1}}$ and for convenience we refer to the levels by their size. Thus the levels from largest to smallest are level N , level $N^{2/3}$, level $N^{4/9}, \dots$, level $X^{9/4}$, level $X^{3/2}$, level X , level $X^{2/3}$, level $X^{4/9}, \dots$, level $c^{9/4}$, level $c^{3/2}$, and level c . In general, a level can contain any number of elements less than or equal to its size, except level N , which always contains $\Theta(N)$ elements. Intuitively, smaller levels store elements with smaller keys or elements that were more recently inserted. In particular, the minimum key element and the most recently inserted element are always in the smallest (lowest) level c . Both insertions and deletions are initially performed on the smallest level and may propagate up through the levels.

Elements are stored in a level in a number of *buffers*, which are also used to transfer elements between levels. Level X consists of one *up buffer* u^X that can store up to X elements, and at most $X^{1/3}$ *down buffers* $d_1^X, \dots, d_{X^{1/3}}^X$ each containing between $(1/2)X^{2/3}$ and $2X^{2/3}$ elements. Thus level X can store up to $3X$ elements. We refer to the maximum possible number of elements that can be stored in a buffer as the *size* of the buffer. Refer to Figure 35.11. Note that the size of a down buffer at one level matches the size (up to a constant factor) of the up buffer one level down.

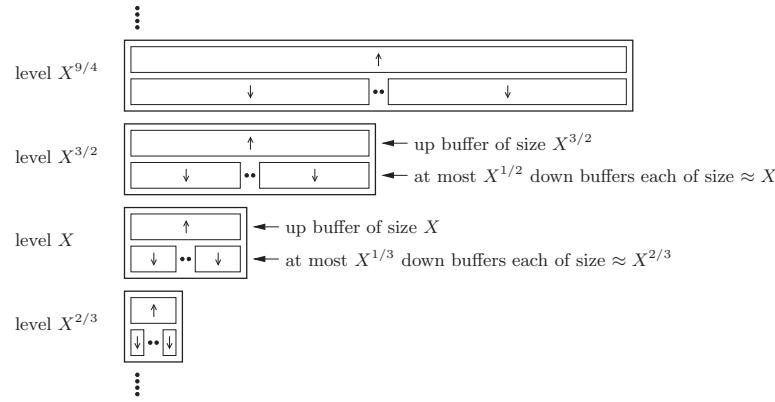

FIGURE 35.11 Levels $X^{2/3}$, X , $X^{3/2}$, and $X^{9/4}$ of the priority queue data structure.

We maintain three invariants about the relationships between the elements in buffers of various levels:

Invariant 35.4

At level X , elements are sorted **among** the down buffers, that is, elements in d_i^X have smaller keys than elements in d_{i+1}^X , but elements within d_i^X are unordered.

The element with largest key in each down buffer d_i^X is called a *pivot element*. Pivot elements mark the boundaries between the ranges of the keys of elements in down buffers.

Invariant 35.5

At level X , the elements in the down buffers have smaller keys than the elements in the up buffer.

Invariant 35.6

The elements in the down buffers at level X have smaller keys than the elements in the down buffers at the next higher level $X^{3/2}$.

The three invariants ensure that the keys of the elements in the down buffers get larger as we go from smaller to larger levels of the structure. Furthermore, an order exists between the buffers on one level: keys of elements in the up buffer are larger than keys of elements in down buffers. Therefore, down buffers are drawn below up buffers on Figure 35.11. However, the keys of the elements in an up buffer are unordered relative to the keys of the elements in down buffers one level up. Intuitively, up buffers store elements that are “on their way up,” that is, they have yet to be resolved as belonging to a particular down buffer in the next (or higher) level. Analogously, down buffers store elements that are “on their way down”—these elements are by the down buffers partitioned into several clusters so that we can quickly find the cluster of smallest key elements of size roughly equal to the next level down. In particular, the element with overall smallest key is in the first down buffer at level c .

35.4.2.2 Layout

The priority queue is laid out in memory such that the levels are stored consecutively from smallest to largest with each level occupying a single region of memory. For level X we reserve space for exactly $3X$ elements: X for the up buffer and $2X^{2/3}$ for each possible down buffer. The up buffer is stored first, followed by the down buffers stored in an arbitrary order but linked together to form an ordered linked list. Thus $O\left(\sum_{i=0}^{\log_{3/2} \log_c N} N^{(2/3)^i}\right) = O(N)$ is an upper bound on the total memory used by the priority queue.

35.4.2.3 Operations

To implement the priority queue operations we use two general operations, *push* and *pull*. Push inserts X elements into level $X^{3/2}$, and pull removes the X elements with smallest keys from level $X^{3/2}$ and returns them in sorted order. An INSERT or a DELETEMIN is performed simply by performing a push or pull on the smallest level c .

Push. To push X elements into level $X^{3/2}$, we first sort the X elements cache-obliviously using $O\left(1 + \frac{X}{B} \log_{M/B} \frac{X}{B}\right)$ memory transfers. Next we distribute the elements in the sorted list into the down buffers of level $X^{3/2}$ by scanning through the list and simultaneously visiting the down buffers in (linked) order. More precisely, we append elements to the end of the current down buffer $d_i^{X^{3/2}}$, and advance to the next down buffer $d_{i+1}^{X^{3/2}}$ as soon as we encounter an element with larger key than the pivot of $d_i^{X^{3/2}}$. Elements with larger keys than the pivot of the last down buffer are inserted in the up buffer $u^{X^{3/2}}$. Scanning through the X elements take $O\left(1 + \frac{X}{B}\right)$ memory transfers. Even though we do not scan through every down buffer, we might perform at least one memory transfer for each of the $X^{1/2}$ possible buffers. Thus the total cost of distributing the X elements is $O\left(\frac{X}{B} + X^{1/2}\right)$ memory transfers.

During the distribution of elements a down buffer may run full, that is, contain $2X$ elements. In this case, we split the buffer into two down buffers each containing X elements using $O\left(1 + \frac{X}{B}\right)$ transfers. We place the new buffer in any free down buffer location for the level and update the linked list accordingly. If the level already has the maximum number $X^{1/2}$ of down buffers, we remove the last down buffer $d_{X^{1/2}}^X$ by inserting its no more than $2X$ elements into the up buffer using $O\left(1 + \frac{X}{B}\right)$ memory transfers. Since X elements must have been inserted since the last time the buffer split, the amortized splitting cost per element is $O\left(\frac{1}{X} + \frac{1}{B}\right)$ transfers. In total, the amortized number of memory transfers used on splitting buffers while distributing the X elements is $O\left(1 + \frac{X}{B}\right)$.

If the up buffer runs full during the above process, that is, contains more than $X^{3/2}$ elements, we recursively *push* all of these elements into the next level up. Note that after such a recursive push, $X^{3/2}$ elements have to be inserted (pushed) into the up buffer of level $X^{3/2}$ before another recursive push is needed.

Overall we can perform a push of X elements from level X into level $X^{3/2}$ in $O\left(X^{1/2} + \frac{X}{B} \log_{M/B} \frac{X}{B}\right)$ memory transfers amortized, not counting the cost of any recursive push operations; it is easy to see that a push maintains all three invariants.

Pull. To describe how to pull the X smallest keys elements from level $X^{3/2}$, we first assume that the down buffers contain at least $\frac{3}{2}X$ elements. In this case the first three down buffers $d_1^{X^{3/2}}$, $d_2^{X^{3/2}}$, and $d_3^{X^{3/2}}$ contain the between $\frac{3}{2}X$ and $6X$ smallest elements (Invariants 4 and 5). We find and remove the X smallest elements simply by sorting these elements using $O\left(1 + \frac{X}{B} \log_{M/B} \frac{X}{B}\right)$ memory transfers. The remaining between $X/2$ and $5X$ elements are left in one, two, or three down buffers containing between $X/2$ and $2X$ elements each. These buffers can easily be constructed in $O\left(1 + \frac{X}{B}\right)$ transfers. Thus we use $O\left(1 + \frac{X}{B} \log_{M/B} \frac{X}{B}\right)$ memory transfers in total. It is easy to see that Invariants 4–6 are maintained.

In the case where the down buffers contain fewer than $\frac{3}{2}X$ elements, we first *pull* the $X^{3/2}$ elements with smallest keys from the next level up. Because these elements do not necessarily have smaller keys than the, say U , elements in the up buffer $u^{X^{3/2}}$, we then sort this up buffer and merge the two sorted lists. Then we insert the U elements with largest keys into the up buffer, and distribute the remaining between $X^{3/2}$ and $X^{3/2} + \frac{3}{2}X$ elements into $X^{1/2}$ down buffers containing between X and $X + \frac{3}{2}X^{1/2}$ each (such that the $O\left(\frac{1}{X} + \frac{1}{B}\right)$ amortized down buffer split bound is maintained). It is easy to see that this maintains the three invariants. Afterwards, we can find the X minimal key elements as above. Note that after a recursive pull, $X^{3/2}$ elements have to be deleted (pulled) from the down buffers of level $X^{3/2}$ before another recursive pull is needed. Note also that a pull on level $X^{3/2}$ does not affect the number of elements in the up buffer $u^{X^{3/2}}$. Since we distribute elements into the down and up buffers after a recursive pull using one sort and one scan of $X^{3/2}$ elements, the cost of doing so is dominated by the cost of the recursive pull operation itself. Thus ignoring the cost of recursive pulls, we have shown that a pull of X elements from level $X^{3/2}$ down to level X can be performed in $O\left(1 + \frac{X}{B} \log_{M/B} \frac{X}{B}\right)$ memory transfers amortized, while maintaining Invariants 4–6.

35.4.2.4 Analysis

To analyze the amortized cost of an **INSERT** or **DELETEMIN** operation, we consider the total number of memory transfers used to perform push and pull operations during $\frac{N}{2}$ operations; to ensure that the structure always consists of $O(\log \log N)$ levels and use $O(N)$ space we rebuild it using $O\left(\frac{N}{B} \log_{M/B} \frac{N}{B}\right)$ memory transfers (or $O\left(\frac{1}{B} \log_{M/B} \frac{N}{B}\right)$ transfers per operation) after every $\frac{N}{2}$ operations [14].

The total cost of $\frac{N}{2}$ such operations is analyzed as follows: We charge a push of X elements from level X up to level $X^{3/2}$ to level X . Since X elements have to be inserted in the up buffer u^X of level X between such pushes, and as elements can only be inserted in u^X when elements are inserted (pushed) into level X , $O(N/X)$ pushes are charged to level X during the $\frac{N}{2}$ operations. Similarly, we charge a pull of X elements from level $X^{3/2}$ down to level X to level X . Since between such pulls $\Theta(X)$ elements have to be deleted from the down buffers of level X by pulls on X , $O(N/X)$ pulls are charged to level X during the $\frac{N}{2}$ operations.

Above we argued that a push or pull charged to level X uses $O\left(X^{1/2} + \frac{X}{B} \log_{M/B} \frac{X}{B}\right)$ memory transfers. We can reduce this cost to $O\left(\frac{X}{B} \log_{M/B} \frac{X}{B}\right)$ by more carefully examining the costs for differently sized levels. First consider a push or pull of $X \geq B^2$

elements into or from level $X^{3/2} \geq B^3$. In this case $\frac{X}{B} \geq \sqrt{X}$, and we trivially have that $O\left(X^{1/2} + \frac{X}{B} \log_{M/B} \frac{X}{B}\right) = O\left(\frac{X}{B} \log_{M/B} \frac{X}{B}\right)$. Next, consider the case $B^{4/3} \leq X < B^2$, where the $X^{1/2}$ term in the push bound can dominate and we have to analyze the cost of a push more carefully. In this case we are working on a level $X^{3/2}$ where $B^2 \leq X^{3/2} < B^3$; there is only one such level. Recall that the $X^{1/2}$ cost was from distributing X sorted elements into the less than $X^{1/2}$ down buffers of level $X^{3/2}$. More precisely, a block of each buffer may have to be loaded and written back without transferring a full block of elements into the buffer. Assuming $M = \Omega(B^2)$, we from $X^{1/2} \leq B$ see that a block for each of the buffers can fit into fast memory. Consequently, if a fraction of the fast memory is used to keep a partially filled block of each buffer of level $X^{3/2}$ ($B^2 \leq X^{3/2} \leq B^3$) in fast memory at all times, and full blocks are written to disk, the $X^{1/2}$ cost would be eliminated. In addition, if all of the levels of size less than B^2 (of total size $O(B^2)$) are also kept in fast memory, all transfer costs associated with them would be eliminated. The optimal paging strategy is able to keep the relevant blocks in fast memory at all times and thus eliminates these costs.

Finally, since each of the $O(N/X)$ push and pull operations charged to level X ($X > B^2$) uses $O\left(\frac{X}{B} \log_{M/B} \frac{X}{B}\right)$ amortized memory transfers, the total amortized transfer cost of an **INSERT** or **DELETEMIN** operation in the sequence of $\frac{N}{2}$ such operations is

$$O\left(\sum_{i=0}^{\infty} \frac{1}{B} \log_{M/B} \frac{N^{(2/3)^i}}{B}\right) = O\left(\frac{1}{B} \log_{M/B} \frac{N}{B}\right).$$

Theorem 35.7

Using $\Theta(M)$ fast memory, N **INSERT**, **DELETEMIN**, and **DELETE** operations can be performed on an initially empty exponential level priority queue using $O(N)$ space in $O\left(\frac{1}{B} \log_{M/B} \frac{N}{B}\right)$ amortized memory transfers each.

35.5 2d Orthogonal Range Searching

As discussed in Section 35.3, there exist cache-oblivious B-trees that support updates and queries in $O(\log_B N)$ memory transfers (e.g., Theorem 35.5); several cache-oblivious B-tree variants can also support (one-dimensional) range queries in $O(\log_B N + \frac{K}{B})$ memory transfers [6,8,9], but at an increased amortized update cost of $O\left(\log_B N + \frac{\log^2 N}{B}\right) = O(\log_B^2 N)$ memory transfers (e.g., Theorem 35.4).

In this section we discuss cache-oblivious data structures for two-dimensional orthogonal range searching, that is, structures for storing a set of N points in the plane such that the points in a axis-parallel query rectangle can be reported efficiently. In Section 35.5.1 we first discuss a cache-oblivious version of a *kd-tree*. This structure uses linear space and answers queries in $O(\sqrt{N/B} + \frac{K}{B})$ memory transfers; this is optimal among linear space structures [24]. It supports updates in $O\left(\frac{\log N}{B} \cdot \log_{M/B} N\right) = O(\log_B^2 N)$ transfers. In Section 35.5.2 we then discuss a cache-oblivious version of a two-dimensional *range tree*. The structure answers queries in the optimal $O(\log_B N + \frac{K}{B})$ memory transfers but uses $O(N \log^2 N)$ space. Both structures were first described by Agarwal et al. [11].

35.5.1 Cache-Oblivious kd-Tree

35.5.1.1 Structure

The cache-oblivious kd-tree is simply a normal kd-tree laid out in memory using the van Emde Boas layout. This structure, proposed by Bentley [25], is a binary tree of height $O(\log N)$ with the N points stored in the leaves of the tree. The internal nodes represent a recursive decomposition of the plane by means of axis-orthogonal lines that partition the set of points into two subsets of equal size. On even levels of the tree the dividing lines are horizontal, and on odd levels they are vertical. In this way a rectangular region R_v is naturally associated with each node v , and the nodes on any particular level of the tree partition the plane into disjoint regions. In particular, the regions associated with the leaves represent a partition of the plane into rectangular regions containing one point each. Refer to Figure 35.12.

35.5.1.2 Query

An orthogonal range query Q on a kd-tree \mathcal{T} is answered recursively starting at the root: At a node v we advance the query to a child v_c of v if Q intersects the region R_{v_c} associated with v_c . At a leaf w we return the point in w if it is contained in Q . A standard argument shows that the number of nodes in \mathcal{T} visited when answering Q , or equivalently, the number of nodes v where R_v intersects Q , is $O(\sqrt{N} + K)$; \sqrt{N} nodes v are visited where R_v is intersected by the boundary of Q and K nodes u with R_u completely contained in Q [25].

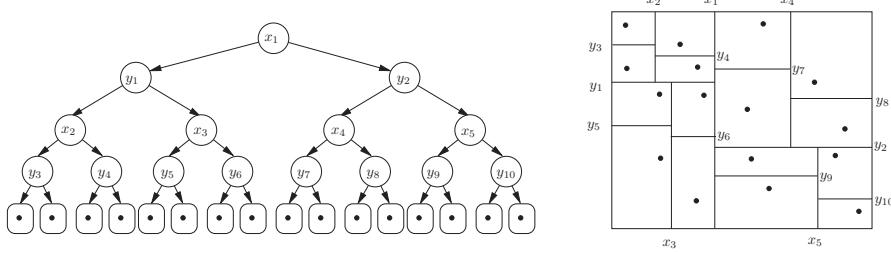

FIGURE 35.12 kd-tree and the corresponding partitioning.

If the kd-tree \mathcal{T} is laid out using the van Emde Boas layout, we can bound the number of memory transfers used to answer a query by considering the nodes $\log B$ levels above the leaves of \mathcal{T} . There are $O(\frac{N}{B})$ such nodes as the subtree \mathcal{T}_v rooted in one such node v contains B leaves. By the standard query argument, the number of these nodes visited by a query is $O(\sqrt{N/B} + \frac{K}{B})$. Thus, the number of memory transfers used to visit nodes more than $\log B$ levels above the leaves is $O(\sqrt{N/B} + \frac{K}{B})$. This is also the overall number of memory transfers used to answer a query, since (as argued in Section 35.2.1) the nodes in \mathcal{T}_v are contained in $O(1)$ blocks, that is, any traversal of (any subset of) the nodes in a subtree \mathcal{T}_v can be performed in $O(1)$ memory transfers.

35.5.1.3 Construction

In the RAM model, a kd-tree on N points can be constructed recursively in $O(N \log N)$ time; the root dividing line is found using an $O(N)$ time median algorithm, the points are distributed into two sets according to this line in $O(N)$ time, and the two subtrees are constructed recursively. Since median finding and distribution can be performed cache-obliviously in $O(N/B)$ memory transfers [4,5], a cache-oblivious kd-tree can be constructed in $O(\frac{N}{B} \log N)$ memory transfers. Agarwal et al. [11] showed how to construct $\log \sqrt{N} = \frac{1}{2} \log N$ levels in $O(\text{Sort}_{M,B}(N))$ memory transfers, leading to a recursive construction algorithms using only $O(\text{Sort}_{M,B}(N))$ memory transfers.

35.5.1.4 Updates

In the RAM model a kd-tree \mathcal{T} can relatively easily be modified to support deletions in $O(\log N)$ time using global rebuilding. To delete a point from \mathcal{T} , we simply find the relevant leaf w in $O(\log N)$ time and remove it. We then remove w 's parent and connect w 's grandparent to w 's sibling. The resulting tree is no longer a kd-tree but it still answers queries in $O(\sqrt{N} + T)$ time, since the standard argument still applies. To ensure that N is proportional to the actual number of points in \mathcal{T} , the structure is completely rebuilt after $\frac{N}{2}$ deletions. Insertions can be supported in $O(\log^2 N)$ time using the so-called logarithmic method [26], that is, by maintaining $\log N$ kd-trees where the i 'th kd-tree is either empty or of size 2^i and then rebuilding a carefully chosen set of these structures when performing an insertion.

Deletes in a cache-oblivious kd-tree is basically done as in the RAM version. However, to still be able to load a subtree \mathcal{T}_v with B leaves in $O(1)$ memory transfers and obtain the $O(\sqrt{N/B} + \frac{K}{B})$ query bound, data locality needs to be carefully maintained. By laying out the kd-tree using (a slightly relaxed version of) the exponential layout (Section 35.3.2) rather than the van Emde Boas layout, and by periodically rebuilding parts of this layout, Agarwal et al. [11] showed how to perform a delete in $O(\log_B N)$ memory transfers amortized while maintaining locality. They also showed how a slightly modified version of the logarithmic method and the $O(\text{Sort}_{M,B}(N))$ construction algorithms can be used to perform inserts in $O\left(\frac{\log N}{B} \log_{M/B} N\right) = O(\log_B^2 N)$ memory transfers amortized.

Theorem 35.8

There exists a cache-oblivious (kd-tree) data structure for storing a set of N points in the plane using linear space, such that an orthogonal range query can be answered in $O(\sqrt{N/B} + \frac{K}{B})$ memory transfers. The structure can be constructed cache-obliviously in $O(\text{Sort}_{M,B}(N))$ memory transfers and supports updates in $O\left(\frac{\log N}{B} \log_{M/B} N\right) = O(\log_B^2 N)$ memory transfers.

35.5.2 Cache-Oblivious Range Tree

The main part of the cache-oblivious range tree structure for answering (four-sided) orthogonal range queries is a structure for answering three-sided queries $Q = [x_l, x_r] \times [y_b, \infty)$, that is, for finding all points with x -coordinates in the interval $[x_l, x_r]$ and y -coordinates above y_b . Below we discuss the two structures separately.

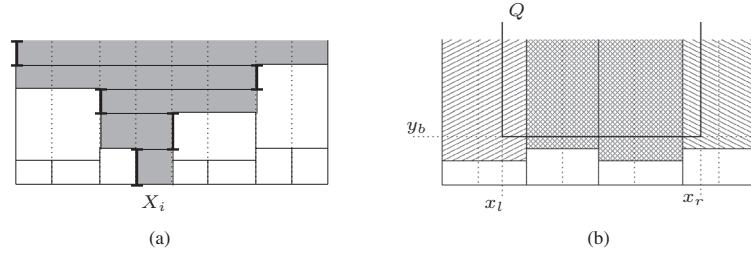

FIGURE 35.13 (a) Active intervals of buckets spanning slab X_i ; (b) Buckets active at y_b .

35.5.2.1 Three-Sided Queries

35.5.2.1.1 Structure

Consider dividing the plane into \sqrt{N} vertical *slabs* $X_1, X_2, \dots, X_{\sqrt{N}}$ containing \sqrt{N} points each. Using these slabs we define $2\sqrt{N} - 1$ *buckets*. A bucket is a rectangular region of the plane that completely spans one or more consecutive slabs and is unbounded in the positive y -direction, like a three-sided query. To define the $2\sqrt{N} - 1$ buckets we start with \sqrt{N} *active* buckets $b_1, b_2, \dots, b_{\sqrt{N}}$ corresponding to the \sqrt{N} slabs. The x -range of the slabs define a natural linear ordering on these buckets. We then imagine sweeping a horizontal sweep line from $y = -\infty$ to $y = \infty$. Every time the total number of points above the sweep line in two adjacent active buckets, b_i and b_j , in the linear order falls to \sqrt{N} , we mark b_i and b_j as *inactive*. Then we construct a new active bucket spanning the slabs spanned by b_i and b_j with a bottom y -boundary equal to the current position of the sweep line. This bucket replaces b_i and b_j in the linear ordering of active buckets. The total number of buckets defined in this way is $2\sqrt{N} - 1$, since we start with \sqrt{N} buckets and the number of active buckets decreases by one every time a new bucket is constructed. Note that the procedure defines an *active* y -interval for each bucket in a natural way. Buckets overlap but the set of buckets with active y -intervals containing a given y -value (the buckets active when the sweep line was at that value) are non-overlapping and span all the slabs. This means that the active y -intervals of buckets spanning a given slab are non-overlapping. Refer to Figure 35.13a.

After defining the $2\sqrt{N} - 1$ buckets, we are ready to present the three-sided query data structure; it is defined recursively: It consists of a cache-oblivious B-tree \mathcal{T} on the \sqrt{N} boundaries defining the \sqrt{N} slabs, as well as a cache-oblivious B-tree for each of the \sqrt{N} slabs; the tree \mathcal{T}_i for slab i contains the bottom endpoint of the active y -intervals of the $O(\sqrt{N})$ buckets spanning the slab. For each bucket b_i we also store the \sqrt{N} points in b_i in a list \mathcal{B}_i sorted by y -coordinate. Finally, recursive structures $\mathcal{S}_1, \mathcal{S}_2, \dots, \mathcal{S}_{2\sqrt{N}-1}$ are built on the \sqrt{N} points in each of the $2\sqrt{N} - 1$ buckets.

35.5.2.1.2 Layout

The layout of the structure in memory consists of $O(N)$ memory locations containing \mathcal{T} , then $\mathcal{T}_1, \dots, \mathcal{T}_{\sqrt{N}}$, and $\mathcal{B}_1, \dots, \mathcal{B}_{2\sqrt{N}-1}$, followed by the recursive structures $\mathcal{S}_1, \dots, \mathcal{S}_{2\sqrt{N}-1}$. Thus the total space use of the structure is $S(N) \leq 2\sqrt{N} \cdot S(\sqrt{N}) + O(N) = O(N \log N)$.

35.5.2.1.3 Query

To answer a three-sided query Q , we consider the buckets whose active y -interval contain y_b . These buckets are non-overlapping and together they contain all points in Q , since they span all slabs and have bottom y -boundary below y_b . We report all points that satisfy Q in each of the buckets with x -range completely between x_l and x_r . At most two other buckets b_l and b_r —the ones containing x_l and x_r —can contain points in Q , and we find these points recursively by advancing the query to \mathcal{S}_l and \mathcal{S}_r . Refer to Figure 35.13b.

We find the buckets b_l and b_r that need to be queried recursively and report the points in the completely spanned buckets as follows. We first query \mathcal{T} using $O(\log_B \sqrt{N})$ memory transfers to find the slab X_l containing x_l . Then we query \mathcal{T}_l using another $O(\log_B \sqrt{N})$ memory transfers to find the bucket b_l with active y -interval containing y_b . We can similarly find b_r in $O(\log_B \sqrt{N})$ memory transfers. If b_l spans slabs X_l, X_{l+1}, \dots, X_m we then query \mathcal{T}_{m+1} with y_b in $O(\log_B \sqrt{N})$ memory transfers to find the active bucket b_i to the right of b_l completely spanned by Q (if it exists). We report the relevant points in b_i by scanning \mathcal{B}_i top-down until we encounter a point not contained in Q . If K' is the number of reported points, a scan of \mathcal{B}_i takes $O(1 + \frac{K'}{B})$ memory transfers. We continue this procedure for each of the completely spanned active buckets. By construction, we know that every two adjacent such buckets contain at least \sqrt{N} points above y_b . First consider the part of the query that takes place on recursive levels of size $N \geq B^2$, such that $\sqrt{N}/B \geq \log_B \sqrt{N} \geq 1$. In this case the $O(\log_B \sqrt{N})$ overhead in finding and processing two consecutive completely spanned buckets is smaller than the $O(\sqrt{N}/B)$ memory transfers used to report output points; thus

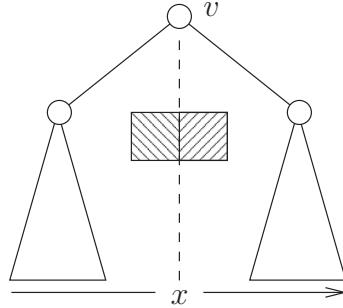

FIGURE 35.14 Answering a four-sided query in v using two three-sided queries in v 's children.

we spend $O\left(\log_B \sqrt{N} + \frac{K_i}{B}\right)$ memory transfers altogether to answer a query, not counting the recursive queries. Since we perform at most two queries on each level of the recursion (in the active buckets containing x_l and x_r), the total cost over all levels of size at least B^2 is $O\left(\sum_{i=1}^{\log \log_B N} \log_B N^{1/2^i} + \frac{K_i}{B}\right) = O\left(\log_B N + \frac{K}{B}\right)$ transfers. Next consider the case where $N = B$. In this case the whole level, that is, $\mathcal{T}, \mathcal{T}_1, \dots, \mathcal{T}_{\sqrt{B}}$ and $\mathcal{B}_1, \dots, \mathcal{B}_{2\sqrt{B}-1}$, is stored in $O(B)$ contiguously memory locations and can thus be loaded in $O(1)$ memory transfers. Thus the optimal paging strategy can ensure that we only spend $O(1)$ transfers on answering a query. In the case where $N \leq \sqrt{B}$, the level and *all* levels of recursion below it occupies $O(\sqrt{B} \log \sqrt{B}) = O(B)$ space. Thus the optimal paging strategy can load it and all relevant lower levels in $O(1)$ memory transfers. This means that overall we answer a query in $O(\log_B N + \frac{K}{B})$ memory transfers, *provided* that N and B are such that we have a level of size B^2 (and thus of size B and \sqrt{B}); when answering a query on a level of size between B and B^2 we cannot charge the $O(\log_B \sqrt{N})$ cost of visiting two active consecutive buckets to the ($< B$) points found in the two buckets. Agarwal et al. [11] showed how to guarantee that we have a level of size B^2 by assuming that $B = 2^{2^d}$ for some non-negative integer d . Using a somewhat different construction, Arge et al. [27] showed how to remove this assumption.

Theorem 35.9

There exists a cache-oblivious data structure for storing N points in the plane using $O(N \log N)$ space, such that a three-sided orthogonal range query can be answered in $O(\log_B N + \frac{K}{B})$ memory transfers.

35.5.2.2 Four-sided queries

Using the structure for three-sided queries, we can construct a cache-oblivious range tree structure for four-sided orthogonal range queries in a standard way. The structure consists of a cache-oblivious B-tree \mathcal{T} on the N points sorted by x -coordinates. With each internal node v we associate a secondary structure for answering three-sided queries on the points stored in the leaves of the subtree rooted at v : If v is the left child of its parent then we have a three-sided structure for answering queries with the opening to the right, and if v is the right child then we have a three-sided structure for answering queries with the opening to the left. The secondary structures on each level of the tree use $O(N \log N)$ space, for a total space usage of $O(N \log^2 N)$.

To answer an orthogonal range query Q , we search down \mathcal{T} using $O(\log_B N)$ memory transfers to find the first node v where the left and right x -coordinate of Q are contained in different children of v . Then we query the right opening secondary structure of the left child of v , and the left opening secondary structure of the right child of v , using $O(\log_B N + \frac{K}{B})$ memory transfers. Refer to Figure 35.14. It is easy to see that this correctly reports all K points in Q .

Theorem 35.10

There exists a cache-oblivious data structure for storing N points in the plane using $O(N \log^2 N)$ space, such that an orthogonal range query can be answered in $O(\log_B N + \frac{K}{B})$ memory transfers.

36.1 Introduction

In this chapter we consider the problem of maintaining properties of a collection of vertex-disjoint trees that change over time as edges are added or deleted. The trees can be rooted or free, and vertices and edges may be associated with real-valued costs that may change as well. A straightforward solution would be to store explicitly with each vertex its parent and cost, if any: with this representation each update would cost only $O(1)$ time, but answering queries would be typically proportional to the size or to the depth of the tree, which may be linear in the worst case. By representing the structure of the trees implicitly, one can reduce the query time while slightly increasing the update time. The typical achieved bounds are logarithmic in the number of vertices of the forest, either in the worst-case or amortized over a sequence of operations.

While the basic tree update operations are edge insertions, edge deletions, and possibly vertex/edge cost changes, many properties of dynamically changing trees have been considered in the literature. The basic query operation is tree membership: while the forest of trees is dynamically changing, we would like to know at any time which tree contains a given vertex, or whether two vertices are in the same tree. Dynamic tree membership is a special case of dynamic connectivity in undirected graphs, and indeed in Chapter 37 we will see that some of the data structures developed here for trees are used to solve the more general problem on graphs. We remark that, if only edge insertions are allowed, the tree membership problem is equivalent to maintaining disjoint sets under union operations and thus the well known set union data structures can solve it [1]. In this chapter we will instead consider the problem in a fully dynamic setting, in which also edge deletions are allowed, and present efficient data structures such as the *linking and cutting trees* of Sleator and Tarjan [2] and the *topology trees* of Frederickson [3].

Other properties that have been considered are finding the least common ancestor of two vertices, the center, the median, or the diameter of a tree [2,4, 5]. When costs are associated either to vertices or to edges, one could also ask what is the minimum or maximum cost in a given path. A variant of topology trees, known as *top trees* [4], are especially well suited at maintaining this kind of path information.

ET trees, first introduced in [6] and much used in [7], allow it to deal easily with forests whose vertices are associated with weighted or unweighted keys, supporting, for example, minkey queries, which require to return a key of minimum weight in the tree that contains a given vertex. *Reachability trees*, introduced by Even and Shiloach in [8], support instead distance and shortest path queries and have been widely used to solve dynamic path problems on directed graphs (see, e.g., [7,9]).

^{*} This chapter has been reprinted from first edition of this Handbook, without any content updates.

36.2 Linking and Cutting Trees

In this section we present a data structure due to Sleator and Tarjan [2] useful to maintain a collection of rooted trees, each of whose vertices has a real-valued cost, under an arbitrary sequence of the following operations:

- **maketree(v):** initialize a new tree consisting of a single vertex v with cost zero.
- **findroot(v):** return the root of the tree containing vertex v .
- **findcost(v):** return a vertex of minimum cost in the path from v to **findroot(v)**.
- **addcost(v, δ):** add the real number δ to the cost of every vertex in the path from v to **findroot(v)**.
- **link(v, w):** merge the trees containing vertices v and w by inserting edge (v, w) . This operation assumes that v and w are in different trees and that v is a tree root.
- **cut(v):** delete the edge from v to its parent, thus splitting the tree containing vertex v into two trees. This operation assumes that v is not a tree root.

The data structure of Sleator and Tarjan is known as *linking and cutting trees* and supports all the above operations in $O(\log n)$ time, by representing the structure of the trees implicitly. Other operations that can be supported within the same time bound are changing the root of a tree, finding the parent of a vertex, and finding the least common ancestor of two vertices. In particular, the possibility of making a given vertex v root of a tree makes the data structure powerful enough to handle problems requiring linking and cutting of free (i.e., unrooted) trees. Furthermore, the same time bounds can be obtained when real costs are associated with edges rather than with vertices.

The rest of this section is organized as follows. In Section 36.2.1 we show how to implement the operations given above using simpler primitives defined on paths (rather than on trees), and in Section 36.2.2 we describe the implementation of these primitives on paths. For simplicity, we only describe a solution that achieves $O(\log n)$ amortized (rather than worst-case) time per operation. Details of all these results may be found in [2].

36.2.1 Using Operations on Vertex-Disjoint Paths

In this section we show the reduction between the operations on trees and a suitable collection of operations on vertex-disjoint paths. Assume we know how to perform the following operations:

- **makepath(v):** initialize a new path consisting of a single vertex v with cost zero;
- **findpath(v):** return the path containing vertex v ;
- **findpathtail(p):** return the tail (last vertex) of path p ;
- **findpathcost(p):** return a vertex of minimum cost in path p ;
- **addpathcost(p, δ):** add the real value δ to the cost of every vertex in path p ;
- **join(p, v, q):** merge path p , vertex v , and path q into a single path by inserting one edge from the tail of p to v , and one edge from v to the head (first vertex) of q , and return the new path. Either p or q can be empty;
- **split(v):** divide the path containing vertex v into at most three paths by deleting the edges incident to v . Return the two new paths p (containing all the vertices before v) and q (containing all the vertices after v). Again, either p or q can be empty.

In order to solve the problem of linking and cutting trees, we partition each tree into a set of vertex disjoint paths. Each tree operation will be defined in terms of one or more path operations. This partition is defined by allowing each tree edge to be either *solid* or *dashed* and by maintaining the invariant that at most one solid edge enters each vertex (we consider an edge oriented from a child to its parent). Removing dashed edges therefore partitions the tree into vertex-disjoint *solid paths*. Dashed edges are represented implicitly: we associate with each path p its *successor*, that is the vertex entered by the dashed edge leaving the tail of p . If the tail of p is a root, $\text{successor}(p)$ is *null*. Each path will be represented by a vertex on it (an empty path being represented by *null*). In order to convert dashed edges to solid (and vice-versa) we will be using the following operation:

- **expose(v):** make the tree path from v to **findroot(v)** solid. This is done by converting dashed edges in the path to solid, and solid edges incident to the path to dashed. Return the resulting solid path.

Now we describe how to implement tree operations in terms of path operations:

- a **maketree(v)** is done by a **makepath(v)** followed by setting $\text{successor}(v)$ to *null*;
- a **findroot(v)** is a **findpathtail(expose(v))**;
- a **findcost(v)** is a **findpathcost(expose(v))**;
- an **addcost(v, δ)** is an **addpathcost(expose(v), δ)**;

```

function expose (v)
1. begin
2.    $p \leftarrow null$ 
3.   while  $v \neq null$  do
4.      $w \leftarrow \text{successor}(\text{findpath}(v))$ 
5.      $[q, r] \leftarrow \text{split}(v)$ 
6.     if  $q \neq null$  then  $\text{successor}(q) \leftarrow v$ 
7.      $p \leftarrow \text{join}(p, v, r)$ 
8.      $v \leftarrow w$ 
9.      $\text{successor}(p) \leftarrow null$ 
10.  end

```

FIGURE 36.1 Implementation of **expose**(v).

- a **link**(v, w) is implemented by performing first an **expose**(v) that makes v into a one-vertex solid path, then an **expose**(w) that makes the path from w to its root solid, and then by joining these two solid paths: in short, this means assigning *null* to **successor**(**join**(*null*, **expose**(v), **expose**(w)));
- to perform a **cut**(v), we first perform an **expose**(v), which leaves v with no entering solid edge. We then perform a **split**(v), which returns paths p and q : since v is the head of its solid path and is not a tree root, p will be empty, while q will be non-empty. We now complete the operation by setting both **successor**(v) and **successor**(q) to *null*.

To conclude, we need to show how to perform an **expose**, that is, how to convert all the dashed edges in the path from a given vertex to the tree root to solid maintaining the invariant that at most one solid edge enters each vertex. Let x be a vertex of this path such that the edge from x to its parent w is dashed (and thus $w = \text{successor}(x)$). What we would like to do is to convert edge (x, w) into solid, and to convert the solid edge previously entering w (if any) into dashed. We call this operation a *splice*. The pseudocode in Figure 36.1 implements **expose**(v) as a sequence of splices. Path p , initialized to be empty, at the end of the execution will contain the solid path from v to **findroot**(v). Each iteration of the **while** loop performs a splice at v by converting to solid the edge from the tail of p to v (if $p \neq null$) and to dashed the edge from the tail of q to v (if $q \neq null$). A step-by-step execution of **expose** on a running example is shown in Figure 36.2.

From the description above, each tree operation takes $O(1)$ path operations and at most one **expose**. Each splice within an **expose** requires $O(1)$ path operations. Hence, in order to compute the running time, we need first to count the number of splices per **expose** and then to show how to implement the path operations. With respect to the former point, Sleator and Tarjan prove that a sequence of m tree operations causes $O(m \log n)$ splices, and thus $O(\log n)$ splices amortized per **expose**.

Theorem 36.1

[2] Any sequence of m tree operations (including n **maketree**) requires $O(m)$ path operations and at most m **expose**. The exposes can be implemented with $O(m \log n)$ splices, each of which requires $O(1)$ path operations.

36.2.2 Implementing Operations on Vertex-Disjoint Paths

We now describe how to represent solid paths in order to implement efficiently tree operations. Each solid path is represented by a binary tree whose nodes in symmetric order are the vertices in the path; each node x contains pointers to its parent $p(x)$, to its left child $l(x)$, and to its right child $r(x)$. We call the tree representing a solid path a *solid tree*. The vertex representing a solid path is the root of the corresponding solid tree, and thus the root of the solid tree contains a pointer to the successor of the path in the dynamic tree.

Vertex costs are represented as follows. Let $\text{cost}(x)$ be the cost of vertex x , and let $\text{mincost}(x)$ be the minimum cost among the descendants of x in its solid tree. Rather than storing these two values, in order to implement **addcost** operations efficiently, we store at x the incremental quantities $\Delta\text{cost}(x)$ and $\Delta\text{min}(x)$ defined as follows:

$$\Delta\text{cost}(x) = \text{cost}(x) - \text{mincost}(x) \tag{36.1}$$

$$\Delta\text{min}(x) = \begin{cases} \text{mincost}(x) & \text{if } x \text{ is a solid tree root} \\ \text{mincost}(x) - \text{mincost}(p(x)) & \text{otherwise} \end{cases} \tag{36.2}$$

An example of this representation is given in Figure 36.3. Given Δcost and Δmin , we can compute $\text{mincost}(x)$ by summing up Δmin for all vertices in the solid tree path from the root to x , and $\text{cost}(x)$ as $\text{mincost}(x) + \Delta\text{cost}(x)$. Moreover, note that $\Delta\text{cost}(x) = 0$ if and only if x is a minimum cost node in the subtree rooted at x . If this is not the case and the minimum cost node is

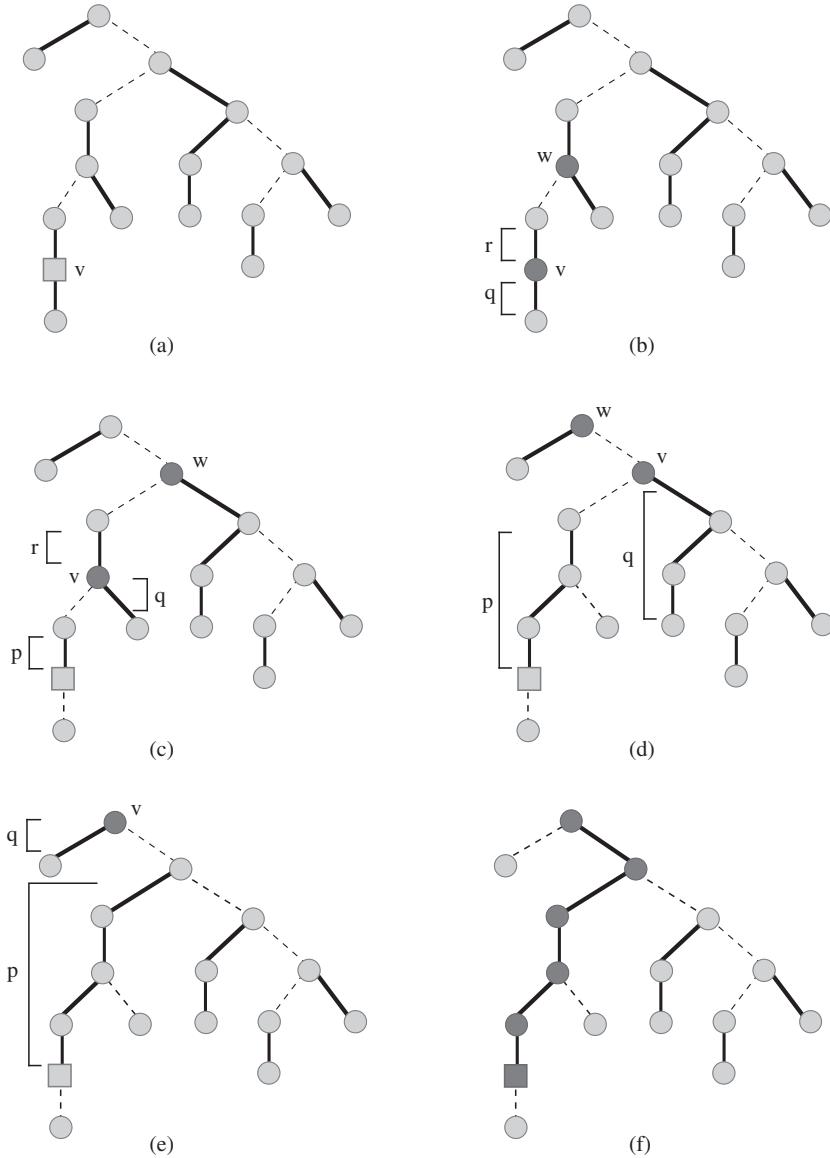

FIGURE 36.2 Effect of `expose(v)`. (a) The original decomposition into solid paths; (b–e) vertices and paths after the execution of line 5 in the four consecutive iterations of the `while` loop; (f) the decomposition into solid paths after `expose(v)`.

in the right subtree, then $\Delta\min(r(x)) = 0$; otherwise $\Delta\min(l(x)) = 0$. With this representation, rotations can be still implemented in $O(1)$ time. The path operations can be carried out as follows:

- **makepath(v)**: initialize a binary tree of one vertex v with $\Delta\min(v) = 0$ and $\Delta\text{cost}(v) = 0$.
- **findpath(v)**: starting from v , follow parent pointers in v 's solid tree until a node with no parent is found. Return this node.
- **findpathtail(p)**: assuming that p is the root of a solid tree, follow right pointers and return the rightmost node in the solid tree.
- **findpathcost(p)**: initialize v to p and repeat the following step until $\Delta\text{cost}(v) = 0$: if v has a right child and $\Delta\min(r(v)) = 0$, replace v by $r(v)$; otherwise, replace v by $l(v)$. At the end, return v .
- **addpathcost(p, δ)**: add δ to $\Delta\min(p)$.
- **join(p, v, q)**: join the solid trees with roots p , v and q .
- **split(v)**: split the solid tree containing node v .

We observe that operations `findpath`, `findpathtail` and `findpathcost` are essentially a look up in a search tree, while `split` and `join` are exactly the same operations on search trees. If we represent solid paths by means of balanced search trees,

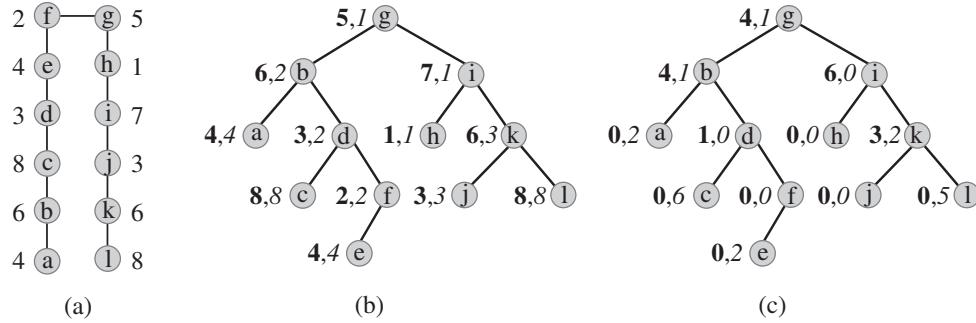

FIGURE 36.3 Representing solid paths with binary trees. (a) A solid path and its vertex costs; (b) solid tree with explicit costs (the bold value is $cost(v)$ and the italic value is $mincost(v)$); (c) corresponding solid tree with incremental costs (the bold value is $\Delta cost(v)$ and the italic value is $\Delta min(v)$).

the time per path operation becomes $O(\log n)$, and by Theorem 36.1 any sequence of m tree operations can be supported in $O(m(\log n)^2)$ time. Using self-adjusting binary search trees [10] to represent solid paths, together with a more careful analysis, yields a better bound:

Theorem 36.2

[2] Any sequence of m tree operations (including `n maketree`) requires $O(m \log n)$ time.

Insights on the use of self-adjusting binary search trees in the implementation of path operations are given in Chapter 13. Using biased search trees [11], the $O(\log n)$ amortized bound given in Theorem 36.2 can be made worst-case. Details can be found in [2].

36.3 Topology Trees

Topology trees have been introduced by Frederickson [3] in order to maintain information about trees subject to insertions and deletions of edges and answer efficiently, for example, tree membership queries. Similarly to the linking and cutting trees of Sleator and Tarjan [2] that we have discussed in Section 36.2, topology trees follow the idea of partitioning a tree into a set of vertex-disjoint paths. However, they are very different in how this partition is chosen, and in the data structures used to represent the paths inside the partition. Indeed, Sleator and Tarjan [2] use a simple partition of the trees based upon a careful choice of sophisticated data structures to represent paths. On the contrary, Frederickson [3] uses a more sophisticated partition that is based upon the topology of the tree; this implies more complicated algorithms but simpler data structures for representing paths.

The basic idea is to partition the tree into a suitable collection of subtrees, called *clusters*, and to implement updates such that only a small number of such clusters is involved. The decomposition defined by the clusters is applied recursively to get faster update and query times.

In order to illustrate how such a recursive decomposition is computed, we assume that T has maximum vertex degree 3: this is without loss of generality, since a standard transformation can be applied if this is not the case [12]. Namely, each vertex v of degree $d > 3$ is replaced by new vertices v_0, \dots, v_{d-1} ; for each neighbor u_i of vertex v , $0 \leq i \leq d-1$, edge (v, u_i) is replaced by (v_i, u_i) , and a new edge (v_i, v_{i+1}) is created if $i < d-1$.

Given a tree T of maximum degree 3, a *cluster* is any connected subgraph of T . The *cardinality* and the *external degree* of a cluster are the number of its vertices and the number of tree edges incident to it, respectively. We now define a partition of the vertices of T such that the resulting clusters possess certain useful properties. Let z be a positive integer.

Definition 36.1

A *restricted partition* of order z w.r.t. T is a partition of the vertex set V into clusters of degree at most 3 such that:

1. Each cluster of external degree 3 has cardinality 1.
2. Each cluster of external degree < 3 has cardinality at most z .
3. No two adjacent clusters can be combined and still satisfy the above.

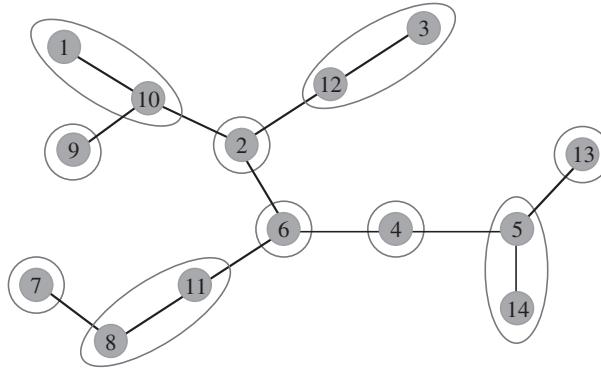

FIGURE 36.4 A restricted partition of order 2 of a tree T .

A restricted partition of order 2 of a tree T is shown in Figure 36.4. There can be several restricted partitions for a given tree T , based upon different choices of the vertices to be unioned. For instance, vertex 8 in Figure 36.4 could be unioned with 7, instead of 11, and the partition would still be valid. It can be proved that a restricted partition of order z has $\Theta(n/z)$ clusters [3,13].

We now show that the partition defined above can be applied recursively for $\Theta(\log n)$ levels. Such a recursive application yields a *restricted multilevel partition* [3,13], from which the topology tree can be finally obtained.

Definition 36.2

A *topology tree* is a hierarchical representation of a tree T such that each level of the topology tree partitions the vertices of T into clusters. Clusters at level 0 contain one vertex each. Clusters at level $\ell \geq 1$ form a restricted partition of order 2 of the vertices of the tree T' obtained by shrinking each cluster at level $\ell - 1$ into a single vertex.

As shown in Figure 36.5, level ℓ of the restricted multilevel partition is obtained by computing a restricted partition of order 2 with respect to the tree resulting from viewing each cluster at level $\ell - 1$ as a single vertex. Figure 36.5 also shows the topology tree corresponding to the restricted multilevel partition. Call any cluster of level $\ell - 1$ *matched* if it is unioned with another cluster to give a cluster of level ℓ : *unmatched* clusters have a unique child in the topology tree. It can be proved that, for any level $\ell > 0$ of a restricted multilevel partition, the number of matched clusters at level $\ell - 1$ is at least $1/3$ of the total number of vertex clusters at level $\ell - 1$. Since each pair of matched clusters is replaced by their union at level ℓ , the number of clusters at level ℓ is at most $5/6$ the number of clusters at level $\ell - 1$. The number of levels of the topology tree is therefore $\Theta(\log n)$.

36.3.1 Construction

It is sufficient to show how to compute a restricted partition: the levels of the topology tree can be then built in a bottom up fashion by repeatedly applying the clustering algorithm as suggested by Definition 36.2. Because of property (3) in Definition 36.1, it is natural to compute a restricted partition according to a locally greedy heuristic, which does not always obtain the minimum number of clusters, but has the advantage of requiring only local adjustments during updates. The tree is first rooted at any vertex of degree 1 and the procedure **cluster** is called with the root as argument. At a generic step, procedure **cluster**(v) works as follows. It initializes the cluster $C(v)$ containing vertex v as $C(v) = \{v\}$. Then, for each child w of v , it recursively calls **cluster**(w), that computes $C(w)$: if $C(w)$ can be unioned with $C(v)$ without violating the size and degree bounds in Definition 36.1, $C(v)$ is updated as $C(v) \cup C(w)$, otherwise $C(w)$ is output as a cluster. As an example, the restricted partition shown in Figure 36.4 is obtained by running procedure **cluster** on the tree rooted at vertex 7.

36.3.2 Updates

We first describe how to update the clusters of a restricted partition when an edge e is inserted in or deleted from the dynamic tree T : this operation is the crux of the update of the entire topology tree.

Update of a restricted partition. We start from edge deletion. First, removing an edge e splits T into two trees, say T_1 and T_2 , which inherit all of the clusters of T , possibly with the following exceptions.

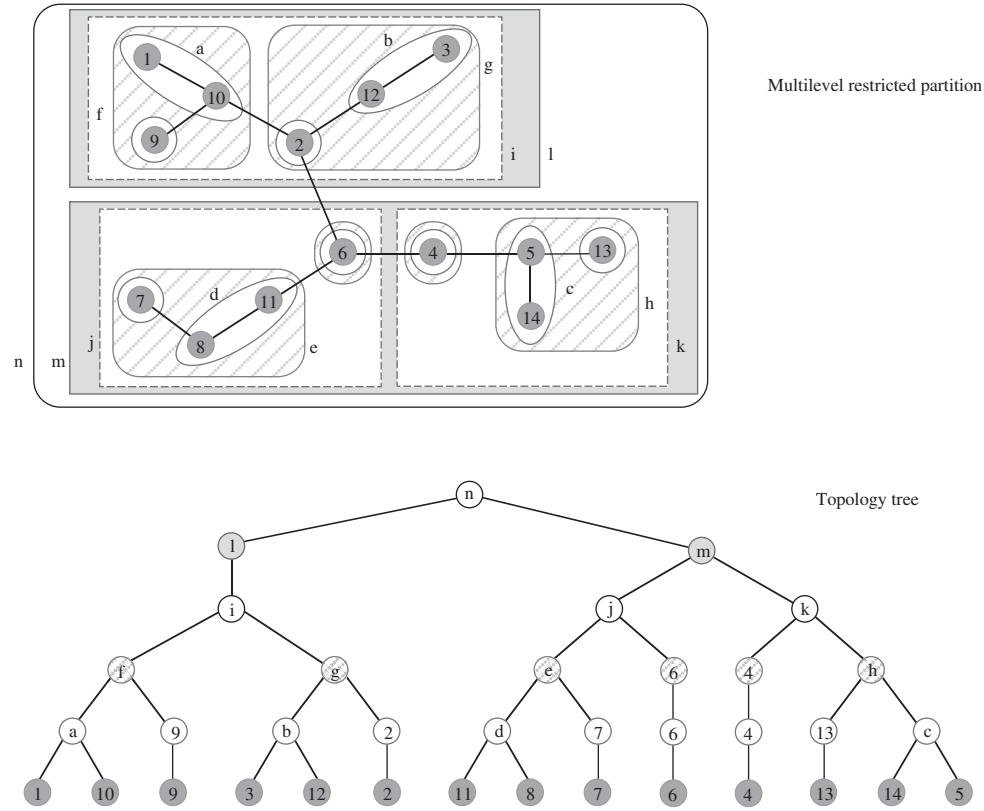

FIGURE 36.5 Restricted multilevel partition and corresponding topology tree.

1. Edge e is entirely contained in a cluster: this cluster is no longer connected and therefore must be split. After the split, we must check whether each of the two resulting clusters is adjacent to a cluster of tree degree at most 2, and if these two adjacent clusters together have cardinality ≤ 2 . If so, we combine these two clusters in order to maintain condition (3).
2. Edge e is between two clusters: in this case no split is needed. However, since the tree degree of the clusters containing the endpoints of e has been decreased, we must check if each cluster should be combined with an adjacent cluster, again because of condition (3).

Similar local manipulations can be applied to restore invariants (1)–(3) in Definition 36.1 in case of edge insertions. We now come to the update of the topology tree.

Update of the topology tree. Each level can be updated upon insertions and deletions of edges in tree T by applying few locally greedy adjustments similar to the ones described above. In particular, a constant number of basic clusters (corresponding to leaves in the topology tree) are examined: the changes in these basic clusters percolate up in the topology tree, possibly causing vertex clusters to be regrouped in different ways. The fact that only a constant amount of work has to be done on $O(\log n)$ topology tree nodes implies a logarithmic bound on the update time.

Theorem 36.3

[3,13] The update of a topology tree because of an edge insertion or deletion in the dynamic tree T can be supported in $O(\log n)$ time, where n is the number of vertices of T .

36.3.3 Applications

In the *fully dynamic tree membership* problem we would like to maintain a forest of unrooted trees under insertion of edges (which merge two trees into one), deletion of edges (which split one tree into two), and membership queries. Typical queries require to return the name of the tree containing a given vertex, or ask whether two vertices are in a same tree. Most of the solutions presented in the literature root each tree arbitrarily at one of its vertices; by keeping extra information at the root (such as the name of the tree), membership queries are equivalent to finding the tree root a vertex.

The dynamic tree clustering techniques of Frederickson have also found wide application in dynamic graph algorithms. Namely, topology trees have been originally designed in order to solve the *fully dynamic minimum spanning tree* problem [3], in which we wish to maintain a minimum spanning tree of a dynamic weighted undirected graph upon insertions/deletions of edges and edge cost changes. Let $G = (V, E)$ be the dynamic graph and let S be a designated spanning tree of G . As G is updated, edges in the spanning tree S may change: for example, if the cost of an edge e is increased in G and e is in the spanning tree, we need to check for the existence of a replacement edge e' of smaller cost, and swap e' with e in S . The clustering approach proposed in [3,13] consists of partitioning the vertex set V into subtrees connected in S , so that each subtree is only adjacent to a few other subtrees. A topology tree is used for representing this recursive partition of the spanning tree S . A generalization of topology trees, called *2-dimensional topology trees*, is also formed from pairs of nodes in the topology tree in order to maintain information about the edges in $E \setminus S$ [3]. Fully dynamic algorithms based only on a single level of clustering obtain typically time bounds of the order of $O(m^{2/3})$ (see for instance [14,15]), where m is the number of edges of the graph. When the partition is applied recursively, better $O(m^{1/2})$ time bounds can be achieved by using 2-dimensional topology trees: we refer the interested reader to [3,13] for details. As we will see in Section 36.5.2, Frederickson's algorithm is not optimal: the fully dynamic minimum spanning tree problem has been later solved in polylogarithmic time [16].

With the same technique, an $O(m^{1/2})$ time bound can be obtained also for *fully dynamic connectivity* and *2-edge connectivity* [3,13]. For instance, [13] shows that edges and vertices can be inserted to or deleted from an undirected graph in $O(m^{1/2})$ time, and a query as to whether two vertices are in the same 2-edge-connected component can be answered in $O(\log n)$ time, n being the number of vertices. This result is based on the use of *ambivalent data structures* [13], a refinement of the clustering technique in which edges can belong to multiple groups, only one of which is actually selected depending on the topology of the given spanning tree.

36.4 Top Trees

Top trees have been introduced by Alstrup et al. [4] to maintain efficiently information about paths in trees, such as, for example, the maximum weight on the path between any pair of vertices in a tree. The basic idea is taken from Frederickson's topology trees, but instead of partitioning vertices, top trees work by partitioning edges: the same vertex can then appear in more than one cluster. Top trees can be also seen as a natural generalization of standard balanced binary trees over dynamic collections of lists that may be concatenated and split, where each node of the balanced binary tree represents a segment of a list. As we will see, in the terminology of top trees this is just a special case of a cluster.

We follow here the presentation in [5]. Similarly to [3,13], a *cluster* is a connected subtree of the dynamic tree T , with the additional constraint that at most two vertices, called *boundary vertices*, have edges out of the subtree. We will denote the boundary of a cluster C as δC . If the boundary contains two vertices u and v , we call *cluster path* of C the unique path between u and v in T and we denote it as $\pi(C)$. If $|\delta C| < 2$, then $\pi(C) = \emptyset$. Two clusters C_1 and C_2 are called *neighbors* if their intersection contains exactly one vertex: since clusters are connected and have no edges in common, the intersection vertex must be in $\delta C_1 \cap \delta C_2$. It is also possible to define a boundary δT , consisting of one or two vertices, for the entire tree T : we will call such vertices, if any, *external boundary vertices*. If external boundary vertices are defined, we have to extend the notion of boundary of a cluster: namely, if a cluster C contains an external boundary vertex v , then $v \in \delta C$ even if v has no edge out of C .

Definition 36.3

A *top tree* \mathcal{T} over a pair $(T, \delta T)$ is a binary tree such that:

- The leaves of \mathcal{T} are the edges of T .
- The internal nodes of \mathcal{T} are clusters of T .
- The subtree represented by each internal node is the union of the subtrees represented by its two children, which must be neighbors.
- The root of \mathcal{T} represents the entire tree T .
- The height of \mathcal{T} is $O(\log n)$, where n is the number of vertices of T .

A tree with a single node has an empty top tree. Figure 36.6 shows the clusters at different levels of the recursive partition and the corresponding top tree. Note that a vertex can appear in many clusters, as many as $\Theta(n)$ in the worst case. However, it can be a non-boundary vertex only in $O(\log n)$ clusters. Indeed, for each vertex v which is neither an external boundary vertex nor a leaf in T , there exists a unique cluster C with children A and B such that $v \in \delta A$, $v \in \delta B$, and $v \notin \delta C$. Then v is non-boundary vertex only in cluster C and in all its ancestors in the top tree.

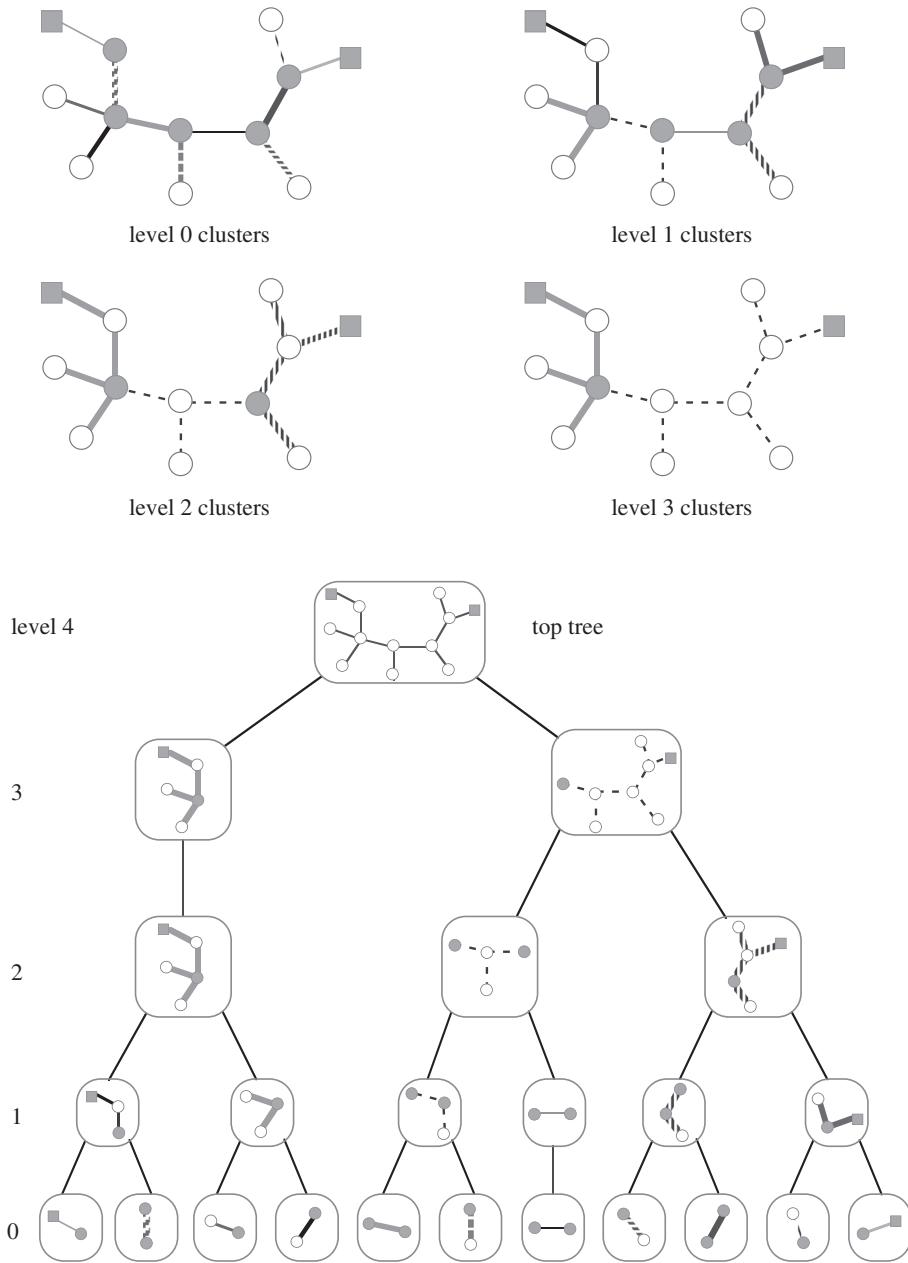

FIGURE 36.6 Clusters and top tree of a tree T . Edges with the same color, thickness, and pattern are in the same cluster. Boundary vertices are grey. External boundary vertices are squared.

A locally greedy approach similar to the one described in Section 36.3.1 for topology trees can be used to build a top tree. The only modifications require to reason in terms of edges, instead of vertices, and to check the condition on the cardinality of the boundary before unioning any two neighboring clusters.

36.4.1 Updates

Given a dynamic forest, top trees over the trees of the forest are maintained under the following operations:

- **link(u, v)**, where u and v are in different trees T_u and T_v of the forest: link trees T_u and T_v by adding edge (u, v) ;
- **cut(e)**: remove edge e from the forest;
- **expose(u, v)**, where u and v are in the same tree T of the forest: make u and v the external boundary vertices of T and return the new root cluster of the top tree over T .

Top trees can be maintained under these operations by making use of two basic **merge** and **split** primitives:

- **merge**: it takes two top trees whose roots are neighbor clusters and joins them to form a unique top tree;
- **split**: this is the reverse operation, deleting the root of a given top tree.

The implementation of update operations starts with a sequence of **split** of all ancestor clusters of edges whose boundary changes and finishes with a sequence of **Merge**. In case of insertion and deletions, since an end-point v of an edge has to be already boundary vertex of the edge if v is not a leaf, an update can change the boundary of at most two edges, excluding the edge being inserted/deleted. From [3–5] we have:

Theorem 36.4

[4,5] For a dynamic forest we can maintain top trees of height $O(\log n)$ supporting each **link**, **cut**, and **expose** operation with a sequence of $O(\log n)$ **split** and **merge**. The sequence itself is identified in $O(\log n)$ time. The space usage of top trees is linear in the size of the dynamic forest.

36.4.2 Representation and Applications

Top trees are represented as standard binary trees, with pointers to parent and children for each node. With each leaf is associated the corresponding edge in T and with each internal node the at most two boundary vertices of the corresponding cluster. In addition, each vertex v of T has a pointer to the deepest cluster for which v is a non-boundary vertex, or to the root cluster containing v if v is an external boundary vertex. Given this representation, top trees can be used as a black box for maintaining different kinds of information. Typically, the user needs to attach extra information to the top tree nodes and to show how such information can be maintained upon **merge** and **split** operations.

A careful choice of the extra information makes it possible to maintain easily path properties of trees, such as the minimum weight of an edge on the path between any two vertices. In this example, the extra information w_C associated with a cluster C is the weight of the lightest edge on the cluster path $\pi(C)$. Before showing how to maintain it, note that if cluster A is a child of cluster C in the top tree and A contains an edge from $\pi(C)$, then $\pi(A) \subseteq \pi(C)$: we call A a *path child* of C . When a cluster is created by a **merge**, we store as extra information the minimum weight stored at its path children. In case of a **split**, we just discard the information. Now, in order to find the minimum weight between any two vertices u and v , we compute the root cluster C of the top tree in which u and v are external boundary vertices by calling **expose(u, v)**. Then $\pi(C)$ is the path between u and v and w_C is exactly the value we are looking for.

Top trees can be used quite easily if the property we wish to maintain is a *local* property, that is, being satisfied by a vertex/edge in a tree implies that the property is also satisfied in all the subtrees containing the vertex/edge. Non-local properties appear to be more challenging. For general non-local searching the user has to supply a function **select** that can be used to guide a binary search towards a desired edge: given the root of a top tree, the function selects one of the two children according to the property to be maintained. Since the property is non-local, in general it is not possible to recurse directly on the selected child as is. However, Alstrup et al. [5] show that the top tree can be temporarily modified by means of a few **merge** operations so that **select** can be provided with the “right” input in the recursive call and guide the search to a correct solution.

Lemma 36.1

Given a top tree, after $O(\log n)$ calls to **select**, **merge**, and **split**, there is a unique edge (u, v) contained in all clusters chosen by **select**, and then (u, v) is returned.

We refer the interested reader to [5] for the proof of Lemma 36.1, which shows how to modify the top tree in order to facilitate calls to **select**. We limit here to use the search as a black box in order to show how to maintain dynamically the *center* of a tree (i.e., a vertex which maximizes the distance from any other vertex) using top trees.

The extra information maintained for a cluster C with boundary vertices a and b are: the distance $dist(C)$ between a and b , and the lengths $\ell_a(C)$ and $\ell_b(C)$ of a longest path in C departing from a and b , respectively. Now we show how to compute the extra information for a cluster C obtained by merging two neighboring clusters A and B . Let c be a boundary vertex of cluster C and, w.l.o.g., let $c \in \delta A$. The longest path from c to a vertex in A has length $\ell_c(A)$. Instead, in order to get from c to a vertex in B , we must traverse a vertex, say x , such that $x \in \delta A \cap \delta B$: thus, the longest path from c to a vertex in B has length $dist(c, x) + \ell_x(B)$. This is equal to $\ell_c(B)$ if $c \in \delta B$ (i.e., if $x = c$), or to $dist(A) + \ell_x(B)$ if $c \notin \delta B$. Now, we set $\ell_c(C) = \max\{\ell_c(A), dist(c, x) + \ell_x(B)\}$. We can compute $dist(C)$ similarly. Finally, function **select** can be implemented as follows. Given a cluster C with children A and B , let u be the vertex in the intersection of A and B : if $\ell_u(A) \geq \ell_u(B)$ **select** picks A , otherwise it picks B . The correctness of **select**

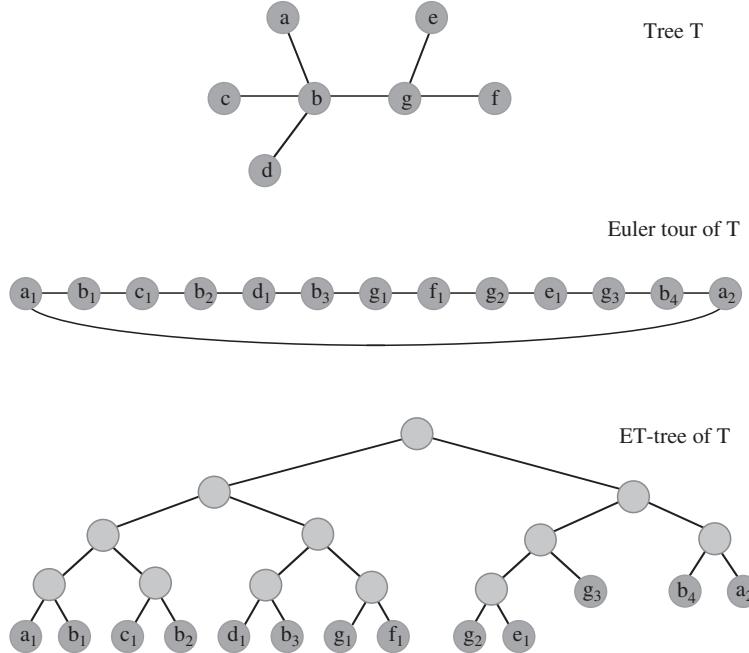

FIGURE 36.7 A tree, an Euler tour, and the corresponding ET tree with $d = 2$.

depends on the fact that if $\ell_u(A) \geq \ell_u(B)$, then A contains all the centers of C . Using Lemma 36.1 we can finally conclude that the center of a tree can be maintained dynamically in $O(\log n)$ time.

We refer the interested reader to [4,5] for other sample applications of top trees, such as maintaining the median or the diameter of dynamic trees. As we will recall in Section 36.5.2, top trees are fundamental in the design of the fastest algorithm for the fully dynamic minimum spanning tree problem [16].

36.5 ET Trees

ET trees, first introduced in [6], have been later used to design algorithms for a variety of problems on dynamic graphs, such as fully dynamic connectivity and bipartiteness (see, e.g., [7,17]). They provide an implicit representation of dynamic forests whose vertices are associated with weighted or unweighted keys. In addition to arbitrary edge insertions and deletions, updates allow it to add or remove the weighted key associated to a vertex. Supported queries are the following:

- **connected**(u, v): tells whether vertices u and v are in the same tree.
- **size**(v): returns the number of vertices in the tree that contains v .
- **minkey**(v): returns a key of minimum weight in the tree that contains v ; if keys are unweighted, an arbitrary key is returned.

The main concept for the definition of ET trees is that of Euler tour.

Definition 36.4

An *Euler tour* of a tree T is a maximal closed walk over the graph obtained by replacing each edge of T by two directed edges with opposite direction.

The Euler tour of a tree can be easily computed in linear time by rooting the tree at an arbitrary vertex and running a depth first visit [18]. Each time a vertex v is encountered on the walk, we call this an *occurrence* of v and we denote it by $o(v)$. A vertex of degree Δ has exactly Δ occurrences, except for the root which is visited $\Delta + 1$ times. Furthermore, the walk traverses each directed edge exactly once; hence, if T has n vertices, the Euler tour has length $2n - 2$. Given an n -vertex tree T , we encode it with a sequence of $2n - 1$ symbols given by an Euler tour. We refer to this encoding as $ET(T)$. For instance, the encoding of the tree given in Figure 36.7 derived from the Euler tour shown below the tree itself is $ET(T) = a\ b\ c\ b\ d\ b\ g\ f\ g\ e\ g\ b\ a$.

Definition 36.5

An *ET tree* is a dynamic balanced d -ary tree over some Euler tour around T . Namely, the leaves of the ET tree are the nodes of the Euler tour, in the same order in which they appear (see Figure 36.7).

An ET tree has $O(n)$ nodes due to the linear length of the Euler tour and to properties of d -ary trees. However, since each vertex of T may occur several times in the Euler tour, an arbitrary occurrence is marked as *representative* of the vertex.

36.5.1 Updates

We first analyze how to update the encoding $ET(T)$ when T is subject to dynamic edge operations. If an edge $e = (u, v)$ is deleted from T , denote by T_u and T_v the two trees obtained after the deletion, with $u \in T_u$ and $v \in T_v$. Let $o_1(u)$, $o_1(v)$, $o_2(u)$ and $o_2(v)$ be the occurrences of u and v encountered during the visit of (u, v) . Without loss of generality assume that $o_1(u) < o_1(v) < o_2(v) < o_2(u)$ so that $ET(T) = \alpha o_1(u) \beta o_1(v) \gamma o_2(v) \delta o_2(u) \epsilon$. Then $ET(T_v)$ is given by the interval $o_1(v) \gamma o_2(v)$, and $ET(T_u)$ can be obtained by splicing out the interval from $ET(T)$, that is, $ET(T_u) = \alpha o_1(u) \beta \delta o_2(u) \epsilon$.

If two trees T_1 and T_2 are joined in a new tree T because of a new edge $e = (u, v)$, with $u \in T_1$ and $v \in T_2$, we first reroot T_2 at v . Now, given $ET(T_1) = \alpha o_1(u) \beta$ and the computed encoding $ET(T_2) = o_1(v) \gamma o_2(v)$, we compute $ET(T) = \alpha o_1(u) o_1(v) \gamma o_2(v) o(u) \beta$, where $o(u)$ is a newly created occurrence of vertex u . To complete the description, we need to show how to change the root of a tree T from r to another vertex s . Let $ET(T) = o(r) \alpha o_1(s) \beta$, where $o_1(s)$ is any occurrence of s . Then, the new encoding will be $o_1(s) \beta \alpha o(s)$, where $o(s)$ is a newly created occurrence of s that is added at the end of the new sequence.

In summary, if trees in the forest are linked or cut, a constant number of the following operations is required: (i) splicing out an interval from the encoding, (ii) inserting an interval into the encoding, (iii) inserting or (iv) deleting a single occurrence from the encoding. If the encoding $ET(T)$ is stored in a balanced search tree of degree d , then one may perform each operation in time $O(d \log_d n)$ while maintaining the balance of the tree.

36.5.2 Applications

The query **connected** (u, v) can be easily supported in time $O(\log n/d)$ by finding the roots of the ET trees containing u and v and checking if they coincide. The same time is sufficient to check whether one element precedes another element in the ordering.

To support **size** and **minkey** queries, each node q of the ET tree maintains two additional values: the number $s(q)$ of representatives below it and the minimum weight key $k(q)$ attached to a representative below it. Such values can be easily maintained during updates and allow it to answer queries of the form **size** (v) and **minkey** (v) in $O(\log n/d)$ time for any vertex v of the forest: the root r of the ET tree containing v is found and values $s(r)$ and $k(r)$ are returned, respectively. We refer the interested reader to [7] for additional details of the method.

In Section 36.4 we will see how ET trees have been used [7,16] to design a polylogarithmic algorithm for fully dynamic connectivity. Here we limit to observe that trees in a spanning forest of the dynamic graph are maintained using the Euler tour data structure, and therefore updates and connectivity queries within the forest can be supported in logarithmic time. The use of randomization and of a logarithmic decomposition makes it possible to maintain also non-tree edges in polylogarithmic time upon changes in the graph.

36.6 Reachability Trees

In this section we consider a tree data structure that has been widely used to solve dynamic path problems on directed graphs.

The first appearance of this tool dates back to 1981, when Even and Shiloach showed how to maintain a breadth-first tree of an undirected graph under any sequence of edge deletions [8]; they used this as a kernel for decremental connectivity on undirected graphs. Later on, Henzinger and King [7] showed how to adapt this data structure to fully dynamic transitive closure in directed graphs. King [9] designed an extension of this tree data structure to weighted directed graphs for solving fully dynamic transitive closure (see Section 37.6.1) and all pairs shortest paths (see Section 37.7.1).

In the unweighted directed version, the goal is to maintain information about breadth-first search (BFS) on a directed graph G undergoing deletions of edges. In particular, in the context of dynamic path problems, we are interested in maintaining BFS trees of depth up to d , with $d \leq n$. Given a directed graph $G = (V, E)$ and a vertex $r \in V$, we would like to support any intermixed sequence of the following operations:

Delete (x, y) : delete edge (x, y) from G .

Level(u): return the level of vertex u in the BFS tree of depth d rooted at r (return $+\infty$ if u is not reachable from r within distance d).

In [9] it is shown how to maintain efficiently the BFS levels, supporting any **Level** operation in constant time and any sequence of **Delete** operations in $O(md)$ overall time:

Lemma 36.2

(King [9]) Maintaining BFS levels up to depth d from a given root requires $O(md)$ time in the worst case throughout any sequence of edge deletions in a directed graph with m initial edges.

Lemma 36.2 implies that maintaining BFS levels requires d times the time needed for constructing them. Since $d \leq n$, we obtain a total bound of $O(mn)$ if there are no limits on the depth of the BFS levels.

As it was shown in [7,9], it is possible to extend the BFS data structure presented in this section to deal with weighted directed graphs. In this case, a shortest path tree is maintained in place of BFS levels: after each edge deletion or edge weight increase, the tree is reconnected by essentially mimicking Dijkstra's algorithm rather than BFS. Details can be found in [9].

36.7 Conclusions

In this chapter we have surveyed data structures for maintaining properties of dynamically changing trees, focusing our attention on linking and cutting trees [2], topology trees [3], top trees [4], ET trees [6,7], and reachability trees [8]. We have shown that these data structures typically support updates and many different kinds of queries in logarithmic (amortized or worst-case) time. Hence, problems such as tree membership, maintaining the center or diameter of a tree, finding the minimum cost on a given path can be solved in $O(\log n)$ time in a fully dynamic setting.

All the data structures for maintaining properties of dynamically changing trees are not only important and interesting on their own, but are often used as building blocks by many dynamic graph algorithms, as we will see in Chapter 37. Some of these data structures, such as the union find data structures and the linking and cutting trees of Sleator and Tarjan have myriads of applications in other problems, such as implementing property grammars, computational geometry problems, testing equivalence of finite state machines, computing the longest common subsequence of two sequences, performing unification in logic programming and theorem proving, finding minimum spanning trees, and maximum flow algorithms. Since all these problems are outside the scope of this survey, we have not mentioned these applications and have restricted our attention to the applications of these data structures to dynamic tree and graph algorithms only.

37.1 Introduction

In many applications of graph algorithms, including communication networks, VLSI design, graphics, and assembly planning, graphs are subject to discrete changes, such as insertions or deletions of vertices or edges. In the last two decades there has been a growing interest in such dynamically changing graphs, and a whole body of algorithmic techniques and data structures for dynamic graphs has been discovered. This chapter is intended as an overview of this field.

An *update on a graph* is an operation that inserts or deletes edges or vertices of the graph or changes attributes associated with edges or vertices, such as cost or color. Throughout this chapter by *dynamic graph* we denote a graph that is subject to a sequence of updates. In a typical dynamic graph problem one would like to answer queries on dynamic graphs, such as, for instance, whether the graph is connected or which is the shortest path between any two vertices. The goal of a dynamic graph algorithm is to update efficiently the solution of a problem after dynamic changes, rather than having to recompute it from scratch each time. Given their powerful versatility, it is not surprising that dynamic algorithms and dynamic data structures are often more difficult to design and to analyze than their static counterparts.

We can classify dynamic graph problems according to the types of updates allowed. In particular, a dynamic graph problem is said to be *fully dynamic* if the update operations include unrestricted insertions and deletions of edges or vertices. A dynamic graph problem is said to be *partially dynamic* if only one type of update, either insertions or deletions, is allowed. More specifically, a dynamic graph problem is said to be *incremental* if only insertions are allowed, while it is said to be *decremental* if only deletions are allowed.

In the first part of this chapter we will present the main algorithmic techniques used to solve dynamic problems on both *undirected* and *directed* graphs. In the second part of the chapter we will deal with dynamic problems on graphs, and we will investigate as paradigmatic problems the dynamic maintenance of minimum spanning trees, connectivity, transitive closure and shortest paths. Interestingly enough, dynamic problems on directed graphs seem much harder to solve than their counterparts on undirected graphs, and require completely different techniques and tools.

[★] This chapter has been reprinted from first edition of this Handbook, without any content updates.

37.2 Techniques for Undirected Graphs

Many of the algorithms proposed in the literature use the same general techniques, and hence we begin by describing these techniques. In this section we focus on undirected graphs, while techniques for directed graphs will be discussed in Section 37.3. Typically, most of these techniques use some sort of graph decomposition, and partition either the vertices or the edges of the graph to be maintained. Moreover, data structures that maintain properties of dynamically changing trees, such as the ones described in Chapter 36 (linking and cutting trees, topology trees, and Euler tour trees), are often used as building blocks by many dynamic graph algorithms.

37.2.1 Clustering

The clustering technique has been introduced by Frederickson [1] and is based upon partitioning the graph into a suitable collection of connected subgraphs, called *clusters*, such that each update involves only a small number of such clusters. Typically, the decomposition defined by the clusters is applied recursively and the information about the subgraphs is combined with the topology trees described in Section 36.3. A refinement of the clustering technique appears in the idea of *ambivalent data structures* [2], in which edges can belong to multiple groups, only one of which is actually selected depending on the topology of the given spanning tree.

As an example, we briefly describe the application of clustering to the problem of maintaining a minimum spanning forest [1]. Let $G = (V, E)$ be a graph with a designated spanning tree S . Clustering is used for partitioning the vertex set V into subtrees connected in S , so that each subtree is only adjacent to a few other subtrees. A topology tree, as described in Section 36.3, is then used for representing a recursive partition of the tree S . Finally, a generalization of topology trees, called *2-dimensional topology trees*, are formed from pairs of nodes in the topology tree and allow it to maintain information about the edges in $E \setminus S$ [1].

Fully dynamic algorithms based only on a single level of clustering obtain typically time bounds of the order of $O(m^{2/3})$ (see for instance [3,4]). When the partition can be applied recursively, better $O(m^{1/2})$ time bounds can be achieved by using 2-dimensional topology trees (see, for instance, [1,2]).

Theorem 37.1: (Frederickson [1])

The minimum spanning forest of an undirected graph can be maintained in time $O(\sqrt{m})$ per update, where m is the current number of edges in the graph.

We refer the interested reader to [1,2] for details about Frederickson's algorithm. With the same technique, an $O(\sqrt{m})$ time bound can be obtained also for fully dynamic connectivity and 2-edge connectivity [1,2].

The type of clustering used can very problem-dependent, however, and makes this technique difficult to be used as a black box.

37.2.2 Sparsification

Sparsification is a general technique due to Eppstein *et al.* [5] that can be used as a black box (without having to know the internal details) in order to design and dynamize graph algorithms. It is a divide-and-conquer technique that allows it to reduce the dependence on the number of edges in a graph, so that the time bounds for maintaining some property of the graph match the times for computing in sparse graphs. More precisely, when the technique is applicable, it speeds up a $T(n, m)$ time bound for a graph with n vertices and m edges to $T(n, O(n))$, that is, to the time needed if the graph were sparse. For instance, if $T(n, m) = O(\sqrt{m})$, we get a better bound of $O(\sqrt{n})$. The technique itself is quite simple. A key concept is the notion of certificate.

Definition 37.1

For any graph property P and graph G , a *certificate* for G is a graph G' such that G has property P if and only if G' has the property.

Let G be a graph with m edges and n vertices. We partition the edges of G into a collection of $O(m/n)$ sparse subgraphs, that is, subgraphs with n vertices and $O(n)$ edges. The information relevant for each subgraph can be summarized in a sparse certificate. Certificates are then merged in pairs, producing larger subgraphs which are made sparse by again computing their certificate. The result is a balanced binary tree in which each node is represented by a sparse certificate. Each update involves $O(\log(m/n))$ ^{*} graphs with $O(n)$ edges each, instead of one graph with m edges.

^{*} Throughout this chapter, we assume that $\log x$ stands for $\max\{1, \log_2 x\}$, so $\log(m/n)$ is never smaller than 1 even if $m < 2n$.

There exist two variants of sparsification. The first variant is used in situations where no previous fully dynamic algorithm is known. A static algorithm is used for recomputing a sparse certificate in each tree node affected by an edge update. If the certificates can be found in time $O(m + n)$, this variant gives time bounds of $O(n)$ per update.

In the second variant, certificates are maintained using a dynamic data structure. For this to work, a *stability* property of certificates is needed, to ensure that a small change in the input graph does not lead to a large change in the certificates. We refer the interested reader to [5] for a precise definition of stability. This variant transforms time bounds of the form $O(m^p)$ into $O(n^p)$.

Definition 37.2

A time bound $T(n)$ is *well-behaved* if, for some $c < 1$, $T(n/2) < cT(n)$. Well-behavedness eliminates strange situations in which a time bound fluctuates wildly with n . For instance, all polynomials are well-behaved.

Theorem 37.2: (Eppstein et al. [5])

Let P be a property for which we can find sparse certificates in time $f(n, m)$ for some well-behaved f , and such that we can construct a data structure for testing property P in time $g(n, m)$ which can answer queries in time $q(n, m)$. Then there is a fully dynamic data structure for testing whether a graph has property P , for which edge insertions and deletions can be performed in time $O(f(n, O(n)) + g(n, O(n)))$, and for which the query time is $q(n, O(n))$.

Theorem 37.3: (Eppstein et al. [5])

Let P be a property for which stable sparse certificates can be maintained in time $f(n, m)$ per update, where f is well-behaved, and for which there is a data structure for property P with update time $g(n, m)$ and query time $q(n, m)$. Then P can be maintained in time $O(f(n, O(n)) + g(n, O(n)))$ per update, with query time $q(n, O(n))$.

Basically, the first version of sparsification (Theorem 37.2) can be used to dynamize static algorithms, in which case we only need to *compute* efficiently *sparse* certificates, while the second version (Theorem 37.3) can be used to speed up existing fully dynamic algorithms, in which case we need to *Maintain* efficiently *stable sparse* certificates.

Sparsification applies to a wide variety of dynamic graph problems, including minimum spanning forests, edge and vertex connectivity. As an example, for the fully dynamic minimum spanning tree problem, it reduces the update time from $O(\sqrt{m})$ [1,2] to $O(\sqrt{n})$ [5].

Since sparsification works on top of a given algorithm, we need not to know the internal details of this algorithm. Consequently, it can be applied orthogonally to other data structuring techniques: in a large number of situations both clustering and sparsification have been combined to produce an efficient dynamic graph algorithm.

37.2.3 Randomization

Clustering and sparsification allow one to design efficient deterministic algorithms for fully dynamic problems. The last technique we present in this section is due to Henzinger and King [6], and allows one to achieve faster update times for some problems by exploiting the power of randomization.

We now sketch how the randomization technique works taking the fully dynamic connectivity problem as an example. Let $G = (V, E)$ be a graph to be maintained dynamically, and let F be a spanning forest of G . We call edges in F *tree edges*, and edges in $E \setminus F$ *non-tree edges*. The algorithm by Henzinger and King is based on the following ingredients.

37.2.3.1 Maintaining Spanning Forests

Trees are maintained using the Euler Tours data structure (ET trees) described in Section 36.5: this allows one to obtain logarithmic updates and queries within the forest.

37.2.3.2 Random Sampling

Another key idea is the following: when e is deleted from a tree T , use random sampling among the non-tree edges incident to T , in order to find quickly a replacement edge for e , if any.

37.2.3.3 Graph Decomposition

The last key idea is to combine randomization with a suitable graph decomposition. We maintain an edge decomposition of the current graph G using $O(\log n)$ edge disjoint subgraphs $G_i = (V, E_i)$. These subgraphs are hierarchically ordered. The lower

levels contain tightly-connected portions of G (i.e., dense edge cuts), while the higher levels contain loosely-connected portions of G (i.e., sparse cuts). For each level i , a spanning forest for the graph defined by all the edges in levels i or below is also maintained.

Note that the hard operation in this problem is the deletion of a tree edge: indeed, a spanning forest is easily maintained with the help of the linking and cutting trees described in Section 36.2 throughout edge insertions, and deleting a non-tree edge does not change the forest.

The goal is an update time of $O(\log^3 n)$: after an edge deletion, in the quest for a replacement edge, we can afford a number of sampled edges of $O(\log^2 n)$. However, if the candidate set of edge e is a small fraction of all non-tree edges which are adjacent to T , it is unlikely to find a replacement edge for e among this small sample. If we found no candidate among the sampled edges, we must check explicitly all the non-tree edges adjacent to T . After random sampling has failed to produce a replacement edge, we need to perform this check explicitly, otherwise we would not be guaranteed to provide correct answers to the queries. Since there might be a lot of edges which are adjacent to T , this explicit check could be an expensive operation, so it should be made a low probability event for the randomized algorithm. This can produce pathological updates, however, since deleting all edges in a relatively small candidate set, reinserting them, deleting them again, and so on will almost surely produce many of those unfortunate events.

The graph decomposition is used to prevent the undesirable behavior described above. If a spanning forest edge e is deleted from a tree at some level i , random sampling is used to quickly find a replacement for e at that level. If random sampling succeeds, the tree is reconnected at level i . If random sampling fails, the edges that can replace e in level i form with high probability a sparse cut. These edges are moved to level $i + 1$ and the same procedure is applied recursively on level $i + 1$.

Theorem 37.4: (Henzinger and King [6])

Let G be a graph with m_0 edges and n vertices subject to edge deletions only. A spanning forest of G can be maintained in $O(\log^3 n)$ expected amortized time per deletion, if there are at least $\Omega(m_0)$ deletions. The time per query is $O(\log n)$.

37.3 Techniques for Directed Graphs

In this section we discuss the main techniques used to solve dynamic path problems on directed graphs. We first address combinatorial and algebraic properties, and then we consider some efficient data structures, which are used as building blocks in designing dynamic algorithms for transitive closure and shortest paths. Similarly to the case of undirected graphs seen in Section 37.2, data structures that maintain properties of dynamically changing trees, such as the ones described in Chapter 36 (reachability trees), are often used as building blocks by many dynamic graph algorithms.

37.3.1 Kleene Closures

Path problems such as transitive closure and shortest paths are tightly related to matrix sum and matrix multiplication over a closed semiring (see [7] for more details). In particular, the transitive closure of a directed graph can be obtained from the adjacency matrix of the graph via operations on the semiring of Boolean matrices, that we denote by $\{+, \cdot, 0, 1\}$. In this case, $+$ and \cdot denote the usual sum and multiplication over Boolean matrices.

Lemma 37.1

Let $G = (V, E)$ be a directed graph and let $TC(G)$ be the (reflexive) transitive closure of G . If X is the Boolean adjacency matrix of G , then the Boolean adjacency matrix of $TC(G)$ is the Kleene closure of X on the $\{+, \cdot, 0, 1\}$ Boolean semiring:

$$X^* = \sum_{i=0}^{n-1} X^i.$$

Similarly, shortest path distances in a directed graph with real-valued edge weights can be obtained from the weight matrix of the graph via operations on the semiring of real-valued matrices, that we denote by $\{\oplus, \odot, \mathcal{R}\}$, or more simply by $\{\min, +\}$. Here, \mathcal{R} is the set of real values and \oplus and \odot are defined as follows. Given two real-valued matrices A and B , $C = A \odot B$ is the matrix product such that $C[x, y] = \min_{1 \leq z \leq n} \{A[x, z] + B[z, y]\}$ and $D = A \oplus B$ is the matrix sum such that $D[x, y] = \min\{A[x, y], B[x, y]\}$. We also denote by AB the product $A \odot B$ and by $AB[x, y]$ entry (x, y) of matrix AB .

Lemma 37.2

Let $G = (V, E)$ be a weighted directed graph with no negative-length cycles. If X is a weight matrix such that $X[x, y]$ is the weight of edge (x, y) in G , then the distance matrix of G is the Kleene closure of X on the $\{\oplus, \odot, \mathcal{R}\}$ semiring:

$$X^* = \bigoplus_{i=0}^{n-1} X^i.$$

We now briefly recall two well-known methods for computing the Kleene closure X^* of X . In the following, we assume that X is an $n \times n$ matrix.

37.3.1.1 Logarithmic Decomposition

A simple method to compute X^* , based on repeated squaring, requires $O(n^\mu \cdot \log n)$ worst-case time, where $O(n^\mu)$ is the time required for computing the product of two matrices over a closed semiring. This method performs $\log_2 n$ sums and products of the form $X_{i+1} = X_i + X_i^2$, where $X = X_0$ and $X^* = X_{\log_2 n}$.

37.3.1.2 Recursive Decomposition

Another method, due to Munro [8], is based on a Divide and Conquer strategy and computes X^* in $O(n^\mu)$ worst-case time. Munro observed that, if we partition X in four submatrices A, B, D, C of size $n/2 \times n/2$ (considered in clockwise order), and X^* similarly in four submatrices E, F, H, G of size $n/2 \times n/2$, then X^* is defined recursively according to the following equations:

$$\boxed{E = (A + BD^*C)^* \quad F = EBD^* \quad G = D^*CE \quad H = D^* + D^*CEBD^*}$$

Surprisingly, using this decomposition the cost of computing X^* starting from X is asymptotically the same as the cost of multiplying two matrices over a closed semiring.

37.3.2 Long Paths

In this section we recall an intuitive combinatorial property of long paths in a graph. Namely, if we pick a subset S of vertices at random from a graph G , then a sufficiently long path will intersect S with high probability. This can be very useful in finding a long path by using short searches.

To the best of our knowledge, the long paths property was first given in [9], and later on it has been used many times in designing efficient algorithms for transitive closure and shortest paths (see e.g., [10–13]). The following theorem is from [12].

Theorem 37.5: (Ullman and Yannakakis [12])

Let $S \subseteq V$ be a set of vertices chosen uniformly at random. Then the probability that a given simple path has a sequence of more than $(cn \log n)/|S|$ vertices, none of which are from S , for any $c > 0$, is, for sufficiently large n , bounded by $2^{-\alpha c}$ for some positive α .

Zwick [13] showed it is possible to choose set S deterministically by a reduction to a hitting set problem [14,15]. King used a similar idea for maintaining fully dynamic shortest paths [11].

37.3.3 Locality

Recently, Demetrescu and Italiano [16] proposed a new approach to dynamic path problems based on maintaining classes of paths characterized by local properties, that is, properties that hold for all proper subpaths, even if they may not hold for the entire paths. They showed that this approach can play a crucial role in the dynamic maintenance of shortest paths. For instance, they considered a class of paths defined as follows:

Definition 37.3

A path π in a graph is *locally shortest* if and only if every proper subpath of π is a shortest path.

This definition is inspired by the optimal-substructure property of shortest paths: all subpaths of a shortest path are shortest. However, a locally shortest path may not be shortest.

The fact that locally shortest paths include shortest paths as a special case makes them an useful tool for computing and maintaining distances in a graph. Indeed, paths defined locally have interesting combinatorial properties in dynamically changing

graphs. For example, it is not difficult to prove that the number of locally shortest paths that may change due to an edge weight update is $O(n^2)$ if updates are partially dynamic, that is, increase-only or decrease-only:

Theorem 37.6

Let G be a graph subject to a sequence of increase-only or decrease-only edge weight updates. Then the amortized number of paths that start or stop being locally shortest at each update is $O(n^2)$.

Unfortunately, Theorem 37.6 does not hold if updates are fully dynamic, that is, increases and decreases of edge weights are intermixed. To cope with pathological sequences, a possible solution is to retain information about the history of a dynamic graph, considering the following class of paths:

Definition 37.4

A *historical shortest path* (in short, *historical path*) is a path that has been shortest at least once since it was last updated.

Here, we assume that a path is updated when the weight of one of its edges is changed. Applying the locality technique to historical paths, we derive locally historical paths:

Definition 37.5

A path π in a graph is *locally historical* if and only if every proper subpath of π is historical.

Like locally shortest paths, also locally historical paths include shortest paths, and this makes them another useful tool for maintaining distances in a graph:

Lemma 37.3

If we denote by SP , LSP , and LHP respectively the sets of shortest paths, locally shortest paths, and locally historical paths in a graph, then at any time the following inclusions hold: $SP \subseteq LSP \subseteq LHP$.

Differently from locally shortest paths, locally historical paths exhibit interesting combinatorial properties in graphs subject to fully dynamic updates. In particular, it is possible to prove that the number of paths that become locally historical in a graph at each edge weight update depends on the number of historical paths in the graph.

Theorem 37.7: (Demetrescu and Italiano [16])

Let G be a graph subject to a sequence of update operations. If at any time throughout the sequence of updates there are at most $O(h)$ historical paths in the graph, then the amortized number of paths that become locally historical at each update is $O(h)$.

To keep changes in locally historical paths small, it is then desirable to have as few historical paths as possible. Indeed, it is possible to transform every update sequence into a slightly longer equivalent sequence that generates only a few historical paths. In particular, there exists a simple *smoothing* strategy that, given any update sequence Σ of length k , produces an operationally equivalent sequence $F(\Sigma)$ of length $O(k \log k)$ that yields only $O(\log k)$ historical shortest paths between each pair of vertices in the graph. We refer the interested reader to [16] for a detailed description of this smoothing strategy. According to Theorem 37.7, this technique implies that only $O(n^2 \log k)$ locally historical paths change at each edge weight update in the smoothed sequence $F(\Sigma)$.

As elaborated in [16], locally historical paths can be maintained very efficiently. Since by Lemma 37.3 locally historical paths include shortest paths, this yields the fastest known algorithm for fully dynamic all pairs shortest paths (see Section 37.7.2).

37.3.4 Matrices

Another useful data structure for keeping information about paths in dynamic directed graphs is based on matrices subject to dynamic changes. As we have seen in Section 37.3.1, Kleene closures can be constructed by evaluating polynomials over matrices. It is therefore natural to consider data structures for maintaining polynomials of matrices subject to updates of entries, like the one introduced in [17].

In the case of Boolean matrices, the problem can be stated as follows. Let P be a polynomial over $n \times n$ Boolean matrices with constant degree, constant number of terms, and variables $X_1 \dots X_k$. We wish to maintain a data structure for P subject to any intermixed sequence of update and query operations of the following kind:

`SetRow($i, \Delta X, X_b$)`: sets to one the entries in the i th row of variable X_b of polynomial P corresponding to one-valued entries in the i th row of matrix ΔX .

`SetCol($i, \Delta X, X_b$)`: sets to one the entries in the i th column of variable X_b of polynomial P corresponding to one-valued entries in the i th column of matrix ΔX .

`Reset($\Delta X, X_b$)`: resets to zero the entries of variable X_b of polynomial P corresponding to one-valued entries in matrix ΔX .

`Lookup()`: returns the maintained value of P .

We add to the previous four operations a further update operation especially designed for maintaining path problems:

`LazySet($\Delta X, X_b$)`: sets to 1 the entries of variable X_b of P corresponding to one-valued entries in matrix ΔX . However, the maintained value of P might not be immediately affected by this operation.

Let C_P be the correct value of P that we would have by recomputing it from scratch after each update, and let M_P be the actual value that we maintain. If no `LazySet` operation is ever performed, then always $M_P = C_P$. Otherwise, M_P is not necessarily equal to C_P , and we guarantee the following weaker property on M_P : if $C_P[u, v]$ flips from 0 to 1 due to a `SetRow`/`SetCol` operation on a variable X_b , then $M_P[u, v]$ flips from 0 to 1 as well. This means that `SetRow` and `SetCol` always correctly reveal new 1's in the maintained value of P , possibly taking into account the 1's inserted through previous `LazySet` operations. This property is crucial for dynamic path problems, since the appearance of new paths in a graph after an edge insertion, which corresponds to setting a bit to one in its adjacency matrix, is always correctly recorded in the data structure.

Lemma 37.4: (Demetrescu and Italiano [17])

Let P be a polynomial with constant degree of matrices over the Boolean semiring. Any `SetRow`, `SetCol`, `LazySet`, and `Reset` operation on a polynomial P can be supported in $O(n^2)$ amortized time. `Lookup` queries are answered in optimal time.

Similar data structures can be given for settings different from the semiring of Boolean matrices. In particular, in [10] the problem of maintaining polynomials of matrices over the $\{\min, +\}$ semiring is addressed.

The running time of operations for maintaining polynomials in this semiring is given below.

Theorem 37.8: (Demetrescu and Italiano [10])

Let P be a polynomial with constant degree of matrices over the $\{\min, +\}$ semiring. Any `SetRow`, `SetCol`, `LazySet`, and `Reset` operation on variables of P can be supported in $O(D \cdot n^2)$ amortized time, where D is the maximum number of different values assumed by entries of variables during the sequence of operations. `Lookup` queries are answered in optimal time.

37.4 Connectivity

In this section and in Section 37.5 we consider dynamic problems on undirected graphs, showing how to deploy some of the techniques and data structures presented in Section 37.2 to obtain efficient algorithms. These algorithms maintain efficiently some property of an undirected graph that is undergoing structural changes defined by insertion and deletion of edges, and/or updates of edge costs. To check the graph property throughout a sequence of these updates, the algorithms must be prepared to answer queries on the graph property efficiently. In particular, in this section we address the *fully dynamic connectivity* problem, where we are interested in algorithms that are capable of inserting edges, deleting edges, and answering a query on whether the graph is connected, or whether two vertices are in the same connected component. We recall that the goal of a dynamic algorithm is to minimize the amount of recomputation required after each update. All the dynamic algorithms that we describe are able to maintain dynamically the graph property at a cost (per update operation) which is significantly smaller than the cost of recomputing the graph property from scratch.

37.4.1 Updates in $O(\log^2 n)$ Time

In this section we give a high level description of the fastest deterministic algorithm for the fully dynamic connectivity problem in undirected graphs [18]: the algorithm, due to Holm, de Lichtenberg and Thorup, answers connectivity queries in $O(\log n / \log \log n)$ worst-case running time while supporting edge insertions and deletions in $O(\log^2 n)$ amortized time.

Similarly to the randomized algorithm in [6], the deterministic algorithm in [18] maintains a spanning forest F of the dynamically changing graph G . As above, we will refer to the edges in F as *tree edges*. Let e be a tree edge of forest F , and let T be the tree of F containing it. When e is deleted, the two trees T_1 and T_2 obtained from T after the deletion of e can be reconnected if and only if there is a non-tree edge in G with one endpoint in T_1 and the other endpoint in T_2 . We call such an edge a *replacement edge* for e . In other words, if there is a replacement edge for e , T is reconnected via this replacement edge; otherwise, the deletion of e creates a new connected component in G .

To accommodate systematic search for replacement edges, the algorithm associates to each edge e a level $\ell(e)$ and, based on edge levels, maintains a set of sub-forests of the spanning forest F : for each level i , forest F_i is the sub-forest induced by tree edges of level $\geq i$. If we denote by L denotes the maximum edge level, we have that:

$$F = F_0 \supseteq F_1 \supseteq F_2 \supseteq \cdots \supseteq F_L,$$

Initially, all edges have level 0; levels are then progressively increased, but never decreased. The changes of edge levels are accomplished so as to maintain the following invariants, which obviously hold at the beginning.

Invariant (1): F is a maximum spanning forest of G if edge levels are interpreted as weights.

Invariant (2): The number of nodes in each tree of F_i is at most $n/2^i$.

Invariant (1) should be interpreted as follows. Let (u, v) be a non-tree edge of level $\ell(u, v)$ and let $u \dots v$ be the unique path between u and v in F (such a path exists since F is a spanning forest of G). Let e be any edge in $u \dots v$ and let $\ell(e)$ be its level. Due to (1), $\ell(e) \geq \ell(u, v)$. Since this holds for each edge in the path, and by construction $F_{\ell(u, v)}$ contains all the tree edges of level $\geq \ell(u, v)$, the entire path is contained in $F_{\ell(u, v)}$, that is, u and v are connected in $F_{\ell(u, v)}$.

Invariant (2) implies that the maximum number of levels is $L \leq \lfloor \log_2 n \rfloor$.

Note that when a new edge is inserted, it is given level 0. Its level can be then increased at most $\lfloor \log_2 n \rfloor$ times as a consequence of edge deletions. When a tree edge $e = (v, w)$ of level $\ell(e)$ is deleted, the algorithm looks for a replacement edge at the highest possible level, if any. Due to invariant (1), such a replacement edge has level $\ell \leq \ell(e)$. Hence, a replacement subroutine $\text{Replace}((u, w), \ell(e))$ is called with parameters e and $\ell(e)$. We now sketch the operations performed by this subroutine.

$\text{Replace}((u, w), \ell)$ finds a replacement edge of the highest level $\leq \ell$, if any. If such a replacement does not exist in level ℓ , we have two cases: if $\ell > 0$, we recurse on level $\ell - 1$; otherwise, $\ell = 0$, and we can conclude that the deletion of (v, w) disconnects v and w in G .

During the search at level ℓ , suitably chosen tree and non-tree edges may be promoted at higher levels as follows. Let T_v and T_w be the trees of forest F_ℓ obtained after deleting (v, w) and let, w.l.o.g., T_v be smaller than T_w . Then T_v contains at most $n/2^{\ell+1}$ vertices, since $T_v \cup T_w \cup \{(v, w)\}$ was a tree at level ℓ and due to invariant (2). Thus, edges in T_v of level ℓ can be promoted at level $\ell + 1$ by maintaining the invariants. Non-tree edges incident to T_v are finally visited one by one: if an edge does connect T_v and T_w , a replacement edge has been found and the search stops, otherwise its level is increased by 1.

We maintain an ET-tree, as described in Section 36.5, for each tree of each forest. Consequently, all the basic operations needed to implement edge insertions and deletions can be supported in $O(\log n)$ time. In addition to inserting and deleting edges from a forest, ET-trees must also support operations such as finding the tree of a forest that contains a given vertex, computing the size of a tree, and, more importantly, finding tree edges of level ℓ in T_v and non-tree edges of level ℓ incident to T_v . This can be done by augmenting the ET-trees with a constant amount of information per node: we refer the interested reader to [18] for details.

Using an amortization argument based on level changes, the claimed $O(\log^2 n)$ bound on the update time can be finally proved. Namely, inserting an edge costs $O(\log n)$, as well as increasing its level. Since this can happen $O(\log n)$ times, the total amortized insertion cost, inclusive of level increases, is $O(\log^2 n)$. With respect to edge deletions, cutting and linking $O(\log n)$ forest has a total cost $O(\log^2 n)$; moreover, there are $O(\log n)$ recursive calls to Replace , each of cost $O(\log n)$ plus the cost amortized over level increases. The ET-trees over $F_0 = F$ allows it to answer connectivity queries in $O(\log n)$ worst-case time. As shown in [18], this can be reduced to $O(\log n / \log \log n)$ by using a $\Theta(\log n)$ -ary version of ET-trees.

Theorem 37.9: (Holm et al. [18])

A dynamic graph G with n vertices can be maintained upon insertions and deletions of edges using $O(\log^2 n)$ amortized time per update and answering connectivity queries in $O(\log n / \log \log n)$ worst-case running time.

37.5 Minimum Spanning Tree

One of the most studied dynamic problem on undirected graphs is the *fully dynamic minimum spanning tree* problem, which consists of maintaining a minimum spanning forest of a graph during insertions of edges, deletions of edges, and edge cost

changes. In this section, we show that a few simple changes to the connectivity algorithm presented in Section 37.4 are sufficient to maintain a minimum spanning forest of a weighted undirected graph upon deletions of edges [18]. A general reduction from [19] can then be applied to make the deletions-only algorithm fully dynamic.

37.5.1 Deletions in $O(\log^2 n)$ Time

In addition to starting from a *minimum* spanning forest, the only change concerns function `Replace`, that should be implemented so as to consider candidate replacement edges of level ℓ in order of increasing weight, and not in arbitrary order. To do so, the ET-trees described in Section 36.5 can be augmented so that each node maintains the minimum weight of a non-tree edge incident to the Euler tour segment below it. All the operations can still be supported in $O(\log n)$ time, yielding the same time bounds as for connectivity.

We now discuss the correctness of the algorithm. In particular, function `Replace` returns a replacement edge of minimum weight on the highest possible level: it is not immediate that such a replacement edge has the minimum weight among all levels. This can be proved by first showing that the following invariant, proved in [18], is maintained by the algorithm:

Invariant (3): Every cycle \mathcal{C} has a non-tree edge of maximum weight and minimum level among all the edges in \mathcal{C} .

Invariant (3) can be used to prove that, among all the replacement edges, the lightest edge is on the maximum level. Let e_1 and e_2 be two replacement edges with $w(e_1) < w(e_2)$, and let \mathcal{C}_i be the cycle induced by e_i in F , $i = 1, 2$. Since F is a minimum spanning forest, e_i has maximum weight among all the edges in \mathcal{C}_i . In particular, since by hypothesis $w(e_1) < w(e_2)$, e_2 is also the heaviest edge in cycle $\mathcal{C} = (\mathcal{C}_1 \cup \mathcal{C}_2) \setminus (\mathcal{C}_1 \cap \mathcal{C}_2)$. Thanks to Invariant (3), e_2 has minimum level in \mathcal{C} , proving that $\ell(e_2) \leq \ell(e_1)$. Thus, considering non-tree edges from higher to lower levels is correct.

Lemma 37.5: (Holm et al. [18])

There exists a deletions-only minimum spanning forest algorithm that can be initialized on a graph with n vertices and m edges and supports any sequence of edge deletions in $O(m \log^2 n)$ total time.

37.5.2 Updates in $O(\log^4 n)$ Time

The reduction used to obtain a fully dynamic algorithm, which involves the top tree data structure discussed in Section 36.4, is a slight generalization of the construction proposed by Henzinger and King [19], and works as follows.

Lemma 37.6: ([18,19])

Suppose we have a deletions-only minimum spanning tree algorithm that, for any k and l , can be initialized on a graph with k vertices and l edges and supports any sequence of $\Omega(l)$ deletions in total time $O(l \cdot t(k, l))$, where t is a non-decreasing function. Then there exists a fully-dynamic minimum spanning tree algorithm for a graph with n nodes starting with no edges, that, for m edges, supports updates in time

$$O\left(\log^3 n + \sum_{i=1}^{3+\log_2 m} \sum_{j=1}^i t(\min\{n, 2^j\}, 2^j)\right)$$

We refer the interested reader to references [18,19] for the description of the construction that proves Lemma 37.6. From Lemma 37.5 we get $t(k, l) = O(\log^2 k)$. Hence, combining Lemmas 37.5 and 37.6, we get the claimed result.

Theorem 37.10: (Holm et al. [18])

There exists a fully-dynamic minimum spanning forest algorithm that, for a graph with n vertices, starting with no edges, maintains a minimum spanning forest in $O(\log^4 n)$ amortized time per edge insertion or deletion.

37.6 Transitive Closure

In the rest of this chapter we survey the newest results for dynamic problems on directed graphs. In particular, we focus on two of the most fundamental problems: transitive closure and shortest paths. These problems play a crucial role in many applications, including network optimization and routing, traffic information systems, databases, compilers, garbage collection, interactive verification systems, industrial robotics, dataflow analysis, and document formatting. In this section we consider the best known

algorithms for fully dynamic transitive closure. Given a directed graph G with n vertices and m edges, the problem consists of supporting any intermixed sequence of operations of the following kind:

`Insert(u, v):` insert edge (u, v) in G ;

`Delete(u, v):` delete edge (u, v) from G ;

`Query(x, y):` answer a reachability query by returning “yes” if there is a path from vertex x to vertex y in G , and “no” otherwise;

A simple-minded solution to this problem consists of maintaining the graph under insertions and deletions, searching if y is reachable from x at any query operation. This yields $O(1)$ time per update (`Insert` and `Delete`), and $O(m)$ time per query, where m is the current number of edges in the maintained graph.

Another simple-minded solution would be to maintain the Kleene closure of the adjacency matrix of the graph, rebuilding it from scratch after each update operation. Using the recursive decomposition of Munro [8] discussed in Section 37.3.1 and fast matrix multiplication [20], this takes constant time per reachability query and $O(n^\omega)$ time per update, where $\omega < 2.38$ is the current best exponent for matrix multiplication.

Despite many years of research in this topic, no better solution to this problem was known until 1995, when Henzinger and King [6] proposed a randomized Monte Carlo algorithm with one-sided error supporting a query time of $O(n/\log n)$ and an amortized update time of $O(n\hat{m}^{0.58}\log^2 n)$, where \hat{m} is the average number of edges in the graph throughout the whole update sequence. Since \hat{m} can be as high as $O(n^2)$, their update time is $O(n^{2.16}\log^2 n)$. Khanna, Motwani and Wilson [21] proved that, when a lookahead of $\Theta(n^{0.18})$ in the updates is permitted, a deterministic update bound of $O(n^{2.18})$ can be achieved.

King and Sagert [22] showed how to support queries in $O(1)$ time and updates in $O(n^{2.26})$ time for general directed graphs and $O(n^2)$ time for directed acyclic graphs; their algorithm is randomized with one-sided error. The bounds of King and Sagert were further improved by King [11], who exhibited a deterministic algorithm on general digraphs with $O(1)$ query time and $O(n^2 \log n)$ amortized time per update operations, where updates are insertions of a set of edges incident to the same vertex and deletions of an arbitrary subset of edges. Using a different framework, in 2000 Demetrescu and Italiano [17] obtained a deterministic fully dynamic algorithm that achieves $O(n^2)$ amortized time per update for general directed graphs. We note that each update might change a portion of the transitive closure as large as $\Omega(n^2)$. Thus, if the transitive closure has to be maintained explicitly after each update so that queries can be answered with one lookup, $O(n^2)$ is the best update bound one could hope for.

If one is willing to pay more for queries, Demetrescu and Italiano [17] showed how to break the $O(n^2)$ barrier on the single-operation complexity of fully dynamic transitive closure: building on a previous path counting technique introduced by King and Sagert [22], they devised a randomized algorithm with one-sided error for directed acyclic graphs that achieves $O(n^{1.58})$ worst-case time per update and $O(n^{0.58})$ worst-case time per query. Other recent results for dynamic transitive closure appear in [23,24].

37.6.1 Updates in $O(n^2 \log n)$ Time

In this section we address the algorithm by King [11], who devised the first deterministic near-quadratic update algorithm for fully dynamic transitive closure. The algorithm is based on the reachability tree data structure considered in Section 36.6 and on the logarithmic decomposition discussed in Section 37.3.1.

It maintains explicitly the transitive closure of a graph G in $O(n^2 \log n)$ amortized time per update, and supports inserting and deleting several edges of the graph with just one operation. Insertion of a bunch of edges incident to a vertex and deletion of any subset of edges in the graph require asymptotically the same time of inserting/deleting just one edge.

The algorithm maintains $\log n + 1$ levels: level i , $0 \leq i \leq \log n$, maintains a graph G_i whose edges represent paths of length up to 2^i in the original graph G . Thus, $G_0 = G$ and $G_{\log n}$ is the transitive closure of G .

Each level graph G_i is built on top of the previous level graph G_{i-1} by keeping two trees of depth ≤ 2 rooted at each vertex v : an out-tree $OUT_i(v)$ maintaining vertices reachable from v by traversing at most two edges in G_{i-1} , and an in-tree $IN_i(v)$ maintaining vertices that reach v by traversing at most two edges in G_{i-1} . Trees $IN_i(v)$ can be constructed by considering the orientation of edges in G_{i-1} reversed. An edge (x, y) will be in G_i if and only if $x \in IN_i(v)$ and $y \in OUT_i(v)$ for some v . In/out trees are maintained with the deletions-only reachability tree data structure considered in Section 36.6.

To update the levels after an insertion of edges around a vertex v in G , the algorithm simply rebuilds $IN_i(v)$ and $OUT_i(v)$ for each i , $1 \leq i \leq \log n$, while other trees are not touched. This means that some trees might not be up to date after an insertion operation. Nevertheless, any path in G is represented in at least the in/out trees rooted at the latest updated vertex in the path, so the reachability information is correctly maintained. This idea is the key ingredient of King’s algorithm.

When an edge is deleted from G_i , it is also deleted from any data structures $IN_i(v)$ and $OUT_i(v)$ that contain it. The interested reader can find further details in [11].

37.6.2 Updates in $O(n^2)$ Time

In this section we address the algorithm by Demetrescu and Italiano [17]. The algorithm is based on the matrix data structure considered in Section 37.3.4 and on the recursive decomposition discussed in Section 37.3.1.

It maintains explicitly the transitive closure of a graph in $O(n^2)$ amortized time per update, supporting the same generalized update operations of King's algorithm, that is, insertion of a bunch of edges incident to a vertex and deletion of any subset of edges in the graph with just one operation. This is the best known update bound for fully dynamic transitive closure with constant query time.

The algorithm maintains the Kleene closure X^* of the $n \times n$ adjacency matrix X of the graph as the sum of two matrices X_1 and X_2 . Let V_1 be the subset of vertices of the graph corresponding to the first half of indices of X , and let V_2 contain the remaining vertices. Both matrices X_1 and X_2 are defined according to Munro's equations of Section 37.3.1, but in such a way that paths appearing due to an insertion of edges around a vertex in V_1 are correctly recorded in X_1 , while paths that appear due to an insertion of edges around a vertex in V_2 are correctly recorded in X_2 . Thus, neither X_1 nor X_2 encode complete information about X^* , but their sum does. In more detail, assuming that X is decomposed in sub-matrices A, B, C, D as explained in Section 37.3.1, and that X_1 , and X_2 are similarly decomposed in sub-matrices E_1, F_1, G_1, H_1 and E_2, F_2, G_2, H_2 , the algorithm maintains X_1 and X_2 with the following 8 polynomials using the data structure discussed in Section 37.3.4:

$$\begin{array}{ll|ll} Q = A + BP^2C & E_2 = E_1BH_2^2CE_1 \\ F_1 = E_1^2BP & F_2 = E_1BH_2^2 \\ G_1 = PCE_1^2 & G_2 = H_2^2CE_1 \\ H_1 = PCE_1^2BP & R = D + CE_1^2B \end{array}$$

where $P = D^*$, $E_1 = Q^*$, and $H_2 = R^*$ are Kleene closures maintained recursively as smaller instances of the problem of size $n/2 \times n/2$.

To support an insertion of edges around a vertex in V_1 , strict updates are performed on polynomials Q, F_1, G_1 , and H_1 using `SetRow` and `SetCol`, while E_2, F_2, G_2 , and R are updated with `LazySet`. Insertions around V_2 are performed symmetrically, while deletions are supported via `Reset` operations on each polynomial in the recursive decomposition. Finally, P, E_1 , and H_2 are updated recursively. The interested reader can find the low-level details of the method in [17].

37.7 All-Pairs Shortest Paths

In this section we survey the best known algorithms for fully dynamic all pairs shortest paths (in short APSP). Given a weighted directed graph G with n vertices and m edges, the problem consists of supporting any intermixed sequence of operations of the following kind:

`Update`(u, v, w): updates the weight of edge (u, v) in G to the new value w (if $w = +\infty$ this corresponds to edge deletion);
`Query`(x, y): returns the distance from vertex x to vertex y in G , or $+\infty$ if no path between them exists;

The dynamic maintenance of shortest paths has a remarkably long history, as the first papers date back to 35 years ago [25–27]. After that, many dynamic shortest paths algorithms have been proposed (see, e.g., [28–33]), but their running times in the worst case were comparable to recomputing APSP from scratch.

The first dynamic shortest path algorithms which are provably faster than recomputing APSP from scratch, only worked on graphs with small integer weights. In particular, Ausiello et al. [34] proposed a decrease-only shortest path algorithm for directed graphs having positive integer weights less than C : the amortized running time of their algorithm is $O(Cn \log n)$ per edge insertion. Henzinger et al. [35] designed a fully dynamic algorithm for APSP on planar graphs with integer weights, with a running time of $O(n^{4/3} \log(nC))$ per operation. Fakcharoemphol and Rao in [36] designed a fully dynamic algorithm for single-source shortest paths in planar directed graphs that supports both queries and edge weight updates in $O(n^{4/5} \log^{13/5} n)$ amortized time per edge operation.

The first big step on general graphs and integer weights was made by King [11], who presented a fully dynamic algorithm for maintaining all pairs shortest paths in directed graphs with positive integer weights less than C : the running time of her algorithm is $O(n^{2.5} \sqrt{C} \log n)$ per update.

Demetrescu and Italiano [10] gave the first algorithm for fully dynamic APSP on general directed graphs with real weights assuming that each edge weight can attain a limited number S of different *real* values throughout the sequence of updates. In particular, the algorithm supports each update in $O(n^{2.5} \sqrt{S \log^3 n})$ amortized time and each query in $O(1)$ worst-case time. The same authors discovered the first algorithm that solves the fully dynamic all pairs shortest paths problem in its generality [16]. The algorithm maintains explicitly information about shortest paths supporting any edge weight update in $O(n^2 \log^3 n)$ amortized

time per operation in directed graphs with non-negative real edge weights. Distance queries are answered with one lookup and actual shortest paths can be reconstructed in optimal time. We note that each update might change a portion of the distance matrix as large as $\Omega(n^2)$. Thus, if the distance matrix has to be maintained explicitly after each update so that queries can be answered with one lookup, $O(n^2)$ is the best update bound one could hope for. Other deletions-only algorithms for APSP, in the simpler case of unweighted graphs, are presented in [37].

37.7.1 Updates in $O(n^{2.5} \sqrt{C \log n})$ Time

In this section we consider the dynamic shortest paths algorithm by King [11]. The algorithm is based on the long paths property discussed in Section 37.3.2 and on the reachability tree data structure Section 36.6.

Similarly to the transitive closure algorithms described in Section 37.6 generalized update operations are supported within the same bounds, that is, insertion (or weight decrease) of a bunch of edges incident to a vertex, and deletion (or weight increase) of any subset of edges in the graph with just one operation.

The main idea of the algorithm is to maintain dynamically all pairs shortest paths up to a distance d , and to recompute longer shortest paths from scratch at each update by stitching together shortest paths of length $\leq d$. For the sake of simplicity, we only consider the case of unweighted graphs: an extension to deal with positive integer weights less than C is described in [11].

To maintain shortest paths up to distance d , similarly to the transitive closure algorithm by King described in Section 37.6, the algorithm keeps a pair of in/out shortest paths trees $IN(v)$ and $OUT(v)$ of depth $\leq d$ rooted at each vertex v . Trees $IN(v)$ and $OUT(v)$ are maintained with the decremental data structure mentioned in Chapter 36. It is easy to prove that, if the distance d_{xy} between any pair of vertices x and y is at most d , then d_{xy} is equal to the minimum of $d_{xv} + d_{vy}$ over all vertices v such that $x \in IN(v)$ and $y \in OUT(v)$. To support updates, insertions of edges around a vertex v are handled by rebuilding only $IN(v)$ and $OUT(v)$, while edge deletions are performed via operations on any trees that contain them. The amortized cost of such updates is $O(n^2 d)$ per operation.

To maintain shortest paths longer than d , the algorithm exploits the long paths property of Theorem 37.5: in particular, it hinges on the observation that, if H is a random subset of $\Theta((n \log n)/d)$ vertices in the graph, then the probability of finding more than d consecutive vertices in a path, none of which are from H , is very small. Thus, if we look at vertices in H as “hubs,” then any shortest path from x to y of length $\geq d$ can be obtained by stitching together shortest subpaths of length $\leq d$ that first go from x to a vertex in H , then jump between vertices in H , and eventually reach y from a vertex in H . This can be done by first computing shortest paths only between vertices in H using any cubic-time static all-pairs shortest paths algorithm, and then by extending them at both endpoints with shortest paths of length $\leq d$ to reach all other vertices. This stitching operation requires $O(n^2 |H|) = O((n^3 \log n)/d)$ time.

Choosing $d = \sqrt{n \log n}$ yields an $O(n^{2.5} \sqrt{\log n})$ amortized update time. As mentioned in Section 37.3.2, since H can be computed deterministically, the algorithm can be derandomized. The interested reader can find further details on the algorithm in [11].

37.7.2 Updates in $O(n^2 \log^3 n)$ Time

In this section we address the algorithm by Demetrescu and Italiano [16], who devised the first deterministic near-quadratic update algorithm for fully dynamic all-pairs shortest paths. This algorithm is also the first solution to the problem in its generality. The algorithm is based on the notions of historical paths and locally historical paths in a graph subject to a sequence of updates, as discussed in Section 37.3.3.

The main idea is to maintain dynamically the locally historical paths of the graph in a data structure. Since by Lemma 37.3 shortest paths are locally historical, this guarantees that information about shortest paths is maintained as well.

To support an edge weight update operation, the algorithm implements the smoothing strategy mentioned in Section 37.3.3 and works in two phases. It first removes from the data structure all maintained paths that contain the updated edge: this is correct since historical shortest paths, in view of their definition, are immediately invalidated as soon as they are touched by an update. This means that also locally historical paths that contain them are invalidated and have to be removed from the data structure. As a second phase, the algorithm runs an all-pairs modification of Dijkstra’s algorithm [38], where at each step a shortest path with minimum weight is extracted from a priority queue and it is combined with existing historical shortest paths to form new locally historical paths. At the end of this phase, paths that become locally historical after the update are correctly inserted in the data structure.

The update algorithm spends constant time for each of the $O(zn^2)$ new locally historical path (see Theorem 37.7). Since the smoothing strategy lets $z = O(\log n)$ and increases the length of the sequence of updates by an additional $O(\log n)$ factor, this yields $O(n^2 \log^3 n)$ amortized time per update. The interested reader can find further details about the algorithm in [16].

37.8 Conclusions

In this chapter we have surveyed the algorithmic techniques underlying the fastest known dynamic graph algorithms for several problems, both on undirected and on directed graphs. Most of the algorithms that we have presented achieve bounds that are close to the best possible. In particular, we have presented fully dynamic algorithms with polylogarithmic amortized time bounds for connectivity and minimum spanning trees [18] on undirected graphs. It remains an interesting open problem to show whether polylogarithmic update bounds can be achieved also in the worst case: we recall that for both problems the current best worst-case bound is $O(\sqrt{n})$ per update, and it is obtained with the sparsification technique [5] described in Section 37.2.

For directed graphs, we have shown how to achieve constant-time query bounds and nearly-quadratic update bounds for transitive closure and all pairs shortest paths. These bounds are close to optimal in the sense that one update can make as many as $\Omega(n^2)$ changes to the transitive closure and to the all pairs shortest paths matrices. If one is willing to pay more for queries, Demetrescu and Italiano [17] have shown how to break the $O(n^2)$ barrier on the single-operation complexity of fully dynamic transitive closure for directed acyclic graphs. This also yields the first efficient update algorithm that maintains reachability in acyclic directed graphs between two fixed vertices s and t , or from s to all other vertices. However, in the case of general graphs or shortest paths, no solution better than the static is known for these problems. In general, it remains an interesting open problem to show whether effective query/update tradeoffs can be achieved for general graphs and for shortest paths problems.

Finally, dynamic algorithms for other fundamental problems such as matching and flow problems deserve further investigation.

38.1 Introduction

Although computer memories, at all levels of the hierarchy, have grown dramatically over the past few years, increased problem sizes continues to outstrip this growth. Minimizing space is crucial not only in keeping data in the fastest memory possible, but also in moving it from one level to another, be it from main memory to cache or from a web site around the world. Standard data compression, say Huffman code or grammar based code, applied to a large text file reduces space dramatically, but basic operations on the text require that it be fully decoded.

In this chapter we focus on representations that are not only terse but also permit the basic operations one would expect on the underlying data type to be performed quickly. Jacobson [1] seems to have been the first to apply the term *succinct* to such structures; the goal is to use the information-theoretic minimum number of bits and to support the expected operations on the data type in optimal time. Our archetypical example (discussed in Section 38.4) is the representation of a binary tree. Suppose, we would like to support the operations of navigating through a binary tree moving to either child or the parent of the current node, asking the size of the subtree rooted at the current node or giving the unique “number” of the node so that data can be stored in that position of an array. At $\lg n$ bits per reference, this adds up to at least $5n \lg n$ bits. However, there are only $(2n+1)/2(n+1)$ binary trees, so the information-theoretic minimum space is fewer than $2n$ bits. Our archetypical data structure is a $2n + o(n)$ -bit representation that supports the operations noted above, and others, in constant time.

We consider a variety of abstract data types, or combinatorial objects, with the goal of producing such succinct data structures. Most, though not all, of the structures we consider are static. In most cases the construction of a succinct data structure from the standard representation is fairly straightforward in linear time.

Memory Model: We study the problems under the RAM model with word size $\Theta(\lg n)$, where n is the input size of the problem under consideration. This supports arithmetic (addition, subtraction, multiplication and division), indexing and bit-wise boolean operations (AND, OR, NOT, XOR etc.) on words, and reading/writing of words from/to the memory in constant time.

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

38.2 Bitvector

A bitvector provides a simple way to represent a set from any universe that is easily mapped onto $[m]$.^{*} Membership queries (checking whether a given element from the universe is present in the set) can be answered in constant time (in fact a single bit probe) using a bitvector. Furthermore, one can easily support updates (inserting and deleting elements) in constant time. The most interesting twist on the bitvector came with Jacobson [1] considering two more operations:

- $\text{rank}(i)$: return the number of 1s before the position i , and
- $\text{select}(i)$: return the position of the i th 1.

As we shall see, these operations are crucial to a number of more complex structures supporting a variety of data types. An immediate use is to support the queries:

- $\text{predecessor}(x)$: find the largest element $y \leq x$ in the set S ,
- $\text{successor}(x)$: find the smallest element $y \geq x$ in the set S .

Given a bitvector of length m , Jacobson [1] gave a structure that takes $o(m)$ bits of additional space and supports rank and select operations by making $O(\lg m)$ bit probes to the structure. On a RAM with word size $\Theta(\lg m)$ bits, the structure given by Munro [2] enhanced this structure and the algorithms to support the operations in $O(1)$ time, without increasing the space bound. We briefly describe the details of this structure (Figure 38.1).

The structure for computing rank, the rank directory, consists of the following:

- Conceptually break the bitvector into blocks of length $\lceil \lg^2 m \rceil$. Keep a table containing the number of 1s up to the last position in each block. This takes $O(m/\lg m)$ bits of space.
- Conceptually break each block into sub-blocks of length $\lceil (1/2) \lg m \rceil$. Keep a table containing the number of 1s within the block up to the last position in each sub-block. This takes $O(m \lg \lg m / \lg m)$ bits.
- Keep a precomputed table giving the number of 1s up to every possible position in every possible distinct sub-block. Since there $O(\sqrt{m})$ distinct possible blocks, and $O(\lg m)$ positions in each, this takes $O(\sqrt{m} \lg m \lg \lg m)$ bits.

Thus, the total space occupied by this auxiliary structure is $o(m)$ bits. The rank of an element is, then, simply the sum of three values, one from each table.

The structure for computing select uses three levels of directories and is more complex. The first one records the position of every $(\lg m \lg \lg m)$ th 1 bit in the bitvector. This takes $O(m/\lg \lg m)$ bits. Let r be the subrange between two values in the first directory, and consider the sub-directory for this range. If $r \geq (\lg m \lg \lg m)^2$ then explicitly store the positions of all ones, which requires $O(r/\lg \lg m)$ bits. Otherwise, subdivide the range and store the position (relative to the beginning of this range) of every $(\lg r \lg \lg m)$ th one bit in the second level directory. This takes $O(r/\lg \lg m)$ bits for each range of size r , and hence $O(m/\lg \lg m)$ bits over the entire bitvector. After one more level of similar range subdivision, the range size will reduce to at most $(\lg \lg m)^4$.

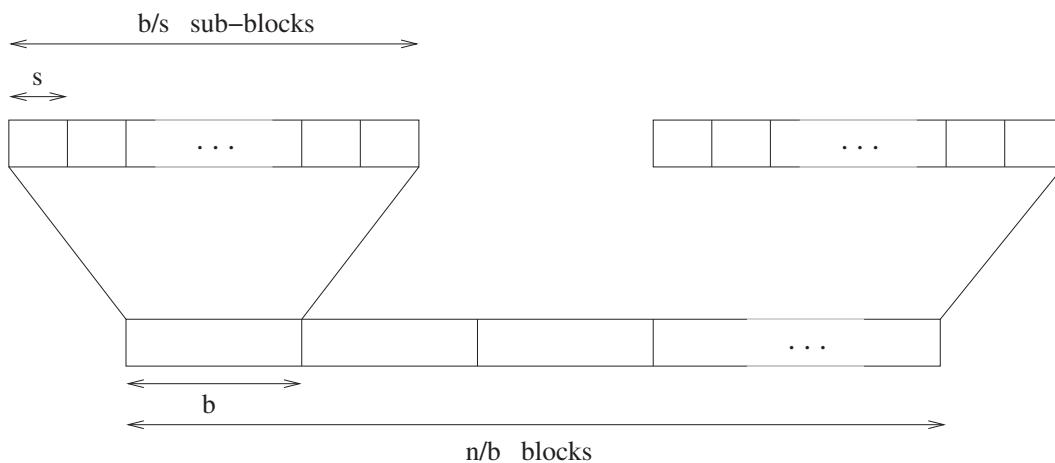

FIGURE 38.1 Two-level rank directory.

^{*} for positive integers m , $[m]$ denotes the set $\{0, 1, \dots, m - 1\}$

Computing select on these small ranges is performed using a precomputed table. The total space occupied by this auxiliary structure is $o(m)$ bits. The query algorithm is straightforward. See [3,4] for details.

This “indexable bitvector” is used as a substructure in several succinct data structures. To represent a bitvector of length m , it takes $m + o(m)$ bits of space. In general, if nothing is known about the bitvector then any representation needs at least m bits to distinguish between all possible bitvectors, and hence this is close to the optimal space. But if we also know the density (the number of ones) of the bitvector, then the space bound is no longer optimal, in general. The “fully indexable dictionary” described in Section 38.3.2 gives a solution that takes nearly optimal space.

Using the ideas involved in constructing rank and select directories, one can also support the following generalizations of these two operations, using $o(m)$ bits of extra space: Given a bitvector of length m , and a fixed binary pattern p of length up to $(1 - \epsilon) \lg m$, for some fixed constant $0 < \epsilon < 1$

- $\text{rank}_p(i)$: return the number of (possibly overlapping) occurrences of p before the position i , and
- $\text{select}_p(i)$: return the i th occurrence of the pattern p .

One can extend the ideas of rank and select directories to support indexing into a fixed or variable length encoded text (e.g., Huffman coding, prefix-free encoding etc.) in constant time, using negligible extra space. See [1,4] for some examples.

38.3 Succinct Dictionaries

The (static) dictionary problem is to store a subset S of size n so that membership queries can be answered efficiently. In our case, the universe is taken to be the set $[m]$. This problem has been widely studied and various solutions have been proposed to support membership queries in constant time.

As we have seen in the last section, a bitvector is a simple way of representing a set from a given universe. But this requires m bits of space. Since there are $\binom{m}{n}$ sets of size n from a universe of size m , one would require only $\mathcal{B} \equiv \lg \binom{m}{n}$ ($\approx n(\lg m - \lg n + \lg e)$), when $n = o(m)$) bits to store a canonical representation of any such set. Thus a bitvector is quite wasteful of space when the set is sparse. A sorted array is another simple representation, but it requires $\Theta(\lg n)$ time to answer queries. A *fusion tree* (see Chapter 40) also takes linear space and supports membership queries in $\Theta(\lg n / \lg \lg n)$ time. In this section, we consider representations of sets whose space complexity is close to the information theoretic minimum and support queries in constant time. (As all the structures outlined below support membership queries in worst case constant time, we do not mention the query complexity explicitly.)

Fredman, Komlós and Szemerédi [5] gave the first linear space structure for the static dictionary problem. This takes $n \lg m + O(n\sqrt{\lg n} + \lg \lg m)$ bits of space. The lower order term was later improved by Schmidt and Siegel [6] to $O(n + \lg \lg m)$. This structure uses a universe reduction function followed by a two-level hash function to hash the given subset one-to-one onto the set $[n]$, and stores the elements of subset in a hash table (in the order determined by the hash function). The hash table takes $n \lg m$ bits and a clever encoding of the hash function takes $O(n + \lg \lg m)$ bits of space. We refer to this as the FKS hashing scheme. Note that the space required for this structure is $\Theta(n \lg n)$ bits more than the optimal bound of \mathcal{B} bits.

Brodnik and Munro [7] gave a static dictionary representation that takes $\mathcal{B} + o(\mathcal{B})$ bits of space. It uses two different solutions depending on the relative values of n and m . When the set is relatively sparse (namely, when $n \leq m / (\lg m)^{\lg \lg m}$), it partitions the elements into buckets based on the first $\lg n - \lg \lg m$ bits of their bit representations, and store explicit pointers to refer to the representations of individual buckets. Each bucket is represented by storing all the elements that fall into it in a perfect hash table for that bucket. Otherwise, when the set is dense, it uses two levels of bucketing (at each level splitting the universe into a number of equal-range buckets, depending only on the universe size) after which the range of these buckets reduces to $\Theta(\lg n)$. These small buckets are stored (almost) optimally by storing pointers into a precomputed table that contains all possible small buckets. In either case the space occupancy can be shown to be $\mathcal{B} + o(\mathcal{B})$ bits.

Pagh [8] observed that each bucket of the hash table may be resolved with respect to the part of the universe hashing to that bucket. Thus, one can save space by compressing the hash table, storing only the *quotient* information, rather than the element itself. From the FKS hash function, one can obtain a quotienting function that takes $\lg(m/n) + O(1)$ bits for each element. Using this idea one can obtain a dictionary structure that takes $n \lg(m/n) + O(n + \lg \lg m)$ bits of space, which is only $\Theta(n)$ bits more than the information-theoretic lower bound (except for the $O(\lg \lg m)$ term). Pagh has also given a dictionary structure that takes only $\mathcal{B} + o(n) + O(\lg \lg m)$ bits of space.

38.3.1 Indexable Dictionary

One useful feature of the sorted array representation of a set is that, given an index i , the i th smallest element in the set can be retrieved in constant time. Furthermore, when we locate an element in the array, we immediately know its rank (the number of elements in the set which are less than the given element). On the other hand, hashing based schemes support membership in

constant time, but typically do not maintain the ordering information. In this section we look at a structure that combines the good features of both these approaches.

An *indexable dictionary* is a structure representing a set S of size n from the universe $[m]$ to support the following queries in constant time:

- $\text{rank}(x, S)$: Given $x \in [m]$, return -1 if $x \notin S$, and $|\{y \in S | y < x\}|$ otherwise, and
- $\text{select}(i, S)$: Given $i \in \{1, \dots, n\}$, return the i th smallest element in S .

Here the rank operation is only supported for the elements present in the set S . Ajtai [9] showed that the more general problem of supporting rank for every element in the universe has a query lower bound of $\Omega(\lg \lg n)$, even if the space used is polynomial in n . As a consequence, we emphasize the need for handling both S and its complement in the next section.

A dictionary that supports rank operation [10], as well as an indexable dictionary is very useful in representing trees [11] (see Section 38.4.3).

Elias [12] considered the indexable dictionary problem and gave a representation that takes $n \lg m - n \lg n + O(n)$ bits and supports the queries in $O(1)$ time, though he only considered the average case time complexity of the queries. Raman et al. [11] have given an indexable dictionary structure that takes $\mathcal{B} + o(n) + O(\lg \lg m)$ bits. The main idea here is, again, to partition the elements into buckets based on their most significant bits, as in the static dictionary structure of Brodnik and Munro [7]. The difference is that instead of storing explicit pointers to the bucket representations, they store the bucket sizes using a succinct representation that supports partial sum queries (see Section 38.8) in constant time. This not only saves a significant amount of space, but also provides the extra functionality needed for supporting rank and select.

Using similar ideas, one can also represent multisets and collections of sets using almost optimal space. See [11] for details.

38.3.2 Fully Indexable Dictionary

Given a set $S \subseteq [m]$, a *fully indexable dictionary* (FID) of S is a representation that supports rank and select operations on both S and its complement $\bar{S} = [m] \setminus S$ in constant time [11].

It is easy to see that the bitvector representation of a set, with auxiliary structures to support rank and select on both the bits as mentioned in Section 38.2, is an FID. But this requires $m + o(m)$ bits, where m is the size of the universe. Here we look at an FID representation that takes $\mathcal{B} + o(m)$ bits of space. Note that when the set is reasonably sparse (namely when $n = m/\omega(\lg m)$) $\mathcal{B} = o(m)$, and hence it improves the space complexity of the bitvector representation.

Let $S \subseteq [m]$ be a given set of size n . Divide $[m]$ into blocks of consecutive elements, with block size $u = \lfloor \frac{1}{2} \lg m \rfloor$. Let S_i be the subset of S that falls into the i th block. Each of the S_i 's is represented by storing an index into a table that contains the characteristic bitvectors of all possible subsets of a particular size from the universe $[u]$. As a consequence, the space occupied by these representations together with all the precomputed tables can be shown to be $\mathcal{B} + o(m)$ bits. To enable fast access to the representations of these subsets, we store the partial sums of the sizes of the subsets, and also the partial sums of the lengths of the representations of these subsets, which take $O(m \lg \lg m / \lg m)$ bits. This can be used to support rank in $O(1)$ time.

To support select, we first store the positions of every $(\lg^2 m)$ th element explicitly in an array, which takes $O(m / \lg m)$ bits. Call the part of the universe that lies between two successive elements in this array a *segment*. If the size of a segment is more than $\lg^4 m$, then we explicitly store all the $\lg^2 m$ elements of S that belong to this segment in sorted order. This takes $\lg^3 m$ bits for every such “sparse” segment, and hence at most $m / \lg m$ bits, over all the sparse segments. Dense segments are handled by constructing a complete tree with branching factor $\sqrt{\lg m}$, and so constant height, whose leaves are the blocks that constitute this segment, and storing some additional information to navigate this tree efficiently (see the *searchable partial sum* structure in Section 38.8).

To support rank and select on \bar{S} , first observe that an implicit representation of a set over a given universe is also an implicit representation of its complement. Thus, we need not store the implicit representations of \bar{S}_i again. Except for this, we repeat the above construction with S_i 's replaced by \bar{S}_i 's.

The overall space requirement of the structure is $\mathcal{B} + O(m \lg \lg m / \lg m)$ bits, and rank and select are supported on both S and \bar{S} in $O(1)$ time. See [11] for details.

38.3.3 Dynamic Dictionary

We have looked at several succinct structures for static dictionaries. We now briefly consider the dynamic dictionary problem where one can add and delete elements from the set while supporting the membership queries.

Model: The model of memory allocation is very important in dynamic data structures. One widely used model [11,13,14] is to assume the existence of a “system” memory manager that would allocate and free memory in variable-sized chunks. In this model, the space complexity of a structure is counted as the total size of all the blocks allocated for that structure, and hence this approach does not account for the space wastage due to *external fragmentation*.

Fundamentally, memory is most easily viewed as a large array. If we are to use the storage, we must manage it. Therefore a simple view is to count all the fragmentation we may cause and count the memory usage as the difference between the addresses of the first and last locations used by the structure. While more complex scenarios may be more realistic in certain cases, we take this simple address difference model as our focus. The methods we discuss are equivalent under either model up to constant factors.

A balanced tree can be used to support all the dynamic dictionary operations in $O(\lg n)$ time using $n \lg m + O(n \lg n)$ bits, where n is the current size of the set. Using the ideas of the FKS dictionary, Dietzfelbinger et al. [15] gave a dynamic dictionary structure that supports membership in $O(1)$ time and updates (insert/delete) in $O(1)$ expected amortized time. This structure takes $O(n \lg m)$ bits of space. There have been several improvements, lowering the space complexity close to the information theoretic-minimum, culminating in a structure that takes $\mathcal{B} + o(\mathcal{B})$ bits with the same query complexity as above. See [7,8,16–18] and the references therein.

All these structures also support associating satellite information with the elements, so that whenever an element is found to be in the set, we can also retrieve the satellite information associated with it in constant time.

38.4 Tree Representations

Trees are one of the most fundamental objects in computer science. We consider the problem of representing large trees succinctly. Storing a tree with a pointer per child as well as other structural information can account for the dominant storage cost. For example, standard representations of a binary tree on n nodes, using pointers, take $O(n \lg n)$ bits of space. Since there are only $\binom{2n+1}{n}/(2n+1)$ different binary trees on n nodes, less than $2n$ bits suffice to distinguish between them. We look at some binary tree representations that take $2n + o(n)$ bits and support the basic navigational operations in constant time.

38.4.1 Binary Trees

First, if the tree is a complete binary tree (i.e., a binary tree in which every level, except possibly the deepest, is completely filled, and the last level is filled from the left as far as required), then there is a unique tree of a given size and we require no additional space to store the tree structure. In fact, by numbering the nodes from 1 to n in the “heap order” [19] (left-to-right level-order traversal of the tree), one can support navigational operations on the tree by observing that the parent of a node numbered i is the node numbered $\lfloor i/2 \rfloor$, and the left and right children of node i are $2i$ and $2i+1$ respectively. But this property does not hold when the tree is not complete.

If the tree is not complete, one could extend it to a complete binary tree with the same height and store a bit vector indicating which nodes are present in the tree (in the heap order of the complete tree) to support the operations efficiently. But this takes space exponential in the number of nodes, in the worst case.

To save space, one can use the following compressed representation due to Jacobson [1]: First, mark all the nodes of the tree with 1 bits. Then add external nodes to the tree, and mark them with 0 bits. Construct a bitvector by reading off the bits that are marking the nodes in left-to-right level-order. (See Figure 38.2.) It is easy to see that the original tree can be reconstructed from this bitvector. For a binary tree with n nodes, this bitvector representation takes $2n+1$ bits. Moving between parent and child is just a slight twist on the method used in a heap. By storing the rank and select directories for this bitvector, one can support the navigational operations in constant time using the following equations:

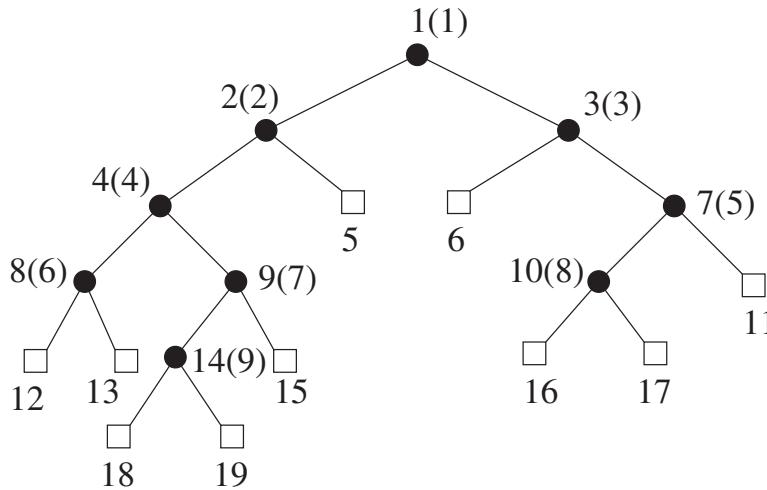

$$\text{parent}(i) = \text{select}(\lfloor i/2 \rfloor); \quad \text{leftchild}(i) = 2 \cdot \text{rank}(i); \quad \text{rightchild}(i) = 2 \cdot \text{rank}(i) + 1.$$

38.4.2 Ordinal Trees

Now, consider optimal representations of trees of higher degree, of which there are two different notions.

An *ordinal tree* is a rooted tree of arbitrary degree in which the children of each node are ordered. Ordinal trees on n nodes are in one to one correspondence with binary trees on n nodes. Hence about $2n$ bits are necessary to represent an arbitrary ordinal tree on n nodes. A *cardinal tree* of degree k is a rooted tree in which each node has k positions for an edge to a child. Hence, a binary tree is a cardinal tree of degree 2. There are $C_n^k \equiv \binom{kn+1}{n}/(kn+1)$ cardinal trees of degree k on n nodes [20]. Hence we need roughly $(\lg(k-1) + k \lg \frac{k}{(k-1)})n$ bits to represent an arbitrary such tree.

The basic operations we would like to support on tree representations are: given a node, finding its parent, i th child, degree and the size of the subtree rooted at that node (subtree size). For the cardinal trees we also need to support the additional operation of finding a child with a given label.

level-order bitmap: 1 1 1 1 0 0 1 1 1 1 0 0 0 1 0 0 0 0 0

FIGURE 38.2 Level-order bitmap representation of a binary tree.

We outline three different representations of an ordinal tree. All the three representations map the n nodes of the tree onto the integers $1, \dots, n$, and hence all are appropriate for applications in which data is to be associated with nodes or leaves.

Level-order unary degree sequence representation: A rooted ordered tree can be represented by storing its degree sequence in any of a number of standard orderings of the nodes. The ordinal tree encoding of Jacobson [1] represents a node of degree d as a string of d 1s followed by a 0. Thus the degree of a node is represented by a binary prefix code. These prefix codes are then written in a level-order traversal of the entire tree. Using auxiliary structures to support rank and select operations on this sequence, one can support finding the parent, the i th child and the degree of any node in constant time. Thus, it gives a representation that takes $2n + o(n)$ bits of space and supports the above three operations in constant time, for an ordered tree on n nodes (Figure 38.3).

Balanced parenthesis representation: The tree encoding of Munro and Raman [21] uses a balanced sequence of parentheses to represent an ordinal tree. This balanced representation is derived from the depth-first traversal of the tree, writing an open parenthesis on the way down and a close parenthesis on the way up. Thus, a tree on n nodes can be represented by a balanced parenthesis sequence of length $2n$. Extending the ideas of Jacobson, they showed how to support the following operations in $O(1)$ time, using negligible extra space ($o(n)$ bits):

- `findopen/findclose(i)`: find the position of the open/close parenthesis matching the given close/open parenthesis in position i .
- `excess(i)`: find the difference between the number of open and closing parentheses before the position i .
- `enclose(i)`: given a parenthesis pair whose open parenthesis is in position i , find the open parenthesis corresponding to its closest enclosing matching parenthesis pair.

The parent of a node can be found in constant time using the enclose operation. In the parenthesis representation, the nodes of a subtree are stored together, which enables us to support the operation of finding the size of the subtree rooted at a given node in constant time. The problem with this representation is that finding the i th child takes $\Theta(i)$ time.

Depth-first unary degree sequence representation: Jacobson's representation allows access to the i th child in constant time, whereas Munro and Raman's representation supports subtree size operation in constant time. To combine the virtues of these two representations, Benoit et al. [22] used a representation that writes the unary degree sequence of each node in the depth-first traversal order of the tree. The representation of each node contains essentially the same information as in Jacobson's level-order degree sequence, but written in a different order. Thus, it gives another $2n$ bit encoding of a tree on n nodes. Replacing the 0's and 1's by open and close parentheses respectively, and adding an extra open parenthesis at the beginning, creates a string of balanced parentheses. Using auxiliary structures to support rank and select operations on this bit string and also the operations on balanced parenthesis sequences defined above, one can support finding the parent, i th child, degree and subtree size of a given node in constant time.

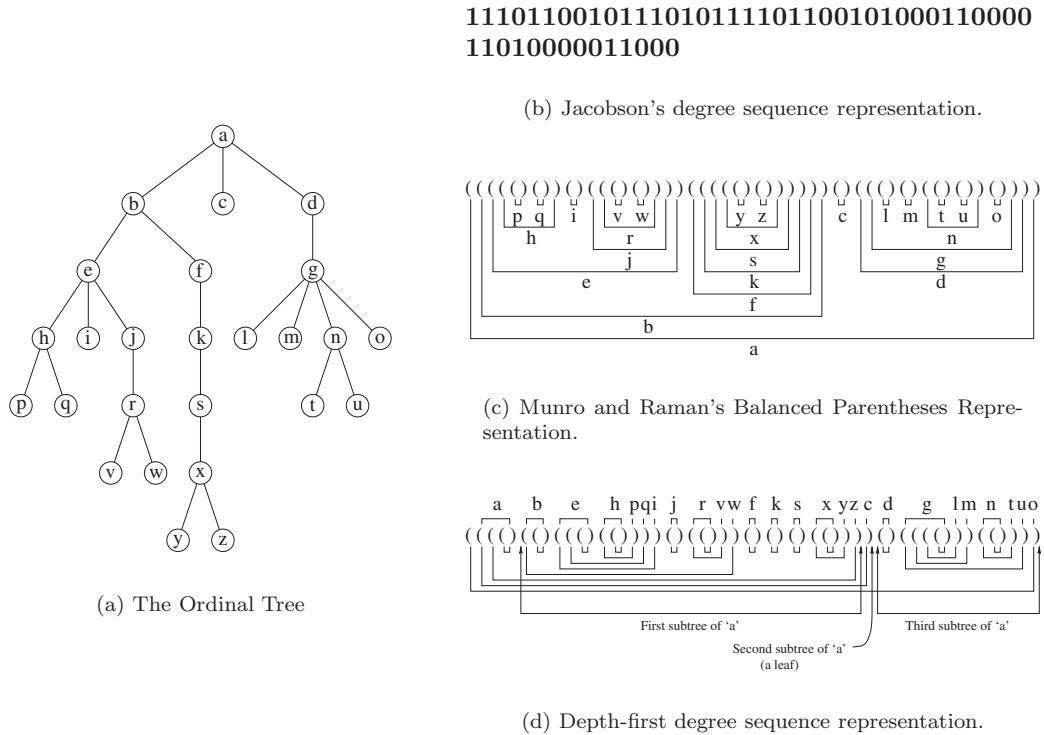

FIGURE 38.3 Three encodings of an ordinal tree. (a) The Ordinal Tree, (b) Jacobson’s degree sequence representation, (c) Munro and Raman’s Balanced Parentheses Representation, (c) Depth-first degree sequence representation.

Other operations: Sadakane [23] has shown that the parenthesis representation of an ordinal tree can be used to support least common ancestor queries in $O(1)$ time using a $o(n)$ -bit auxiliary structure. Munro and Rao [24] have shown that one can also support the level ancestor queries in $O(1)$ time, using an additional $o(n)$ bit auxiliary structure by storing the parenthesis representation. Geary et al. [25] obtained another structure that takes $2n + o(n)$ bits and supports level-ancestor queries, in addition to all the other navigational operations mentioned above in $O(1)$ time.

38.4.3 Cardinal Trees

A simple cardinal tree encoding can be obtained as follows: Encode each node of a k -ary tree by k bits, where the i th bit specifies whether child i is present. These can be written in any fixed ordering of the tree nodes, such as level order or depth-first order, to obtain the tree encoding. By storing the rank and select directories for this bitvector encoding, one can support parent, i th child and degree queries in constant time. This encoding has the major disadvantage of taking kn bits, far from the lower bound of roughly $(\lg k + \lg e)n$ bits, as there are $C_n^k \equiv \binom{kn+1}{n} / (kn+1)$ k -ary cardinal trees on n nodes.

Using some probabilistic assumptions, Darragh et al. [26] have implemented a structure that takes $\lg k + O(1)$ bits per node, though the implementation treats $\lg \lg n$ as “a constant” (indeed 5). This structure supports the navigational operations in constant expected time and also supports updates “efficiently” (compared with other linear space representations), and was also shown to perform well in practice.

To achieve a better space bound with good worst-case performance, one can use the ordinal tree encoding to store the underlying tree, and store some additional information about which children are present at each node. The ordinal information (using the depth-first unary degree sequence representation) can be used to support the parent, i th child, degree and subtree size queries in constant time.

Let $S_x = \{i_1, i_2, \dots, i_d\}$ be the child labels of a node x with degree d in the cardinal tree. To find the child labeled j of node x , it suffices to find $i = \text{rank}(j)$ in the set S_x , if $j \in S_x$. If $i = -1$ (i.e., $j \notin S_x$), then there is no child labeled j at node x , otherwise the i th child of x is the child labeled j of node x . The i th child can be found using the ordinal information. Storing each of these sets S_x using the indexable dictionary representation of Section 38.3.1, which takes $d \lg k + o(d) + O(\lg \lg k)$ bits for each S_x , requires $n \lg k + o(n) + O(n \lg \lg k)$ bits in the worst case. Using a representation that stores a collection of indexable dictionaries efficiently [11], one can reduce the space consumption to $n \lg k + o(n) + O(\lg \lg k)$ bits.

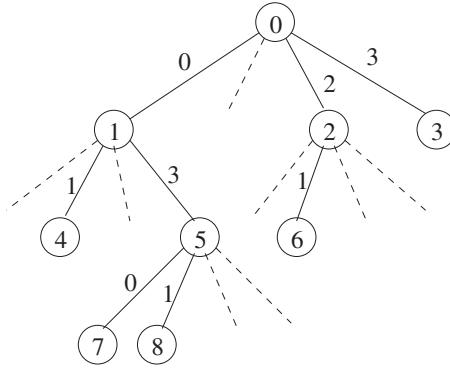

FIGURE 38.4 The tree is represented by storing an indexable dictionary of the set $\{(0, 0), (0, 2), (0, 3), (1, 1), (1, 3), (2, 1), (5, 0), (5, 1)\}$.

Thus, this structure uses $2n + o(n)$ bits to represent the underlying ordinal tree, $n \lg k + o(n + \lg k)$ bits to represent the labels of the children at each node, and supports all the navigational operations and the subtree size operation in $O(1)$ time.

Using the succinct indexable dictionary structure mentioned in Section 38.3, Raman et al. [11] obtained an optimal space cardinal tree representation. The main idea is to store the set of all pairs, (i, j) such that the i th node, in the level-order of the nodes, has a child labeled j , using an indexable dictionary representation. (See Figure 38.4 for an example.) Since this set is of size n from the universe $[nk]$, it requires $\lg \binom{nk}{n} + o(n + \lg k) = C_n^k + o(n + \lg k)$ bits to store an indexable dictionary for this set. One can easily map the navigational operations on the tree to the operations on this set, to support them in constant time. But this structure does not support the subtree size operation efficiently.

38.4.4 Dynamic Binary Trees

All the tree representations mentioned so far are static. Even to make a minor modification to the tree, such as adding a leaf, the entire structure has to be reconstructed (in the worst case). In this section we look at some representations that are more efficient in supporting updates to the tree.

Munro et al. [14] gave a binary tree representation that takes $2n + o(n)$ bits, and supports parent, left child, right child and subtree size operations in $O(1)$ time. Updating the tree (adding a leaf or adding a node along an edge) requires $O(\lg^c n)$ time, for some constant $c \geq 1$ which depends on the size of the data associated with the nodes. Extending some of the ideas involved in this, Raman and Rao [18] improved the update time to $O((\lg \lg n)^\epsilon)$, for any fixed $\epsilon > 0$, while maintaining the other time and space bounds (Figure 38.5).

We briefly outline the key issues involved in the construction of these structures. First, we divide the tree into blocks of size $\Theta(\lg^c n)$, for some $c \geq 2$, and each block in turn into sub-blocks of size $\epsilon \lg n$, for some fixed $\epsilon < 1$. The sub-blocks are stored using an implicit representation and are operated upon using precomputed tables. The block structure of the tree is stored using explicit pointers. Since there are only $\Theta(\lg^{c-1} n)$ sub-blocks in each block, we can store the sub-block structure within a block explicitly using $\Theta(\lg \lg n)$ sized pointers. Each block stores its parent block and the size, using a constant number of words. Thus,

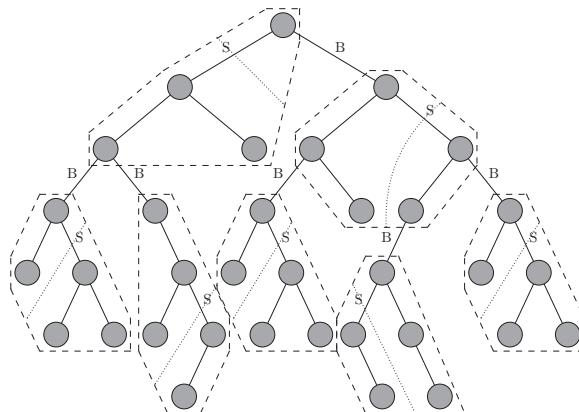

FIGURE 38.5 Dynamic binary tree representation. B denotes an inter-block pointer and S denotes an inter-subblock pointer.

the overall block structure of the tree is easily handled by conventional means (storing explicit pointers) and only takes $O(n/\lg n)$ bits. The blocks and sub-blocks tolerate some slack in their sizes and are moved to appropriate sized areas to avoid wasting space. Ultimately, the key issues boil down to the memory management.

To support subtree size, we maintain the subtree sizes of the roots of all blocks and sub-blocks. Since each update changes the subtree sizes of several nodes, it is not possible to update all the effected blocks and sub-blocks in constant time, in general. For this reason, we assume that the navigation through the tree begins at the root and may end at any point (or at the root, to achieve worst-case constant time for updates), and navigates the tree by moving from a node only to either its parent or one of its children. Hence, updates to a node higher in the tree regarding the insertions and deletions to descendants are made on return to that node.

38.5 Graph Representations

In this section, we briefly describe some space efficient representations of graphs. In particular, we consider representations that take close to the information theoretic minimum space and support degree and adjacency queries efficiently. A degree query asks for the degree of a given node in the graph, and an adjacency query asks whether two given vertices are adjacent or not in the graph. In addition, we would also like to support listing all the vertices adjacent to a given vertex.

Turán [27] gave a linear time constructible representation of an arbitrary planar graph that takes at most 12 bits per node. Though this gives a space efficient representation of planar graphs, it does not support the queries efficiently. Kannan et al. [28] have given an *implicit* (linear space) graph representation that supports adjacency queries using $O(\lg n)$ bit probes.

Jacobson [1] gave a representation that takes $O(n)$ bits of space to represent a planar graph on n nodes and supports degree and adjacency queries in constant time. It uses a simple mapping of one-page graphs to sequences of balanced parentheses, and the fact that a planar graph always has a 4-page embedding. By storing auxiliary structures to support some natural operations on these sequences (see Section 38.4.2), one can also support the navigational operations in optimal time.

Munro and Raman [21] improved the space to $8n + 2m + o(n)$ bits, for a planar graph on n vertices with m edges, still supporting the queries in constant time. In general, their representation takes $2kn + 2m + o(nk + m)$ bits to store a k page graph on n vertices and m edges and supports degree and adjacency queries in $O(k)$ time.

There have been several improvements [29–33], improving the space close to the information theoretic-lower bound, simultaneously expanding the class of graphs for which the scheme works. In particular, Lu [33] gave an optimal space (within lower-order terms) representation that can be constructed in linear time. This supports degree and adjacency queries in $O(1)$ time for constant-genus graphs.

The main idea is to partition the given graph G on n vertices into $o(n/\lg n)$ disjoint subgraphs of size $O(\lg^6 n)$ by removing a subgraph H of size $o(n/\lg n)$. This is done using a “planarization algorithm” for bounded genus graphs, and an algorithm to construct a “separator decomposition tree” of a planar graph. The representation of G is obtained by storing a rerepresentation of H , and recursing on each of the smaller subgraphs upto a constant number of levels, after which one can use a precomputed table to operate on the small subgraphs. See [33] for details.

38.6 Succinct Structures for Indexing

A *text index* is a data structure storing a *text* (a string or a set of strings) and supporting string matching queries: given a pattern P , find all the occurrences of P in the text. Two well-known and widely used index structures are the suffix trees and suffix arrays. In this section we briefly describe some succinct data structures for these two.

A *suffix tree* for a text is the *compressed digital trie* of all the suffixes of the text [34,35]. A suffix tree for a text of length n has n leaves and at most $n - 1$ internal nodes. The space bound is a consequence of skipping nodes with only one child, hence there are precisely $n - 1$ internal nodes if we use a binary trie. Each leaf points to the position in the text of the corresponding suffix it represents uniquely. The edges are labeled by substrings of the text, which are usually represented by storing a position in the text where the substring starts and its length. Thus, a standard representation of a suffix tree for a text of length n takes $O(n \lg n)$ bits. Searching for an occurrence of a pattern of length m using a suffix tree takes $O(m)$ time.

The *suffix array* of a text is an array storing pointers to the suffixes of the text in their lexicographic order. Thus, a suffix array for a text of length n takes $n \lceil \lg n \rceil$ bits. Note that the leaf labels of a suffix tree written from left to right form the suffix array, if the children of each node are arranged in lexicographic order of their edge labels. Searching for an occurrence of a pattern of length m using a suffix array takes $O(m + \lg n)$ time.

We now briefly sketch the ideas involved in representing a suffix tree (and hence also a suffix array) using $O(n)$ bits. We first convert the trie into binary by using a fixed length encoding of the characters of the alphabet. We then store the parenthesis representation of the underlying tree structure (see Section 38.4.2). The edge labels of a suffix tree can be omitted, as this can

be determined by finding the longest common prefix of the leftmost and rightmost leaves of the parent node (of the edge). The parenthesis representation of an ordinal tree can be augmented with $o(n)$ -bit additional structure to support finding the leftmost and rightmost leaves of a given node in constant time. Thus, one can use this tree representation to store the tree structure of a suffix tree, and store the leaf pointers (suffix array) explicitly. This gives a suffix tree representation that takes $n \lg n + O(n)$ bits of space and supports indexing queries in optimal time. See [4] for details.

The above structure uses $n \lceil \lg n \rceil$ bits to represent the pointers to the text or the suffix array. Grossi and Vitter [36] obtained a suffix array structure that takes $O(n)$ bits and supports finding the i th element in the suffix array (lookup queries) in $O(\lg^\epsilon n)$ time, for any fixed $\epsilon > 0$. Using this structure they also obtained a suffix tree representation that takes $O(n)$ bits of space and supports finding all the s occurrences of a given pattern of length m in $O(m + s \lg^\epsilon n)$ time. The structure given by Rao [37] generalizes the suffix array structure of Grossi and Vitter, which takes $O(nt(\lg n)^{1/(t+1)})$ bits and supports lookup in $O(t)$ time, for any parameter $1 \leq t \leq \lg \lg n$. Using this structure, one can get an index structure that takes $o(n \lg n)$ bits and supports finding all the s occurrences of a given pattern of length m in $O(m + s + \lg^\epsilon n)$ time.

Ferragina and Manzini [38] presented an *opportunistic* data structure taking $O(nH_k(n)) + o(n)$ bits of space, where $H_k(n)$ denotes the k th order entropy of the given text of length n . This supports finding all the occurrences of a pattern of length m in $O((m + s) \lg^\epsilon n)$ time, where s is the number of occurrences of the pattern. They also presented its practical performance [39].

Sadakane [23] gave a data structure that takes $O(n \cdot (1 + H_0) + O(|\Sigma| \lg |\Sigma|))$ bits for a text of length n over an alphabet Σ , where $H_0 \leq \lg |\Sigma|$ is the order-0 entropy for the text. This supports finding all the s occurrences of a given pattern P in $O(|P| \lg n + s \lg^\epsilon n)$ time, and *decompress* a portion of the text of length l in $O(l + \lg^\epsilon n)$ time, for any fixed $\epsilon > 0$.

Grossi et al. [40] gave another index structure that takes $nH_k(n) + O(n \lg \lg n \lg |\Sigma| / \lg n)$ bits for a text of length n over an alphabet Σ . Finding an occurrence of a pattern of length m using this structure takes $O(m \lg |\Sigma| + \text{polylog}(n))$ time. This is also shown to perform well, in terms of space as well as query times, in practice [41].

38.7 Permutations and Functions

38.7.1 Permutations

Permutations are fundamental in computer science and have been the focus of extensive study. Here we consider the problem of representing permutations succinctly to support computing $\pi^k(i)$ for any integer k , where $\pi^0(i) = i$ for all i ; $\pi^k(i) = \pi(\pi^{k-1}(i))$ when $k > 0$ and $\pi^k(i) = \pi^{-1}(\pi^{k+1}(i))$ when $k < 0$.

The most obvious way of representing an arbitrary permutation, π , of the integers $\{0, 1, \dots, n - 1\}$ is to store the sequence $\pi(0), \pi(1), \dots, \pi(n - 1)$. This takes $n \lceil \lg n \rceil$ bits, which is $\Theta(n)$ bits more than the information-theoretic lower bound of $\lg(n!) \approx n \lg n - n \lg e$ bits. This representation can be used to find $\pi(i)$ in $O(1)$ time, but finding $\pi^{-1}(i)$ takes $O(n)$ time in the worst case, for $0 \leq i \leq n - 1$. Using this representation, one can easily compute $\pi^k(i)$ in k steps, for $k \geq 1$. To facilitate the computation in constant time, one could store $\pi^k(i)$ for all i and k ($|k| \leq n$, along with its cycle length), but that would require $\Theta(n^2 \lg n)$ bits. The most natural compromise is to retain $\pi^k(i)$ with $|k| \leq n$ a power of 2. Unfortunately, this $n \lceil \lg n^2 \rceil$ bit representation leaves us with a logarithmic time evaluation scheme and a factor of $\lg n$ from the minimal space representation.

We first show how to augment the standard representation to support π^{-1} queries efficiently, while avoiding most of the extra storage cost one would expect. In addition to storing the standard representation, we trace the cycle structure of the permutation, and for every cycle whose length is at least t , we store a shortcut pointer with the elements which are at a distance of a multiple of t steps from an arbitrary starting point. The shortcut pointer points to the element which is t steps before it in the cycle of the permutation. This *shortcut representation* of a permutation can be stored using $(1 + 1/t)n \lg n + o(n)$ bits, and it supports π queries in $O(1)$ time and π^{-1} queries in $O(t)$ time, for any parameter $1 \leq t \leq n$.

Consider the cycle representation of a permutation π over $\{0, 1, \dots, n - 1\}$, which is a collection of disjoint cycles of π (where the cycles are ordered arbitrarily). Let σ be this permutation, that is, the standard representation of σ is a cycle representation of π . Let B be a bit vector of length n that has a **1** corresponding to the starting position of each cycle of π and **0** everywhere else, together with its rank and select directories with respect to both bits. Let S be a representation of σ that supports $\sigma(i)$ and $\sigma^{-1}(i)$ queries efficiently. Then to find $\pi^k(i)$, first find the index j of the cycle to which $\sigma^{-1}(i)$ belongs, using B and S . Find the length l of the j th cycle and the number p of elements up to (but not including) the j th cycle. Then, one can verify that $\pi^k(i) = \sigma(p + (i - p + k \bmod l))$. Combining this with the shortcut representation, one can get a representation taking $(1 + \epsilon)n \lg n + O(1)$ bits that supports computing arbitrary powers in $O(1)$ time.

Benes network: A Benes network [42] is a communication network composed of a number of switches. Each switch has 2 inputs x_0 and x_1 and 2 outputs y_0 and y_1 and can be configured either so that x_0 is connected to y_0 (i.e., a packet that is input along x_0 comes out of y_0) and x_1 is connected to y_1 , or the other way around. An r -Benes network has 2^r inputs and outputs, and is defined as follows. For $r = 1$, the Benes network is a single switch with 2 inputs and 2 outputs. An $(r + 1)$ -Benes network is composed of 2^{r+1} switches and two r -Benes networks, connected as shown in Figure 38.6a. A particular setting of the switches

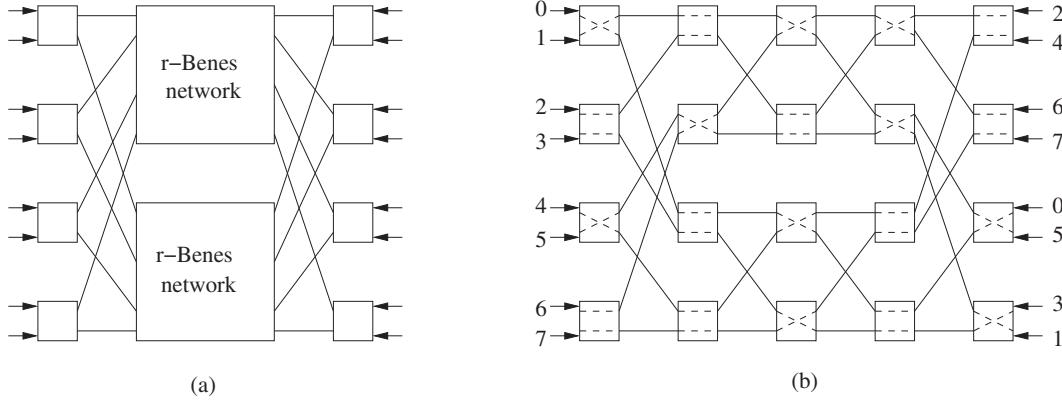

FIGURE 38.6 Benes network: (a) construction of $(r + 1)$ -Benes network (b) Benes network realizing the permutation $(4, 7, 0, 6, 1, 5, 2, 3)$.

of a Benes network *realizes* a permutation π if a packet introduced at input i comes out at output $\pi(i)$, for all i . See Figure 38.6b for an example.

Clearly, a Benes network may be used to represent a permutation. For example, if $n = 2^r$, a representation of a permutation π on $[n]$ may be obtained by configuring an r -Benes network to realize π and then listing the settings of the switches in some canonical order (e.g., level-order). This represents π using $r2^r - 2^{r-1} = n \lg n - n/2$ bits. Given i , one can trace the path taken by a packet at input i by inspecting the appropriate bits in this representation, and thereby calculate $\pi(i)$ in $O(\lg n)$ time (indeed, in $O(\lg n)$ bit-probes). In fact, by tracing the path back from output i we can also compute $\pi^{-1}(i)$ in $O(\lg n)$ time.

One can compress the middle levels of a Benes network by storing an implicit representation of the permutation represented by the middle $O(\lg n / \lg \lg n)$ levels. This reduces the space to $\lg(n!) + o(n)$ bits. One can also group the remaining bits of this Benes network into words of size $\Theta(\lg n)$ bits (by taking $O(\lg \lg n)$ consecutive levels and $O(\lg \lg n)$ appropriate rows). This enables us to traverse $\Theta(\lg \lg n)$ levels in a Benes network in $O(1)$ time. Thus, it gives a representation that takes the optimal $\lceil \lg(n!) \rceil + o(n)$ bits, and supports computing arbitrary powers in $O(\lg n / \lg \lg n)$ time.

One can obtain a structure with same time and space bounds even when n is not a power of 2. See [43] for details.

38.7.2 Functions

Now consider the problem of representing arbitrary functions $f : [n] \rightarrow [n]$, so that queries for $f^k(i)$, for any integer k can be answered efficiently. Here $f^0(i) = i$ and for any $k > 0$, $f^k(i) = f(f^{k-1}(i))$ and $f^{-k}(i) = \{j | f^k(j) = i\}$, for all i . This is a generalization of the problem considered in the previous section. Since there are n^n functions from $[n]$ to $[n]$, any representation scheme takes at least $\lceil n \lg n \rceil$ bits to store an arbitrary function.

A standard way of representing a function is to store the sequence $f(i)$, for $i = 0, \dots, n - 1$. This representation does not support the efficient evaluation of $f^k(i)$ for $k \gg 1$. We look at a representation that takes $(1 + \epsilon)n \lg n + O(1)$ bits of space to store a function $f : [n] \rightarrow [n]$ and supports computing arbitrary positive powers in constant time and negative powers $f^{-k}(i)$, in $O(1 + |f^{-k}(i)|)$ time.

Given an arbitrary function $f : [n] \rightarrow [n]$, consider the directed graph, $G_f = (V, E)$, obtained from it, where $V = [n]$ and $E = \{(i, j) : f(i) = j\}$. In general this directed graph consists of a disjoint set of subgraphs, each of which is a directed cycle with trees rooted at the nodes on the cycle and edges directed towards the roots. See Figure 38.7 for an example.

The main idea of the solution is as follows: in each directed cycle, we re-order the nodes of each tree such that the leftmost path of any subtree is the longest path in that subtree. This enables finding a node at a given depth from any internal node, if it exists, in constant time using the parenthesis representation. We then preprocess each of the trees and store auxiliary structures to support level-ancestor queries on them in constant time (see Section 38.4.2). Observe that finding $f^k(i)$, for $k > 0$, can be translated to finding the ancestor of node i which is k levels above it, if i is at a depth at least k in its tree T . Otherwise, we have to traverse the cycle to which the root of T belongs, to find the required answer. This can be done by storing these cycles as a permutation.

When i belongs to one of the trees in a subgraph, one can answer $f^k(i)$ queries for $k < 0$ in optimal time by finding all the nodes that are at the k th level in the subtree rooted at i . Otherwise, if i is part of the cycle in the subgraph, we store an auxiliary structure that, for any given i and k , outputs all the trees in the subgraph containing i that have an answer in time proportional to the number of such nodes. From this, one can easily find the required answer in optimal time. The auxiliary structure takes $O(m)$ bits for a subgraph with m nodes, and hence $O(n)$ bits overall. See [24] for details.

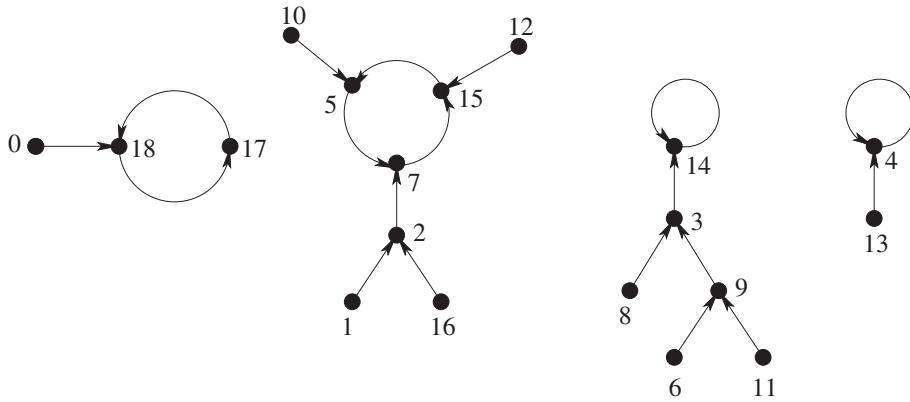

FIGURE 38.7 Graph representation of the function $f(x) = (x^2 + 2x - 1) \bmod 19$, for $0 \leq x \leq 18$.

For functions from $[n] \rightarrow [m]$ one can show the following: If there is a representation of a permutation that takes $P(n)$ space to represent a permutation on $[n]$ and supports forward in t_1 time and inverse in t_2 time, then there is a representation of a function from $[n]$ to $[m]$, $m \leq n$ that takes $(n - m) \lg m + P(m) + O(m)$ bits, and supports $f^k(i)$ in $O(t_1 + t_2)$ time, for any positive integer k and for any $i \in [n]$. When $m > n$, larger powers are not defined in general. In this case, we can have a structure that takes $n \lg m + P(n) + O(n)$ bits of space and answers queries for positive powers (returns the power if defined or returns -1 otherwise) in $O(t_1 + t_2)$ time.

38.8 Partial Sums

Let a_1, a_2, \dots, a_n be a sequence of n non-negative k -bit numbers. The *partial sums* problem maintains the sequence under the following operations:

- $\text{sum}(i)$: return $\sum_{j=1}^i a_j$,
 - $\text{update}(i, \delta)$: set $a_i \leftarrow a_i + \delta$, for some integer δ such that $0 \leq a_i + \delta \leq 2^k - 1$. Our later solutions have the additional constraint that $|\delta| \leq \lg^{O(1)} n$.

Dietz [44] gave a structure for the partial sum problem that supports sum and update in $O(\lg n / \lg \lg n)$ time using $O(n \lg n)$ bits of extra space, for the case when $k = \Theta(\lg n)$ and no constraints on δ . The time bounds are optimal due to the lower bound of Fredman and Saks [45]. As the information-theoretic space lower bound is kn bits, this structure uses space within a constant factor of the optimal.

The main idea of this structure is to store the elements at the leaves of a complete tree with branching factor $O(\lg^\epsilon n)$ for some $\epsilon < 1$. The operations are performed by traversing a path from a leaf to the root, querying/updating the nodes along the path.

The *searchable partial sums* problem is an extension of the partial sums problem that also supports the following operation:

- $\text{search}(j)$: find the smallest i such that $\text{sum}(i) \geq j$.

When $k = 1$ (i.e., each element is a bit), the special case is commonly known as the *dynamic bit vector* problem, which maintains a bit vector of length n under rank, select and flip (update) operations.

For the searchable partial sums problem there is a structure that supports all operations in $O(\lg n / \lg \lg n)$ time, and uses $kn + o(kn)$ bits of space [46]. For $k = O(\lg \lg n)$, one can also obtain a structure that again takes $kn + o(kn)$ bits and supports sum and search in $O(\log_b n)$ time and update in $O(b)$ amortized time, for any parameter $b \geq \lg n / \lg \lg n$ [47]. For the partial sums problem, one can support the above trade-off for $k = O(\lg n)$ [46], and the time bounds can be shown to be optimal [45].

For the dynamic bit vector problem, one can support rank and select in $O(\log_b n)$ time and flip in $O(b)$ (worst-case) time, for any parameter $\lg n / \lg \lg n \leq b \leq n$, using $o(n)$ bits of extra space. One can also extend the above trade-off for $k = O(\lg \lg n)$, using $kn + o(kn)$ bits of space.

See [46,47] for details.

38.9 Arrays

38.9.1 Resizable Arrays

A basic problem that arises in many applications is accumulating elements into a list when the number of elements is unknown ahead of time. The operations needed from such a structure are the ability to append elements to the end of the structure, removing the last element from the structure (in applications such as implementing a stack) and some method of accessing the elements currently in the structure.

One simple solution is a linked list which can easily grow and shrink, and supports sequential access. But this does not support random access to the elements. Moreover, its space overhead is $O(n)$ pointers to store n elements.

Another standard solution is the *doubling technique* [48]. Here the elements are stored in an array. Whenever the array becomes full, an array of double its size is allocated and all the elements are copied to it. Similarly, whenever the array shrinks so that it is only one-fourth full, an array of half its size is allocated and all the elements are copied to it. The advantage of this solution over the linked lists is that random access to the elements takes only $O(1)$ time (as opposed to $O(n)$ for linked lists). The amortized update time is $O(1)$, though the worst-case update time is $O(n)$. The space overhead of this solution is $O(n)$.

Sitariski [49] has proposed a solution whose space overhead is only $O(\sqrt{n})$. The idea is to divide the given list of n elements into sublists of size $\lceil \sqrt{n} \rceil$, store them in separate arrays, and store an array (of length $O(\sqrt{n})$) of pointers to these sublists (in order). Whenever $\lceil \sqrt{n} \rceil$ changes, the entire structure is reconstructed with the new size. Thus the amortized update time is $O(1)$ (though the worst-case time is $O(n)$). This also supports random access in $O(1)$ time.

Brodnik et al. [13] gave a structure that takes $O(\sqrt{n})$ extra locations, where n is the current size of the array, and supports the operations in $O(1)$ time. One advantage of this structure is that elements are never re-allocated. They have also shown that any such structure requires $\Omega(\sqrt{n})$ extra locations even if there are no constraints on the access time.

38.9.2 Dynamic Arrays

A resizable array supports adding/deleting elements only at the end of the list, but does not support insertion/deletion of elements at arbitrary positions in the array. A *dynamic array* is data structure that maintains a sequence of records under the following operations:

- $\text{access}(i)$: return the i th record in the sequence,
- $\text{insert}(r, i)$: insert the record r at position i in the sequence, and
- $\text{delete}(i)$: delete the i th record in the sequence.

A standard way of implementing a dynamic array is to store the records in an array and maintain it using the doubling technique. This supports access in $O(1)$ but requires $O(n)$ time to support insert and delete operations.

Goodrich and Kloss [50] gave a structure, the *tiered vector*, that takes $n + O(\sqrt{n})$ words of space to represent a sequence of length n , where each record fits in a word. This structure supports access in $O(1)$ time and updates in $O(\sqrt{n})$ amortized time. The major component of a tiered vector is a set of *indexable circular deques*. A deque is a linear list which provides constant time insert and delete operations at either the head or the tail of the list [51]. A circular deque is a list which is stored in a sequential section of memory of fixed size. An indexable circular deque maintains pointers h and t , which reference the index in memory of the head and tail of this list. A tiered vector is a set of indexable circular deques. Insertions and deletions in an arbitrary indexable circular deque require time linear in its size, but inserting/deleting at either the head or the tail of the list takes $O(1)$ time.

Thus, by maintaining the given sequence of n elements using $O(\sqrt{n})$ indexable circular deques each of size $O(\sqrt{n})$, one can support access in $O(1)$ time and updates in $O(\sqrt{n})$ amortized time. One can easily generalize this structure to one that supports access in $O(1/\epsilon)$ time and updates in $O(n^\epsilon)$ time, for any parameter $0 < \epsilon \leq 1$.

Using this structure to represent a block of $O(\lg^{O(1)} n)$ records, Raman et al. [46] gave a structure that supports access and updates in $O(\lg n / \lg \lg n)$ amortized time, using $o(n)$ bits of extra space. The main idea is to divide the given list of length n into sublists of length between $(1/2) \lg^4 n$ and $2 \lg^4 n$, and store the sublists using the above dynamic array structure. One can maintain these sublists as the leaves of a weight-balanced B-tree with branching factor $O(\sqrt{\lg n})$, and hence height $O(\lg n / \lg \lg n)$.

By restricting the length of the array, Raman and Rao [18] obtained a dynamic array structure that maintains a sequence of $l = O(w^{O(1)})$ records of $r = O(w)$ bits each, where w is the word size. This structure supports *access* in $O(1)$ time and updates in $O(1 + lr/kw)$ amortized time, and uses $lr + O(k \lg l)$ bits, for any parameter $k \leq l$. The data structure also requires a precomputed table of size $O(2^{\epsilon w})$ bits, for any fixed $\epsilon > 0$. The main idea is to store the newly added elements separately from the existing elements, and store a structure to indicate all the positions of the “updated” elements. The structure is rebuilt after every k updates.

38.10 Conclusions

We looked at several succinct data structures that achieve almost optimal space while supporting the required operations efficiently. Apart from being of theoretical interest, succinct data structures will also have many practical applications due to the enormous growth in the amount of data that needs to be stored in a structured fashion.

Most of the succinct data structures we presented here can be constructed in linear time from the standard representation. But this method requires more space than necessary during the construction. Developing algorithms that directly construct the succinct representations without using more space during construction, preferably in optimal time, is an important open problem. See [52] for an example.

Another aspect, that is more of theoretical significance, is to study the cell probe (in particular, bit probe) complexity of succinct data structures [53–55]. For most problems, no bounds other than the straightforward translations from the bounds on the RAM model are known. It is also interesting to consider the time-space trade-offs of these structures.

39.1 Introduction

Let $G = (V, E)$ be an undirected weighted graph on $n = |V|$ vertices and $m = |E|$ edges. Length of a path between two vertices is the sum of the weights of all the edges of the path. The shortest path between a pair of vertices is the path of least length among all possible paths between the two vertices in the graph. The length of the shortest path between two vertices is also called the distance between the two vertices. An α -approximate shortest path between two vertices is a path of length at-most α times the length of the shortest path.

Computing all-pairs exact or approximate distances in G is one of the most fundamental graph algorithmic problem. In this chapter, we present two randomized graph data-structures for all-pairs approximate shortest paths (APASP) problem in static and dynamic environments. Both the data-structures are hierarchical data-structures and their construction involves random sampling of vertices or edges of the given graph.

The first data-structure is a randomized data-structure designed for efficiently computing APASP in a given static graph. In order to answer a distance query in constant time, most of the existing algorithms for APASP problem output a data-structure which is an $n \times n$ matrix that stores the exact/approximate distance between each pair of vertices explicitly. Recently a remarkable data-structure of $o(n^2)$ size has been designed for reporting all-pairs approximate distances in undirected graph. This data-structure is called *approximate distance oracle* because of its ability to answer a distance query in constant time in spite of its sub-quadratic size. We present the details of this novel data-structure and an efficient algorithm to build it.

The second data-structure is a dynamic data-structure designed for efficiently maintaining APASP in a graph that is undergoing deletion of edges. For a given graph $G = (V, E)$ and a distance parameter $d \leq n$, this data-structure provides the first $o(nd)$ update time algorithm for maintaining α -approximate shortest paths for all pairs of vertices separated by distance $\leq d$ in the graph.

39.2 A Randomized Data-Structure for Static APASP: Approximate Distance Oracles

There exist classical algorithms that require $O(mn \log n)$ time for solving all-pairs shortest paths (APSP) problem. There also exist algorithms based on fast matrix multiplication that achieve sub-cubic time. However, there is still no combinatorial algorithm

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

that could achieve $O(n^{3-\epsilon})$ running time for APSP problem. In recent past, many simple combinatorial algorithms have been designed that compute all-pairs approximate shortest paths (APASP) for undirected graphs. These algorithms achieve significant improvement in the running time compared to those designed for APSP, but the distance reported has some additive or/and multiplicative error. An algorithm is said to compute all pairs α -approximate shortest paths, if for each pair of vertices $u, v \in V$, the distance reported is bounded by $\alpha\delta(u, v)$, where $\delta(u, v)$ denotes the actual distance between u and v .

Among all the data-structures and algorithms designed for computing all-pairs approximate shortest paths, the approximate distance oracles are unique in the sense that they achieves simultaneous improvement in running time (sub-cubic) as well as space (sub-quadratic), and still answers any approximate distance query in constant time. For any $k \geq 1$, it takes $O(kmn^{1/k})$ time to compute $(2k - 1)$ -approximate distance oracle of size $O(kn^{1+1/k})$ that would answer any $(2k - 1)$ -approximate distance query in $O(k)$ time.

39.2.1 3-Approximate Distance Oracle

For a given undirected graph, storing distance information from each vertex to all the vertices requires $\theta(n^2)$ space. To achieve sub-quadratic space, the following simple idea comes to mind.

\mathcal{I} : *From each vertex, if we store distance information to a small number of vertices, can we still be able to report distance between any pair of vertices?*

The above idea can indeed be realized using a simple random sampling technique, but at the expense of reporting approximate, instead of exact, distance as an answer to a distance query. We describe the construction of 3-approximate distance oracle as follows.

1. Let $R \subset V$ be a subset of vertices formed by picking each vertex randomly independently with probability γ (the value of γ will be fixed later on).
2. For each vertex $u \in V$, store the distances to all the vertices of the sample set R .
3. For each vertex $u \in V$, let $p(u)$ be the vertex nearest to u among all the sampled vertices, and let S_u be the set of all the vertices of the graph G that lie closer to u than the vertex $p(u)$. Store the vertices of set S_u along with their distance from u .

For each vertex $u \in V$, storing distance to vertices S_u helps in answering distance query to vertices in locality of u , whereas storing distance from all the vertices of the graph to all the sampled vertices will be required (as shown below) to answer distance query for vertices that are not present in locality of each other. In order to extract distance information in constant time, for each vertex $u \in V$, we use two *hash tables* (see Reference 1, chapter 12), for storing distances from u to vertices of sets S_u and R respectively. The size of each hash-table is of the order of the size of corresponding set (S_u or R). A typical hash table would require $O(1)$ expected time to determine whether $w \in S_u$, and if so, report the distance $\delta(u, w)$. In order to achieve $O(1)$ worst case time, the *2-level hash table* (see Fredman, Komlos, Szemerédi, [2]) of optimal size is employed.

The collection of these hash-tables (two tables per vertex) constitute a data-structure that we call approximate distance oracle. Let $u, v \in V$ be any two vertices whose intermediate distance is to be determined approximately. If either u or v belong to set R , we can report exact distance between the two. Otherwise also exact distance $\delta(u, v)$ will be reported if v lies in S_u or vice versa. The only case, that is left, is when neither $v \in S_u$ nor $u \in S_v$. In this case, we report $\delta(u, p(u)) + \delta(v, p(v))$ as approximate distance between u and v . This distance is bounded by $3\delta(u, v)$ as shown below.

$$\begin{aligned} \delta(u, p(u)) + \delta(v, p(v)) &\leq \delta(u, p(u)) + (\delta(v, u) + \delta(u, p(u))) \quad \{\text{using triangle inequality}\} \\ &= 2\delta(u, p(u)) + \delta(u, v) \quad \{\text{since graph is undirected}\} \\ &\leq 2\delta(u, v) + \delta(u, v) \quad \{\text{since } v \text{ lies farther to } u \text{ than } p(u), \text{ see Figure 39.1}\} \\ &= 3\delta(u, v) \end{aligned}$$

Hence distance reported by the approximate distance oracle described above is no more than three times the actual distance between the two vertices. In other words, the oracle is a 3-approximate distance oracle. Now, we shall bound the expected size of the oracle. Using linearity of expectation, the expected size of the sample set R is ny . Hence storing the distance from each vertex to all the vertices of sample set will take a total of $O(n^2y)$ space. The following lemma gives a bound on the expected size of the sets S_u , $u \in V$.

Lemma 39.1

Given a graph $G = (V, E)$, let $R \subset V$ be a set formed by picking each vertex independently with probability γ . For a vertex $u \in V$, the expected number of vertices in the set S_u is bounded by $1/\gamma$.

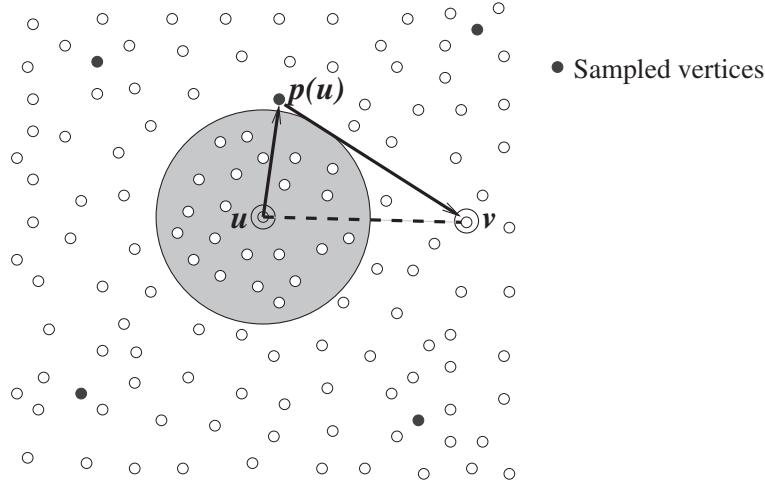

FIGURE 39.1 v is farther to u than $p(u)$, bounding $\delta(p(u), v)$ using triangle inequality.

Proof. Let $\{v_1, v_2, \dots, v_{n-1}\}$ be the sequence of vertices of set $V \setminus \{u\}$ arranged in non-decreasing order of their distance from u . The set S_u consists of all those vertices of the set $V \setminus \{u\}$ that lie closer to u than any vertex of set R . Note that the vertex v_i belongs to S_u if none of the vertices of set $\{v_1, v_2, \dots, v_{i-1}\}$ (i.e., the vertices preceding v_i in the sequence above) is picked in the sample R . Since each vertex is picked independently with probability p , therefore the probability that vertex v_i belongs to set S_u is $(1 - \gamma)^{i-1}$. Using linearity of expectation, the expected number of vertices lying closer to u than any sampled vertex is

$$\sum_{i=1}^{n-1} (1 - \gamma)^{i-1} \leq \frac{1}{\gamma}$$

Hence the expected number of vertices in the set S_u is no more than $1/\gamma$. ■

So the total expected size of the 3-approximate distance oracle is $O(n^2\gamma + n/\gamma)$. Choosing $\gamma = 1/\sqrt{n}$ to minimize the size, we conclude that there is a 3-approximate distance oracle of expected size $n^{3/2}$.

39.2.2 Preliminaries

In the previous subsection, 3-approximate distance oracle was presented based on the idea \mathcal{I} . The $(2k - 1)$ -approximate distance oracle is a k -level hierarchical data-structure. An important construct of the data-structure is $Ball(\cdot)$ defined as follows.

Definition 39.1

For a vertex u , and subsets $X, Y \subset V$, the set $Ball(u, X, Y)$ is the set consisting of all those vertices of the set X that lie closer to u than any vertex from set Y . (see [Figure 39.2](#))

It follows from the definition given above that $Ball(u, X, \emptyset)$ is the set X itself, whereas $Ball(u, X, X) = \emptyset$. It can also be seen that the 3-approximate distance oracle described in the previous subsection stores $Ball(u, V, R)$ and $Ball(u, R, \emptyset)$ for each vertex $u \in V$.

If the set Y is formed by picking each vertex of set X independently with probability γ , it follows from Lemma 39.1 that the expected size of $Ball(u, X, Y)$ is bounded by $1/\gamma$.

Lemma 39.2

Let $G = (V, E)$ be a weighted graph, and $X \subset V$ be a set of vertices. If $Y \subset X$ is formed by selecting each vertex independently with probability γ , the expected number of vertices in $Ball(u, X, Y)$ for any vertex $u \in V$ is at-most $1/\gamma$.

39.2.3 $(2k - 1)$ -Approximate Distance Oracle

In this subsection we shall give the construction of a $(2k - 1)$ -approximate distance oracle which is also based on the idea \mathcal{I} , and can be viewed as a generalization of 3-approximate distance oracle.

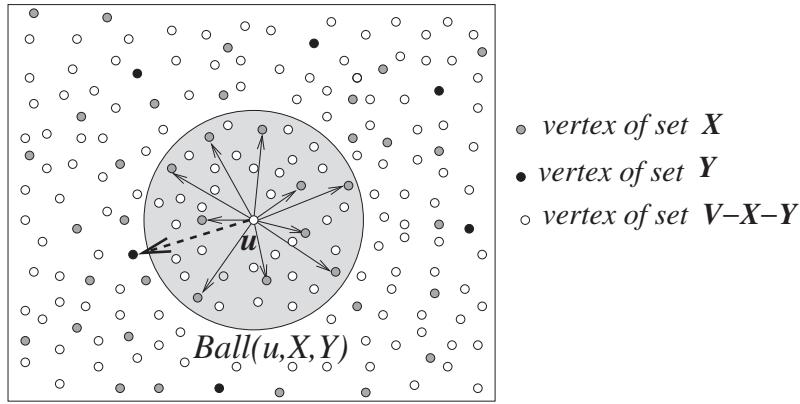

FIGURE 39.2 The vertices pointed by solid-arrows constitute $\text{Ball}(u, X, Y)$.

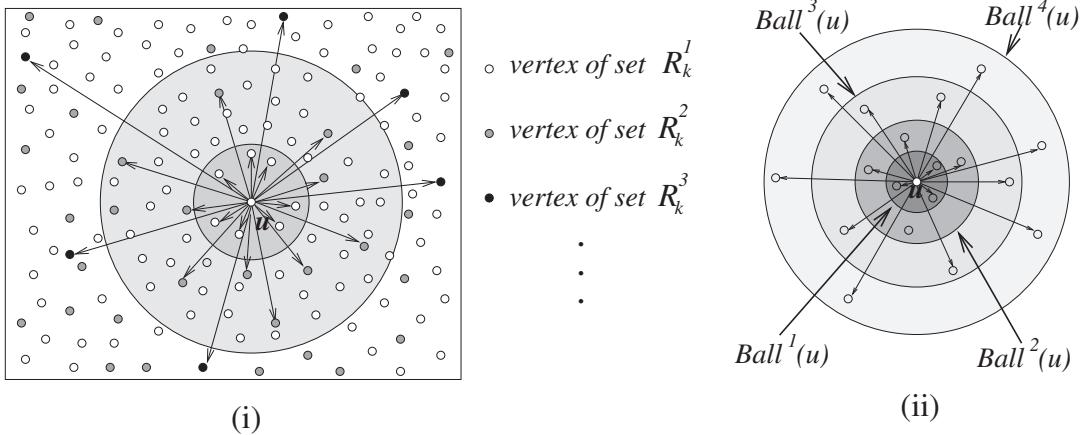

FIGURE 39.3 (i) Close description of $\text{Ball}^i(u)$, $i < k$, (ii) hierarchy of balls around u .

The $(2k - 1)$ -approximate distance oracle is obtained as follows.

1. Let $\mathcal{R}_k^1 \supset \mathcal{R}_k^2 \supset \dots \supset \mathcal{R}_k^k$ be a hierarchy of subsets of vertices with $\mathcal{R}_k^1 = V$, and $\mathcal{R}_k^i, i > 1$ is formed by selecting each vertex of set \mathcal{R}_k^{i-1} independently with probability $n^{-1/k}$.
2. For each vertex $u \in V$, store the distance from u to all the vertices of $\text{Ball}(u, \mathcal{R}_k^k, \emptyset)$ in a hash table.
3. For each $u \in V$ and each $i < k$, store the vertices of $\text{Ball}(u, \mathcal{R}_k^i, \mathcal{R}_k^{i+1})$ along with their distance from u in a hash table.
For sake of conciseness and without causing any ambiguity in notations, henceforth we shall use $\text{Ball}^i(u)$ to denote $\text{Ball}(u, \mathcal{R}_k^i, \mathcal{R}_k^{i+1})$ or the corresponding hash-table storing $\text{Ball}(u, \mathcal{R}_k^i, \mathcal{R}_k^{i+1})$ for $i < k$.

The collection of the hash-tables $\text{Ball}^i(u) : u \in V, i \leq k$ constitute the data-structure that will facilitate answering of any approximate distance query in constant time. To provide a better insight into the data-structure, Figure 39.3 depicts the set of vertices constituting $\{\text{Ball}^i(u) \mid i \leq k\}$.

39.2.3.1 Reporting Distance with Stretch At-most (2k – 1)

Given any two vertices $u, v \in V$ whose intermediate distance has to be determined approximately. We shall now present the procedure to find approximate distance between the two vertices using the k -level data-structure described above.

Let $p^1(u) = u$ and let $p^i(u), i > 1$ be the vertex from the set \mathcal{R}_k^i nearest to u . Since $p^i(u) \in \text{Ball}^i(u)$ for each $u \in V$, so distance from each u to $p^i(u)$ is known for each $i \leq k$.

The query answering process performs at-most k search steps. In the first step, we search $\text{Ball}^1(u)$ for the vertex $p^1(v)$. If $p^1(v)$ is not present in $\text{Ball}^1(u)$, we move to the next level and in the second step we search $\text{Ball}^2(v)$ for vertex $p^2(u)$. We proceed in this

way querying balls of u and v alternatively: In i th step, we search $\text{Ball}^i(x)$ for $p^i(y)$, where $(x = u, y = v)$ if i is odd, and $(x = v, y = u)$ otherwise. The search ends at i th step if $p^i(y)$ belongs to $\text{Ball}^i(x)$, and then we report $\delta(x, p^i(y)) + \delta(y, p^i(y))$ as an approximate distance between u and v .

Distance_Report(u, v)
<i>Algorithm for reporting $(2k - 1)$-approximate distance between $u, v \in V$</i>
<pre> $l \leftarrow 1,$ $x \leftarrow u, y \leftarrow v$ While ($p^l(y) \notin \text{Ball}^l(x)$) do swap($x, y$), $l \leftarrow l + 1$ return $\delta(y, p^l(y)) + \delta(x, p^l(y))$ </pre>

Note that $p^k(y) \in \mathcal{R}_k^k$, and we store the distance from x to all the vertices of set \mathcal{R}_k^k in $\text{Ball}^k(x)$ (which is $\text{Ball}(x, \mathcal{R}_k^k, \emptyset)$). Therefore, the “while loop” of the distance reporting algorithm will execute at-most $k - 1$ iterations, spending $O(1)$ time querying a hash table in each iteration.

In order to ensure that the above algorithm reports $(2k - 1)$ -approximate distance between $u, v \in V$, we first show that the following assertion holds:

\mathcal{A}_i : At the end of i th iteration of the “while loop”, $\delta(y, p^{i+1}(y)) \leq i\delta(u, v)$.

The assertion \mathcal{A}_i can be proved using induction on i as follows. First note that the variables x and y take the values u and v alternatively during the “while-loop”. So $\delta(x, y) = \delta(u, v)$ always.

For the base case ($i = 0$), $p^1(y)$ is same as y , and y is v . So $\delta(y, p^1(y)) = 0$. Hence \mathcal{A}_0 is true. For the rest of the inductive proof, it suffices to show that if \mathcal{A}_j is true, then after $(j + 1)$ th iteration \mathcal{A}_{j+1} is also true. The proof is as follows.

We consider the case of “even j ,” the arguments for the case of “odd j ” are similar. For even j , at the end of j th iteration, $\{x = u, y = v\}$. Thus \mathcal{A}_j implies that at the end of j th iteration $\delta(v, p^{j+1}(v)) \leq j\delta(u, v)$. Consider the $(j + 1)$ th iteration. For the execution of $(j + 1)$ th iteration, the condition in the “while-loop” must have been true. Thus $p^{j+1}(v)$ does not belong to $\text{Ball}(u, \mathcal{R}_k^{j+1}, \mathcal{R}_k^{j+2})$. Hence by Definition 39.1, the vertex $p^{j+2}(u)$ must be lying closer to u than the vertex $p^{j+1}(v)$. So at the end of $(j + 1)$ th iteration, $\delta(y, p^{j+2}(y))$ can be bounded as follows

$$\begin{aligned}
\delta(y, p^{j+2}(y)) &= \delta(u, p^{j+2}(u)) \\
&\leq \delta(u, p^{j+1}(v)) \\
&\leq \delta(u, v) + \delta(v, p^{j+1}(v)) \quad \{\text{using triangle inequality}\} \\
&\leq \delta(u, v) + j\delta(u, v) \quad \{\text{using } \mathcal{A}_j\} \\
&= (j + 1)\delta(u, v)
\end{aligned}$$

Thus the assertion \mathcal{A}_{j+1} holds.

Theorem 39.1

The algorithm *Distance_Report(u, v)* reports $(2k - 1)$ -approximate distance between u and v

Proof. As an approximate distance between u and v , note that the algorithm *Distance_Report(u, v)* would output $\delta(y, p^l(y)) + \delta(x, p^l(y))$, which by triangle inequality is no more than $2\delta(y, p^l(y)) + \delta(x, y)$. Since $\delta(x, y) = \delta(u, v)$, and $\delta(y, p^l(y)) \leq (l - 1)\delta(u, v)$ as follows from assertion \mathcal{A}_l . Therefore, the distance reported is no more than $(2l - 1)\delta(u, v)$. Since the “while loop” will execute at-most $k - 1$ iterations, so $l = k$, and therefore the distance reported by the oracle is at-most $(2k - 1)\delta(u, v)$. ■

39.2.3.2 Size of the $(2k - 1)$ -approximate Distance Oracle

The expected size of the set R_k^k is $O(n^{1/k})$, and the expected size of each $\text{Ball}^i(u)$ is $n^{1/k}$ using Lemma 39.2. So the expected size of the $(2k - 1)$ -approximate distance oracle is $O(n^{1/k} \cdot n + (k - 1) \cdot n \cdot n^{1/k}) = O(kn^{1 + 1/k})$.

39.2.4 Computing Approximate Distance Oracles

In this subsection, a sub-cubic running time algorithm is presented for computing $(2k - 1)$ -approximate distance oracles. It follows from the description of the data-structure associated with approximate distance oracle that after forming the sampled sets of vertices \mathcal{R}_k^i , that takes $O(m)$ time, all that is required is the computation of $\text{Ball}^i(u)$ along with the distance from u to the vertices belonging to these balls for each u and $i \leq k$.

Since $\text{Ball}^i(u)$ is the set of all the vertices of set \mathcal{R}_k^i that lie closer to u than the vertex $p^{i+1}(u)$. So, in order to compute $\text{Ball}^i(u)$, first we compute $p^i(u)$ for all $u \in V, i \leq k$.

39.2.4.1 Computing $p^i(u), \forall u \in V$

Recall from definition itself that $p^i(u)$ is the vertex of the set \mathcal{R}_k^i that is nearest to u . Hence, computing $p^i(u)$ for each $u \in V$ requires solving the following problem with $X = \mathcal{R}_k^i, Y = V \setminus X$.

Given $X, Y \subset V$ in a graph $G = (V, E)$, with $X \cap Y = \emptyset$, compute the nearest vertex of set X for each vertex $y \in Y$.

The above problem can be solved by running a single source shortest path algorithm (Dijkstra's algorithm) on a modified graph as follows. Modify the original graph G by adding a dummy vertex s to the set V , and joining it to each vertex of the set X by an edge of zero weight. Let G' be the modified graph. Running Dijkstra's algorithm from the vertex s as the source, it can be seen that the distance from s to a vertex $y \in Y$ is indeed the distance from y to the nearest vertex of set X . Moreover, if $e(s, x), x \in X$ is the edge leading to the shortest path from s to y , then x is the vertex from the set X that lies nearest to y . The running time of the Dijkstra's algorithm is $O(m \log n)$, we can thus state the following lemma.

Lemma 39.3

Given $X, Y \subset V$ in a graph $G = (V, E)$, with $X \cap Y = \emptyset$, it takes $O(m \log n)$ to compute the nearest vertex of set X for each vertex $y \in Y$.

Corollary 39.1

Given a weighted undirected graph $G = (V, E)$, and a hierarchy of subsets $\{\mathcal{R}_k^i \mid i \leq k\}$, we can compute $p^i(u)$ for all $i \leq k, u \in V$ in $O(km \log n)$ time.

39.2.4.2 Computing $\text{Ball}^i(u)$ Efficiently

In order to compute $\text{Ball}^i(u)$ for each vertex $u \in V$ efficiently, we first compute clusters $\{C(v, \mathcal{R}_k^{i+1}) \mid v \in \mathcal{R}_k^i\}$ which are defined as follows:

Definition 39.2

For a graph $G = (V, E)$, and a set $X \subset V$, the cluster $C(v, X)$ consists of each vertex $w \in V$ for whom v lies closer than any vertex of set X . That is, $\delta(w, v) < \delta(w, x)$ for each $x \in X$.

It follows from the definition given above that $u \in C(v, \mathcal{R}_k^{i+1})$ if and only if $v \in \text{Ball}^i(u)$. So, given clusters $\{C(v, \mathcal{R}_k^{i+1}) \mid v \in \mathcal{R}_k^i\}$, we can compute $\{\text{Ball}^i(u) : u \in V\}$ as follows.

```

For each  $v \in \mathcal{R}_k^i$  do
    For each  $u \in C(v, \mathcal{R}_k^{i+1})$  do
         $\text{Ball}^i(u) \leftarrow \text{Ball}^i(u) \cup \{v\}$ 
    
```

Hence we can state the following Lemma.

Lemma 39.4

Given the family of clusters $\{C(v, \mathcal{R}_k^{i+1}) \mid v \in \mathcal{R}_k^i\}$, the time required to compute $\{\text{Ball}^i(u)\}$ is bounded by $O(\sum_{u \in V} |\text{Ball}^i(u)|)$.

The following property of the cluster $C(v, \mathcal{R}_k^{i+1})$ will be used in its efficient computation.

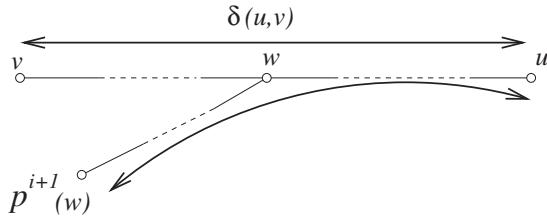

FIGURE 39.4 if w does not lie in $C(v, \mathcal{R}_k^{i+1})$, then $p^{i+1}(w)$ would lie closer to u than v .

Lemma 39.5

If $u \in C(v, \mathcal{R}_k^{i+1})$, then all the vertices on the shortest path from v to u also belong to the set $C(v, \mathcal{R}_k^{i+1})$.

Proof. We give a proof by contradiction. Given that $u \in C(v, \mathcal{R}_k^{i+1})$, let w be any vertex on the shortest path from v to u . If $w \notin C(v, \mathcal{R}_k^{i+1})$, the vertex v doesn't lie closer to w than the vertex $p^{i+1}(w)$. See Figure 39.4. In other words $\delta(w, v) \geq \delta(w, p^{i+1}(w))$. Hence

$$\delta(u, v) = \delta(u, w) + \delta(w, v) \geq \delta(u, w) + \delta(w, p^{i+1}(w)) \geq \delta(u, p^{i+1}(w))$$

Thus v does not lie closer to u than $p^{i+1}(w)$ which is a vertex of set \mathcal{R}_k^{i+1} . Hence by definition, $u \notin C(v, \mathcal{R}_k^{i+1})$, thus a contradiction. ■

From Lemma 39.5, it follows that the graph induced by the vertices of the cluster $C(v, \mathcal{R}_k^{i+1})$ is connected (hence the name cluster). Moreover, the entire cluster $C(v, \mathcal{R}_k^{i+1})$ appears as a sub-tree of the shortest path tree rooted at v in the graph. As follows from the definition, for each vertex $x \in C(v, \mathcal{R}_k^{i+1})$, $\delta(v, x) < \delta(x, p^{i+1}(x))$. Based on these two observations, here follows an efficient algorithm that computes the set $C(v, \mathcal{R}_k^{i+1})$. The algorithm performs a restricted Dijkstra's algorithm from the vertex v , wherein we don't proceed along any vertex that does not belong to the set $C(v, \mathcal{R}_k^{i+1})$.

A restricted Dijkstra's algorithm: Note that the Dijkstra's algorithm starts with singleton tree $\{v\}$ and performs $n - 1$ steps to grow the complete shortest path tree. Each vertex $x \in V \setminus \{v\}$ is assigned a label $L(x)$, which is infinity in the beginning, but eventually becomes the distance from v to x . Let V_i denotes the set of i nearest vertices from v . The algorithm maintains the following invariant at the end of l th step:

$\mathcal{I}(l)$: For all the vertices of the set V_l , the label $L(x) = \delta(v, x)$, and for every other vertex $y \in V \setminus V_l$, the label $L(y)$ is equal to the length of the shortest path from v to y that passes through vertices of V_l only.

During the $(j+1)$ th step, we select the vertex, say w from set $V - V_j$ with least value of $L(\cdot)$. Since all the edge weights are positive, it follows from the invariant $\mathcal{I}(j)$ that $L(w) = \delta(w, v)$. Thus we add w to set V_j to get the set V_{j+1} . Now in order to satisfy the invariant $\mathcal{I}(j+1)$, we relax each edge $e(w, y)$ incident from w to a vertex $y \in V - V_{j+1}$ as follows: $L(y) \leftarrow \min\{L(y), L(w) + \text{weight}(w, y)\}$. It is easy to observe that this ensures the validity of the invariant $\mathcal{I}(j+1)$.

In the restricted Dijkstra's algorithm, we will put the following restriction on relaxation of an edge $e(w, y)$: we relax the edge $e(w, y)$ only if $L(w) + \text{weight}(w, y)$ is less than $\delta(y, p^i(y))$. This will ensure that a vertex $y \notin C(v, \mathcal{R}_k^{i+1})$ will never be visited during the algorithm. The fact that the vertices of the cluster $C(v, \mathcal{R}_k^{i+1})$ form a sub-tree of the shortest path tree rooted at v , ensures that the above restricted Dijkstra's algorithm indeed finds all the vertices (along with their distance from v) that form the cluster $C(v, \mathcal{R}_k^{i+1})$. Since the running time of Dijkstra's algorithm is dominated by the number of edges relaxed, and each edge relaxation takes $\log(n)$ time only, therefore, the restricted Dijkstra's algorithm will run in time of the order of $\sum_{x \in C(v, \mathcal{R}_k^{i+1})} \text{degree}(x) \log n$.

Thus the total time for computing all the clusters $\{C(v, \mathcal{R}_k^{i+1}) \mid v \in \mathcal{R}_k^i\}$ is given by:

$$\begin{aligned} \sum_{v \in \mathcal{R}_k^i, x \in C(v, \mathcal{R}_k^{i+1})} \text{degree}(x) \log n &= \left(\sum_{x \in V, v \in \text{Ball}^i(x)} \text{degree}(x) \right) \log n \\ &= \left(\sum_{x \in V} |\text{Ball}^i(x)| \cdot \text{degree}(x) \right) \log n \end{aligned}$$

By Lemma 39.2, the expected size of $\text{Ball}^i(x)$ is bounded by $n^{1/k}$, hence using linearity of expectation, the total expected cost of computing $\{C(v, \mathcal{R}_k^{i+1}) \mid v \in \mathcal{R}_k^i\}$ is asymptotically bounded by

$$\sum_{x \in V} n^{1/k} \cdot \text{degree}(x) \log n = 2mn^{1/k} \log n$$

Using the above result and Lemma 39.4, we can thus conclude that for a given weighted graph $G = (V, E)$ and an integer k , it takes a total of $\tilde{O}(kmn^{1/k} \log n)$ time for computing $\{\text{Ball}^i(u) \mid i < k, u \in V\}$. If we use Fibonacci heaps instead of binary heaps in implementation of the restricted Dijkstra's algorithm, we can get rid of the logarithmic factor in the running time. Hence the total expected running time for building the data-structure is $O(kmn^{1/k})$. As mentioned before, the expected size of the data-structure will be $O(kn^{1+1/k})$. To get $O(kn^{1+1/k})$ bound on the worst case size of the data-structure, we repeat the preprocessing algorithm. The expected number of iterations will be just a constant. Hence, we can state the following theorem.

Theorem 39.2

Given a weighted undirected graph $G = (V, E)$ and an integer k , a data-structure of size $O(kn^{1+1/k})$ can be built in $O(kmn^{1/k})$ expected time so that given any pair of vertices, $(2k - 1)$ -approximate distance between them can be reported in $O(k)$ time.

39.3 A Randomized Data-Structure for Incremental APASP

There are a number of applications that require efficient solutions of the APASP problem for a dynamic graph. In these applications, an initial graph is given, followed by an on-line sequence of queries interspersed with updates that can be insertion or deletion of edges. We have to carry out the updates and answer the queries on-line in an efficient manner. The goal of a dynamic graph algorithm is to update the solution efficiently after the dynamic changes, rather than having to re-compute it from scratch each time.

The approximate distance oracles described in the previous section can be used for answering approximate distance query in a static graph. However, there does not seem to be any efficient way to dynamize these oracles in order to answer distance queries in a graph under deletion of edges. In this section we shall describe a hierarchical data structure for efficiently maintaining APASP in an undirected unweighted graph under deletion of edges. In addition to maintaining approximate shortest paths for all-pairs of vertices, this scheme has been used for efficiently maintaining approximate shortest paths for pair of vertices separated by distance in an interval $[a, b]$ for any $1 \leq a < b \leq n$. However, to avoid giving too much detail in this chapter, we would outline an efficient algorithm for the following problem only.

APASP-d: Given an undirected unweighted graph $G = (V, E)$ that is undergoing deletion of edges, and a distance parameter $d \leq n$, maintain approximate shortest paths for all-pairs of vertices separated by distance at-most d .

39.3.1 Main Idea

For an undirected unweighted graph $G = (V, E)$, a breadth-first-search (BFS) tree rooted at a vertex $u \in V$ stores distance information with respect to the vertex u . So in order to maintain shortest paths for all-pairs of vertices separated by distance $\leq d$, it suffices to maintain a BFS tree of depth d rooted at each vertex under deletion of edges. This is the approach taken by the previously existing algorithms.

The main idea underlying the hierarchical data-structure that would provide efficient update time for maintaining APASP can be summarized as follows: Instead of maintaining exact distance information separately from each vertex, keep *small* BFS trees around each vertex for maintaining distance information within locality of each vertex, and some what *larger* BFS trees around *fewer* vertices for maintaining global distance information.

We now provide the underlying intuition of the above idea and a brief outline of the new techniques used.

Let B_u^d denote the BFS tree of depth d rooted at vertex $u \in V$. There exists a simple algorithm for maintaining a BFS tree B_u^d under deletion of edges that takes a total of $\mu(B_u^d) \cdot d$ time, where $\mu(t)$ is the number of edges in the graph induced by tree t . Thus the total update time for maintaining shortest path for all-pairs separated by distance at-most d is of the order of $\sum_{u \in V} \mu(B_u^d) \cdot d$. Potentially $\mu(B_u^d)$ can be as large as $\theta(m)$, and so the total update time over any sequence of edge deletions will be $O(nd)$. Dividing this total update cost uniformly over the entire sequence of edge deletions, we can see that it takes $O(nd)$ amortized update time per edge deletion, and $O(1)$ time for reporting exact distance between any pair of vertices separated by distance at-most d .

In order to achieve $o(nd)$ bound on the update time for the problem APASP-d, we closely look at the expression of total update time $\sum_{u \in V} \mu(B_u^d) \cdot d$. There are n terms in this expression each of potential size $\theta(m)$. A decrease in either the total number of

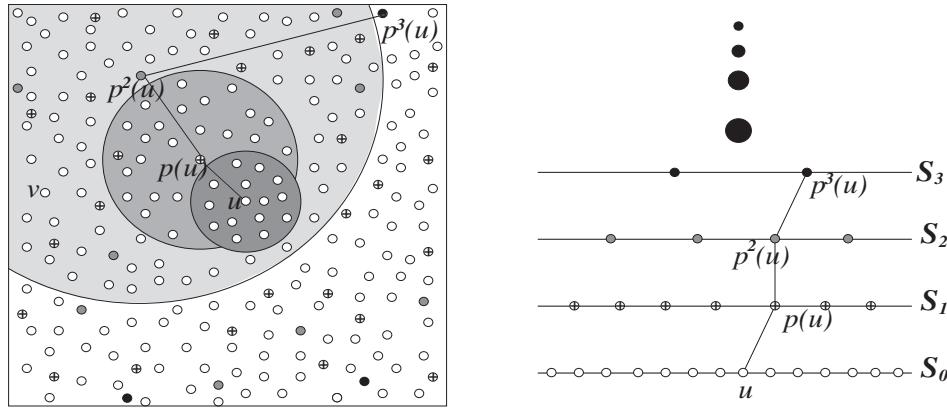

FIGURE 39.5 Hierarchical scheme for maintaining approximate distance.

terms or the size of each term would give an improvement in the total update time. Thus the following simple ideas come to mind.

- Is it possible to solve the problem APASP- d by keeping very few depth- d BFS trees?
- Is there some other alternative t for depth bounded BFS tree B_u^d that has $o(m)$ bound on $\mu(t)$?

While it appears difficult for any of the above ideas to succeed individually, they can be combined in the following way: *Build and maintain BFS trees of depth $2d$ on vertices of a set $S \subset V$ of size $o(n)$, called the set of special vertices, and for each remaining vertex $u \in V \setminus S$, maintain a BFS tree (denoted by B_u^S) rooted at u and containing all the vertices that lie closer to u than the nearest special vertex, say $\mathcal{N}(u, S)$.*

Along the above lines, we present a 2-level data-structure (and its generalization to k -levels) for the problem APASP- d .

It can be seen that unlike the tree B_u^d , the new BFS tree B_u^S might not contain all the vertices lying within distance d from u . In order to ensure that our scheme leads to a solution of problem APASP- d , we use the following observation similar to that of 3-approximate distance oracle in the previous section. If v is a vertex lying within distance d from u but not present in B_u^S , an approximate distance from u to v can be extracted from the tree rooted at the nearest special vertex $\mathcal{N}(u, S)$. This is because (by triangle inequality) the distance from $\mathcal{N}(u, S)$ to v is at most twice the distance from u to v .

For our hierarchical scheme to lead to improved update time, it is crucial that we establish sub-linear upper bounds on $\mu(B_u^S)$. We show that if the set S is formed by picking each vertex independently with *suitable* probability, then $\mu(B_u^S) = \tilde{O}(m/|S|)$ with probability arbitrarily close to 1.

39.3.2 Notations

For an undirected unweighted graph $G = (V, E)$, $S \subset V$, and a distance parameter $d \leq n$,

- $\delta(u, v)$: distance between u and v .
- $\mathcal{N}(v, S)$: the vertex of the set $S \subset V$ nearest to v .
- B_v^d : The BFS tree of depth d rooted at $v \in V$.
- B_v^S : The BFS tree of depth $(\delta(u, \mathcal{N}(u, S)) - 1)$ rooted at v .
- $B_v^{d, S}$: The BFS tree of depth $\min\{d, \delta(v, \mathcal{N}(v, S)) - 1\}$ rooted at v .
- $\mu(t)$: the number of edges in the sub-graph (of G) induced by the tree t .
- $v(t)$: the number of vertices in tree t .
- For a sequence $\{S_0, S_1, \dots, S_{k-1}\}$, $S_i \subset V$, and a vertex $u \in S_0$, we define

$$p^0(u) = u.$$

$$p^{i+1}(u) = \text{the vertex from set } S_{i+1} \text{ nearest to } p^i(u).$$

- $\bar{\alpha}$: the smallest integer of the form 2^i which is greater than α .

39.3.3 Hierarchical Distance Maintaining Data-Structure

Based on the idea of “keeping many *small* trees, and a few large trees,” we define a k -level hierarchical data-structure for efficiently maintaining approximate distance information as follows. (See Figure 39.5)

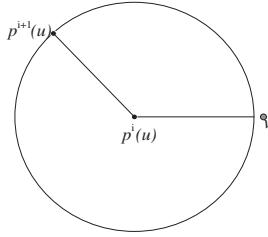

FIGURE 39.6 Bounding the approximate distance between $p^{i+1}(u)$ and v .

Let $\mathcal{S} = \{S_0, S_1, \dots, S_{k-1} : S_i \subset V, |S_{i+1}| < |S_i|\}$ be a sequence. For a given distance parameter $d \leq n$ and $i < k - 1$, let \mathcal{F}_i be the collection $\{B_u^{2^i d, S_{i+1}} : u \in S_i\}$ of BFS trees, and \mathcal{F}_{k-1} be the collection of BFS trees of depth $2^{k-1}d$ rooted at each $u \in S_{k-1}$. We shall denote the set $\{(S_0, \mathcal{F}_0), (S_1, \mathcal{F}_1), \dots, (S_{k-1}, \mathcal{F}_{k-1})\}$ as the k -level hierarchy \mathcal{H}_d^k induced by the sequence \mathcal{S} .

Let v be a vertex within distance d from u . If v is present in B_u^{d, S_1} , we can report exact distance between them. Otherwise, (as will soon become clear) we can extract the approximate distance between u and v from the collection of the BFS trees rooted at the vertices $u, p(u), \dots, p^{k-1}(u)$ (see Figure 39.5). The following Lemma is the basis for estimating the distance between two vertices using the hierarchy \mathcal{H}_d^k .

Lemma 39.6

Given a hierarchy \mathcal{H}_d^k , if $j < k - 1$ is such that v is not present in any of the BFS trees $\{B_{p^i(u)}^{2^i d, S_{i+1}} \mid 0 \leq i \leq j\}$, then for all $i \leq j$

$$\delta(p^{i+1}(u), p^i(u)) \leq 2^i \delta(u, v) \quad \text{and} \quad \delta(p^{i+1}(u), v) \leq 2^{i+1} \delta(u, v).$$

Proof. We give a proof by induction on j .

Base Case ($j = 0$): Since v is not present in $B_u^{S_1}$, so the vertex $p(u)$ must be lying equidistant or closer to u than v . Hence $\delta(p(u), u) \leq \delta(u, v)$. Using triangle inequality, it follows that $\delta(p(u), v) \leq \delta(p(u), u) + \delta(u, v) = 2\delta(u, v)$.

Induction Hypothesis:

$$\delta(p^{i+1}(u), p^i(u)) \leq 2^i \delta(u, v), \text{ and}$$

$$\delta(p^{i+1}(u), v) \leq 2^{i+1} \delta(u, v), \text{ for all } i < l.$$

Induction Step ($j = l$): if $v \neq B_{p^l(u)}^{S_{l+1}}$, then the distance between p^{l+1} and $p^l(u)$ must not be longer than $\delta(p^l(u), v)$, which is less than $2^l \delta(u, v)$ (using induction hypothesis).

Now using triangle inequality (see the Figure 39.6) we can bound $\delta(p^{l+1}(u), v)$ as follows.

$$\begin{aligned} \delta(p^{l+1}(u), v) &\leq \delta(p^{l+1}(u), p^l(u)) + \delta(p^l(u), v) \\ &\leq 2^l \delta(u, v) + \delta(p^l(u), v) \\ &\leq 2^l \delta(u, v) + 2^l \delta(u, v) \quad \{\text{using I.H.}\} \\ &= 2^{l+1} \delta(u, v) \end{aligned}$$

■

Since the depth of a BFS tree at $(k-1)$ th level of hierarchy \mathcal{H}_d^k is $2^{k-1}d$, therefore the following corollary holds true.

Corollary 39.2

If $\delta(u, v) \leq d$, then there is some $p^i(u), i < k$ such that v is present in the BFS tree rooted at $p^i(u)$ in the hierarchy \mathcal{H}_d^k .

Lemma 39.7

Given a hierarchy \mathcal{H}_d^k , if $j < k - 1$ is such that v is not present in any of the BFS trees $\{B_{p^i(u)}^{2^i d, S_{i+1}} \mid 0 \leq i \leq j\}$, then $\delta(p^{i+1}(u), u) \leq (2^{i+1} - 1)\delta(u, v)$, for all $i \leq j$.

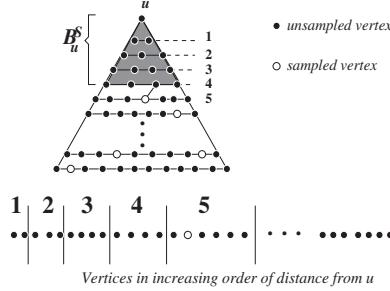

FIGURE 39.7 Bounding the size of B_u^S .

Proof. Using simple triangle inequality, it follows that

$$\begin{aligned}\delta(p^{i+1}(u), u) &\leq \sum_{l \leq i} \delta(p^{l+1}(u), p^l(u)) \\ &\leq \sum_{l \leq i} 2^l \delta(u, v) = (2^{i+1} - 1)\delta(u, v)\end{aligned}$$

■

It follows from Lemmas 39.6 and 39.7 that if l is the smallest integer such that v is present in the BFS tree rooted at $p^l(u)$ in the hierarchy \mathcal{H}_d^k , then we can report $\delta(p^l(u), u) + \delta(p^l(u), v)$ as an approximate distance between u and v . Along these lines, we shall present an improved decremental algorithms for APASP- d .

39.3.4 Bounding the Size of $B_u^{d,S}$ under Edge-Deletions

We shall now present a scheme based on random sampling to find a set $S \subset V$ of vertices that will establish a sub-linear bound on the number of vertices ($v(B_u^S)$) as well as the number of edges ($\mu(B_u^S)$) induced by B_u^S under deletion of edges. Since $B_u^{d,S} \subset B_u^S$, so these upper bounds also hold for $B_u^{d,S}$.

Build the set S of vertices by picking each vertex from V independently with probability $\frac{n^c}{n}$. The expected size of S is $O(n^c)$. Consider an ordering of vertices V according to their levels in the BFS tree B_u^S (see Figure 39.7). The set of vertices lying at higher levels than the nearest sampled vertex in this ordering is what constitutes the BFS tree B_u^S . Along similar lines as that of Lemma 39.1, it follows that the expected size of this set (and hence $v(B_u^S)$) is $\frac{n^c}{n^c}$. Moreover, it can be shown that $v(B_u^S)$ is no more than $\frac{4n \ln n}{n^c}$ with probability $> 1 - \frac{1}{n^4}$. Now as the edges are being deleted, the levels of the vertices in the tree B_u^S may fall, and so the ordering of the vertices may change. There will be a total of m such orderings during the entire course of edge deletions. Since the vertices are picked randomly and independently, therefore, the upper bound of $\frac{4n \ln n}{n^c}$ holds for $v(B_u^S)$ with probability $(1 - \frac{1}{n^4})$ for any of these orderings. So we can conclude that $v(B_u^S)$, the number of vertices of tree B_u^S never exceeds $(\frac{4n \ln n}{n^c})$ during the entire course of edge deletions with probability $> 1 - \frac{1}{n^2}$.

To bound the number of edges induced by B_u^S , consider the following scheme. Pick every edge independently with probability $\frac{n^c}{m}$. The set S consists of the end points of the sampled edges. The expected size of S is $O(n^c)$. Consider an ordering of the edges according to their level in B_u^S (level of an edge is defined as the minimum of the levels of its end points). Along the lines of arguments given above (for bounding the the number of vertices of B_u^S), it can be shown that $\mu(B_u^S)$, the number of edges induced by B_u^S remains $\leq \frac{4m \ln n}{n^c}$ with probability $> 1 - \frac{1}{n^2}$ during the entire course of edge deletions.

Note that in the sampling scheme to bound the number of vertices of tree B_u^S , a vertex v is picked with probability $\frac{n^c}{n}$. Whereas in the sampling scheme for bounding the number of edges in the sub-graph induced by B_u^S , a vertex v is picked with probability $\frac{\text{degree}(v) \cdot n^c}{m}$. It can thus be seen that both the bounds can be achieved simultaneously by the following random sampling scheme:

$$\mathcal{R}(c) : \text{Pick each vertex } v \in V \text{ independently with probability } \frac{n^c}{n} + \frac{\text{degree}(v) \cdot n^c}{m}.$$

It is easy to see that the expected size of the set formed by the sampling scheme $\mathcal{R}(c)$ will be $O(n^c)$.

Theorem 39.3

Given an undirected unweighted graph $G = (V, E)$, a constant $c < 1$, and a distance parameter d ; a set S of size $O(n^c)$ vertices can be found that will ensure the following bound on the number of vertices and number of edges in the sub-graph of G induced by $B_u^{d,S}$.

$$\nu(B_u^{d,S}) = O\left(\frac{n \ln n}{n^c}\right), \quad \mu(B_u^{d,S}) = O\left(\frac{m \ln n}{n^c}\right)$$

with probability $\Omega(1 - \frac{1}{n^2})$ during the entire sequence of edge deletions.

39.3.4.1 Maintaining the BFS Tree $B_u^{d,S}$ under Edge Deletions

Even and Shiloach [3] design an algorithm for maintaining a depth- d BFS tree in an undirected unweighted graph.

Lemma 39.8: (Even, Shiloach [3])

Given a graph under deletion of edges, a BFS tree B_u^d , $u \in V$ can be maintained in $O(d)$ amortized time per edge deletion.

For maintaining a $B_u^{d,S}$ tree under edge deletions, we shall use the same algorithm of [3] with the modification that whenever the depth of $B_u^{d,S}$ has to be increased (due to recent edge deletion), we grow the tree to its new level $\min\{d, \delta(u, \mathcal{N}(u, S)) - 1\}$. We analyze the total update time required for maintaining $B_u^{d,S}$ as follows.

There are two computational tasks: one extending the level of the tree, and another that of maintaining the levels of the vertices in the tree $B_u^{d,S}$ under edge deletions. For the first task, the time required is bounded by the edges of the new level introduced which is $O(\mu(B_u^{d,S}))$. For the second task, we give a variant of the proof of Even and Shiloach [3] (for details, please refer [3]). The running time is dominated by the processing of the edges in this process. In-between two consecutive processing of an edge, level of one of the end-points of the edge falls down by at least one unit. The processing cost of an edge can thus be charged to the level from which it has fallen. Clearly the maximum number of edges passing a level i is bounded by $\mu(B_u^{d,S})$. The number of levels in the tree $B_u^{d,S}$ is $\min\{d, \nu(B_u^{d,S})\}$. Thus the total cost for maintaining the BFS tree $B_u^{d,S}$ over the entire sequence of edge deletions is $O(\mu(B_u^{d,S}) \cdot \min\{d, \nu(B_u^{d,S})\})$.

Lemma 39.9

Given an undirected unweighted graph $G = (V, E)$ under edge deletions, a distance parameter d , and a set $S \subset V$; a BFS tree $B_u^{d,S}$ can be maintained in

$$O\left(\frac{\mu(B_u^{d,S})}{m} \cdot \min\{d, \nu(B_u^{d,S})\}\right)$$

amortized update time per edge deletion.

39.3.4.2 Some Technical Details

As the edges are being deleted, we need an efficient mechanism to detect any increase in the depth of tree $B_u^{d,S}$. We outline one such mechanism as follows.

For every vertex $v \neq S$, we keep a count $C[v]$ of the vertices of the S that are neighbors of v . It is easy to maintain $C[u], \forall u \in V$ under edge-deletions. We use the count $C[v]$ in order to detect any increase in the depth of a tree $B_u^{d,S}$ as follows. Note that when depth of a tree $B_u^{d,S}$ is less than d , there has to be at-least one vertex w at leaf-level in $B_u^{d,S}$ with $C[w] \geq 1$ (as an indicator that the vertex $p(u)$ is at next level). Therefore, after an edge deletion if there is no vertex w at leaf level with $C[w] \geq 1$, we grow the BFS tree $B_u^{d,S}$ beyond its previous level until either depth becomes d or we reach some vertex w' with $C[w'] \geq 1$.

Another technical issue is that when an edge $e(x, y)$ is deleted, we must update only those trees which contain x and y . For this purpose, we maintain for each vertex, a set of roots of all the BFS trees containing it. We maintain this set using any dynamic search tree.

39.3.5 Improved Decremental Algorithm for APASP up to Distance d

Let $\{(S_0, \mathcal{F}_0), (S_1, \mathcal{F}_1), \dots, (S_{k-1}, \mathcal{F}_{k-1})\}$ be a k -level hierarchy \mathcal{H}_d^k with $S_0 = V$ and $n^{c_i} = |S_i|$, where each $c_i, i < k$ is a fraction to be specified soon. Each set $S_i, i > 0$ is formed by picking the vertices from set V using the random sampling scheme \mathcal{R} mentioned in the previous subsection.

To report distance from u to v , we start from the level 0. We first inquire if v lies in B_u^{d, S_1} . If v does not lie in the tree, we move to the first level and inquire if v lies in $B_{p(u)}^{2d, S_2}$. It follows from the Corollary 39.2 that if $\delta(u, v) \leq d$, then proceeding in this way, we eventually find a vertex $p^l(u), l \leq k - 1$ in the hierarchy \mathcal{H}_d^k such that v is present in the BFS tree rooted at $p^l(u)$. (See Figure 39.5). We then report the sum of distances from $p^l(u)$ to both u and v .

Algorithm for reporting approximate distance using \mathcal{H}_d^k

```

Distance( $u, v$ )
{
   $D \leftarrow 0; l \leftarrow 0$ 
  While ( $v \notin B_{p^l(u)}^{2^l d, S_{l+1}} \wedge l < k - 1$ ) do
  {
    If  $u \in B_{p^l(u)}^{2^l d, S_{l+1}}$ , then  $D \leftarrow \delta(p^l(u), u)$ ,
     $D \leftarrow D + \delta(p^l(u), p^{l+1}(u))$ 
     $l \leftarrow l + 1;$ 
  }
  If  $v \notin B_{p^l(u)}^{2^l d, S_{l+1}}$ , then “ $\delta(u, v)$  is greater than  $d$ ”,
    else return  $\delta(p^l(u), v) + D$ 
}

```

The approximation factor ensured by the above algorithm can be bounded as follows.

It follows from the Lemma 39.7 that the final value of D in the algorithm given above is bounded by $(2^l - 1)\delta(u, v)$, and it follows from Lemma 39.6 that $\delta(p^l(u), v)$ is bounded by $2^l\delta(u, v)$. Since $l \leq k - 1$, therefore the distance reported by the algorithm is bounded by $(2^k - 1)\delta(u, v)$ if v is at distance $\leq d$.

Lemma 39.10

Given an undirected unweighted graph $G = (V, E)$, and a distance parameter d . If α is the desired approximation factor, then there exists a hierarchical scheme \mathcal{H}_d^k with $k = \log_2 \bar{\alpha}$, that can report α -approximate shortest distance between any two vertices separated by distance $\leq d$, in time $O(k)$.

Update time for maintaining the hierarchy \mathcal{H}_d^k : The update time per edge deletion for maintaining the hierarchy \mathcal{H}_d^k is the sum total of the update time for maintaining the set of BFS trees $\mathcal{F}_i, i \leq k - 1$.

Each BFS tree from the set \mathcal{F}_{k-1} has depth $2^{k-1}d$, and edges $O(m)$. Therefore, using Lemma 39.8, each tree from set \mathcal{F}_{k-1} requires $O(2^{k-1}d)$ amortized update time per edge deletion. So, the amortized update time T_{k-1} per edge deletion for maintaining the set \mathcal{F}_{k-1} is

$$T_{k-1} = O(n^{c_{k-1}} 2^{k-1} d)$$

It follows from the Theorem 39.3 that a tree t from a set $\mathcal{F}_i, i < (k - 1)$, has $\mu(t) = m \ln n / n^{c_{i+1}}$, and depth $= \min\{2^i d, n \ln n / n^{c_{i+1}}\}$. Therefore, using the Lemma 39.9, each tree $t \in \mathcal{F}_i, i < k - 1$ requires $O(\min\{2^i d / n^{c_{i+1}}, n \ln n / n^{2c_{i+1}}\})$ amortized update time per edge deletion. So the amortized update time T_i per edge deletion for maintaining the set \mathcal{F}_i is

$$T_i = O\left(\min\left\{2^i d \frac{n^{c_i}}{n^{c_{i+1}}} \ln n, \frac{n^{1+c_i}}{n^{2c_{i+1}}} \ln^2 n\right\}\right), \quad i < k - 1$$

Hence, the amortized update time T per edge deletion for maintaining the hierarchy \mathcal{H}_d^k is

$$\begin{aligned} T &= T_{k-1} + \sum_{i < k-1} T_i \\ &= O(n^{c_{k-1}} 2^{k-1} d) + \sum_{i=0}^{i=k-2} O\left(\min\left\{2^i d \frac{n^{c_i}}{n^{c_{i+1}}} \ln n, \frac{n^{1+c_i}}{n^{2c_{i+1}}} \ln^2 n\right\}\right) \end{aligned}$$

To minimize the sum on right hand side in the above equation, we balance all the terms constituting the sum, and get

$$T = \tilde{O}\left(2^{k-1} \cdot \min\left\{\sqrt[k]{nd}, (nd)^{\frac{2}{2^{k-1}}}\right\}\right)$$

If α is the desired approximation factor, then it follows from Lemma 39.10 that the number of levels k , in the hierarchy are $\log_2 \bar{\alpha}$. So the amortized update time required is $\tilde{O}(\alpha \cdot \min\{\sqrt[\log_2 \bar{\alpha}]{nd}, (nd)^{\frac{\bar{\alpha}}{2(\bar{\alpha}-1)}}\})$.

TABLE 39.1 Maintaining α -approximate distances for all-pairs of vertices separated by distance $\leq d$.

Data-structure	α (the approximation factor)	Amortized update time per edge deletion
$\dot{\mathcal{D}}_3(1, d)$	3	$\tilde{O}(\min(\sqrt{nd}, (nd)^{2/3}))$
$\dot{\mathcal{D}}_7(1, d)$	7	$\tilde{O}(\min(\sqrt[3]{nd}, (nd)^{4/7}))$
$\dot{\mathcal{D}}_{15}(1, d)$	15	$\tilde{O}(\min(\sqrt[4]{nd}, (nd)^{8/15}))$

Theorem 39.4

Let $G = (V, E)$ be an undirected unweighted graph undergoing edge deletions, d be a distance parameter, and $\alpha > 2$ be the desired approximation factor. There exists a data-structure $\dot{\mathcal{D}}_\alpha(1, d)$ for maintaining α -approximate distances for all-pairs separated by distance $\leq d$ in $\tilde{O}(\alpha \cdot \min\{\sqrt[log_2 \alpha]{nd}, (nd)^{\frac{\alpha}{2(\alpha-1)}}\})$ amortized update time per edge deletion, and $O(\log \alpha)$ query time.

Based on the data-structure of [3], the previous best algorithm for maintaining all-pairs exact shortest paths of length $\leq d$ requires $O(nd)$ amortized update time. We have been able to achieve $o(nd)$ update time at the expense of introducing approximation as shown in Table 39.1 on the following page.

39.4 Further Reading and Bibliography

Zwick [4] presents a very recent and comprehensive survey on the existing algorithms for all-pairs approximate/exact shortest paths. Based on the fastest known matrix multiplication algorithms given by Coppersmith and Winograd [5], the best bound for computing all-pairs shortest paths is $O(n^{2.575})$ [6].

Approximate distance oracles are designed by Thorup and Zwick [7]. Based on a 1963 girth conjecture of Erdős [8], they also show that $\Omega(n^{1+1/k})$ space is needed in the worst case for any oracle that achieves stretch strictly smaller than $(2k+1)$. The space requirement of their approximate distance oracle is, therefore, essentially optimal. Also note that the preprocessing time of $(2k-1)$ -approximate distance oracle is $O(mn^{1/k})$, which is sub-cubic. However, for further improvement in the computation time for approximate distance oracles, Thorup and Zwick pose the following question: *Can $(2k-1)$ -approximate distance oracle be computed in $\tilde{O}(n^2)$ time?* Recently Baswana and Sen [9] answer their question in affirmative for unweighted graphs. However, the question for weighted graphs is still open.

For maintaining fully dynamic all-pairs shortest paths in graphs, the best known algorithm is due to Demetrescu and Italiano [10]. They show that it takes $O(n^2)$ amortized time to maintain all-pairs exact shortest paths after each update in the graph. Baswana et al. [11] present a hierarchical data-structure based on random sampling that provides efficient decremental algorithm for maintaining APASP in undirected unweighted graphs. In addition to achieving $o(nd)$ update time for the problem APASP- d (as described in this chapter), they also employ the same hierarchical scheme for designing efficient data-structures for maintaining approximate distance information for all-pairs of vertices separated by distance in an interval $[a, b]$, $1 \leq a < b \leq n$.

40.1 Introduction

In many cases of algorithm design, the comparison-based model of computation is not the obvious choice. In this chapter, we show how to design data structures with very good complexity on a realistic model of computation where keys are regarded as binary strings, each one contained in one or more machine words (registers). This model is sometimes referred to as the *RAM model*,[†] and it may be argued that it reflects real computers more accurately than the comparison-based model.

In the RAM-model the *word length* becomes a natural part of the model. A comparison does not necessarily take constant time, on the other hand we may use a larger variety of operations on data. This model allows for comparison-based algorithms to be used but also for algorithms like tries, bucket sort, radix sort etc, which are known to be efficient in practice.

40.2 Model of Computation

We use a unit-cost RAM with word size w . In the standard case we assume that the n keys are w -bit keys that can be treated as binary strings or integers, but we may also consider key that occupy multiple words. It should be noted that the assumption that keys can be treated as binary strings or integers also holds for floating-point numbers (*cf.* IEEE 754 floating-point standard [1, p. 228]).

In the RAM-model, we can use other operations than comparisons, for instance indirect addressing, shifting, bitwise logical operations, and multiplication. Without loss of generality, we assume that $w = \Omega(\log n)$, since otherwise we could not even fit the number n , or a pointer, into a machine word. (If we can not fit the number n into a constant number of words, the traditional analysis for comparison-based algorithms would also fail.)

Our complexity analysis has *two* parameters, the number of keys n and the word length w . In cases where the complexity is expressed only in terms of n , it is supposed to hold for any possible value of w , and vice versa.

For the searching problem, we assume that an ordered set is maintained and that operations like range queries and neighbour queries are supported. We say that we study ordered dictionaries, as defined below.

^{*} This chapter has been reprinted from first edition of this Handbook, without any content updates.

[†] The term RAM is used for many models. There are also RAM models with infinite word length.

Definition 40.1

A dictionary is ordered if neighbour queries and range queries are supported at the same cost as member queries (plus the reporting cost), and if the keys can be reported in sorted order in linear time.

40.3 Overview

The basic purpose of this chapter is to introduce some of the basic techniques and give references to recent development:

- We start by presenting some simple data structures, which allow us to explain how the “information-theoretic $O(\log n)$ barrier” may be surpassed. These data structures use a two-step approach: First, *range reduction* is used to decrease key length, such that we only need to consider keys that are much shorter than w . Secondly, we treat these short keys efficiently by *packed computing* where many keys are packed together in words.
- Next, we discuss some more elaborate data structures. In particular, we show how to achieve low worst-case complexity in linear space.
 - i. The fusion tree, the first data structure presented that achieved sublogarithmic complexity.
 - ii. The *exponential search tree*, which achieves tight worst-case bound on dynamic ordered dictionaries.
- We also give references to recent results on efficient priority queue implementations and sorting.

40.4 Achieving Sub-Logarithmic Time per Element by Simple Means

In this section, we show that it is surprisingly simple to achieve a sublogarithmic complexity in n independent of w , which implies sorting and searching asymptotically faster than comparison-based algorithms.

We use indirect addressing and large arrays. As a consequence, the data structures will need much space. However, all algorithms presented here can be fit into linear space with randomization (i.e., with universal hashing [2]).

In some cases, we will consider keys that are shorter than w , we will then use b or k to denote key length.

In this section, we will use $F(n, b)$ to express the complexity of searching, as specified below.

Definition 40.2

Let $F(n, b)$ be the worst-case cost of performing one search or update in an ordered dictionary storing n keys of length b .

Unless we use hashing to obtain linear space, the methods discussed in this section can all be implemented with a simple instruction set. All necessary instructions are standard, they are even in AC^0 . (An instruction is in AC^0 if it is implementable by a constant depth, unbounded fan-in (AND,OR,NOT)-circuit of size $w^{O(1)}$. An example of a non- AC^0 instruction is multiplication [3].)

40.4.1 Range Reduction

One way to simplify a computational problem is by *range reduction*. In this case, we reduce the problem of dealing with w -bit keys to that of dealing with k -bit keys, $k < w$.

Assume that we view our w -bit keys as consisting of two $w/2$ -bit characters and store these in a trie of height 2. Each internal node in the trie contains

- a reference to the min-element below the node; the min-element is not stored in any subtrie;
- a table of subtrees, where each existing subtree is represented by a $w/2$ -bit key;
- a data structure for efficient neighbour search among the $w/2$ -bit keys representing the subtrees.

Since each node except the root has one incoming edge and each node contains exactly one element (the min-element), the trie has exactly n nodes and $n - 1$ edges.

We make neighbour searches in the following way: Traverse down the trie. If we find a leaf, the search ends, otherwise we end up at an empty entry in the subtree table of some node. By making a neighbour search in that node, we are done. The cost for traversing the trie is $O(1)$ and the cost for a local neighbour search is $O(F(n, b/2))$ by definition.

The space requirements depend on how the table of subtree pointers is implemented. If the table is implemented as an array of length $2^{b/2}$, each node in the trie requires $\Theta(2^{b/2})$ space. If we instead represent each table as a hash table, the total space of all hash tables is proportional to the total number of edges in the trie, which is $n - 1$.

We summarize this in the following equation.

$$F(n, w) = O(1) + F\left(\frac{n, w}{2}\right). \quad (40.1)$$

We can use the same construction recursively. That is, the local data structure for neighbour search among $w/2$ -bit keys can be a trie of height 2 where $w/4$ bits are used for branching, etc.

In order to apply recursion properly, we have to be a bit careful with the space consumption. First, note that if the number of edges in a trie with n elements was larger than n , for instance $2n$, the total space (number of edges) would grow exponentially with the number of recursive levels. Therefore, we need to ensure that the number of edges in a trie is not just $O(n)$ but actually at most n . This is the reason why each node contains a min-element; in this way we guarantee that the number of edges is $n - 1$.

Secondly, even when we can guarantee that the space per recursive level does not increase, we are still faced with $\Theta(n)$ space (with hashing) per level. If we use more than a constant number of levels, this will require superlinear space. This is handled in the following way: When we apply the recursive construction r times, we only keep a small part of the elements in the recursive structure. Instead, the elements are kept in sorted lists of size $\Theta(r)$, and we keep only the smallest element from each list in our recursive trie. When searching for a key, we first search for its list in the recursive trie structure, we then scan the list. Insertions and deletions are made in the lists, and the sizes of the lists are maintained by merging and splitting lists. Now, the total space taken by each level of the recursive trie construction is $\Theta(n/r)$ and the total space for r recursive levels is $\Theta(n)$. Searching, splitting and merging within the lists only takes $O(r)$ time. In summary, setting $r = \log(w/k)$ we get the following lemma.

Lemma 40.1

$$F(n, w) = O(\log(w/k)) + F(n, k).$$

This recursive reduction was first used in van Emde Boas trees [4–7].

40.4.2 Packing Keys

If the word length is small enough—as in today’s computers—the range reduction technique discussed above will decrease the key length to a constant at a low cost. However, in order to make a really convincing comparison between comparison-based algorithms and algorithms based on indirect addressing, we must make the complexity independent of the word size. This can be done by combining range reduction with *packed computation*. The basic idea behind packed computation is to exploit the bit-parallelism in a computer; many short keys can be packed in a word and treated simultaneously.

The central observation is due to Paul and Simon [8]; they observed that one subtraction can be used to perform comparisons in parallel. Assume that the keys are of length k . We may then pack $\Theta(w/k)$ keys in a word in the following way: Each key is represented by a $(k+1)$ -bit field. The first (leftmost) bit is a *test bit* and the following bits contain the key, cf. Figure 40.1. Let X and Y be two words containing the same number of packed keys, all test bits in X are 0 and all test bits in Y are 1. Let M be a fixed mask in which all test bits are 1 and all other bits are 0. Let

$$R \leftarrow (Y - X) \text{ AND } M. \quad (40.2)$$

Then, the i th test bit in R will be 1 if and only if $y_i > x_i$. All other test bits, as well as all other bits, in R will be 0.

We use packed comparisons to achieve the following result.

Lemma 40.2

$$F(n, k) = O\left(\log(w/k) + \frac{\log n}{\log(w/k)}\right).$$

Y	1	00010	1	00111	1	01001	1	01110	1	10101	1	11000	1	11011	1	11110
X	0	01011	0	01011	0	01011	0	01011	0	01011	0	01011	0	01011	0	01011
$Y - X$	0	10111	0	11100	0	11110	1	00011	1	01010	1	01101	1	10000	0	10011
M	1	00000	1	00000	1	00000	1	00000	1	00000	1	00000	1	00000	1	00000
$(Y - X) \text{ AND } M$	0	00000	0	00000	0	00000	1	00000	1	00000	1	00000	1	00000	1	00000

FIGURE 40.1 A multiple comparison in a packed B-tree.

Proof. (Sketch) We use a packed B-tree [9].

The packed B-tree has nodes of degree $\Theta(w/k)$. In each node, the search keys are packed together in a single word, in sorted order from left to right. When searching for a k -bit key x in a packed B-tree, we take the following two steps:

1. We construct a word X containing multiple copies of the query key x . X is created by a simple doubling technique: Starting with a word containing x in the rightmost part, we copy the word, shift the copy $k+1$ steps and unite the words with a bitwise or. The resulting word is copied, shifted $2k+2$ steps and united, etc. Altogether X is generated in $O(\log(w/k))$ time.
2. After the word X has been constructed, we traverse the tree. At each node, we compute the rank of x in constant time with a packed comparison. The cost of the traversal is proportional to the height of the tree, which is $O(\log n / \log(w/k))$.

A packed comparison at a node is done as in Expression 40.2. The keys in the B-tree node are stored in Y and X contains multiple copies of the query key. After subtraction and masking, the rightmost p test bits in R will be 1 if and only if there are p keys in Y which are greater than x . This is illustrated in Figure 40.1. Hence, by finding the position of the leftmost 1-bit in R we can compute the rank of x among the keys in Y . In order to find the leftmost key, we can simply store all possible values of R in a lookup table. Since the number of possible values equals the number of keys in a B-tree node plus one, a hash table implementation of this lookup table would require only $\Theta(w/k)$ space. ■

Above, we omitted a lot of details, such as how to perform updates and how pointers within a packed B-tree are represented. Details can be found in [9].

40.4.3 Combining

We can now derive our first bounds for searching. First, we state bounds in terms of w . The following bound holds for searching [4–6]:

Theorem 40.1

$$F(n, w) = O(\log w).$$

Proof. (Sketch) Apply Lemma 40.1 with $k = 1$. ■

Next, we show how to remove the dependency of word length [9]:

Theorem 40.2

$$F(n, w) = O(\sqrt{\log n}).$$

Proof. (Sketch) If $\log w = O(\sqrt{\log n})$, Theorem 40.1 is sufficient. Otherwise, Lemma 40.1 with $k = w/2\sqrt{\log n}$ gives $F(n, w) = O(\sqrt{\log n}) + F(n, w/2\sqrt{\log n})$. Lemma 40.2 gives that $F(n, w/2\sqrt{\log n}) = O(\sqrt{\log n})$. ■

40.5 Deterministic Algorithms and Linear Space

The data structures in this section are more complicated than the previous ones. They also need more powerful—but standard—instructions, like multiplication. On the other hand, these structures achieves linear space without randomization (i.e., without hashing).

Definition 40.3

Let $D(n)$ be the worst-case search cost and the amortized update cost in an ordered dictionary storing n keys in $O(n)$ space.

40.5.1 Fusion Trees

The fusion tree was the first data structure to surpass the logarithmic barrier for searching. The central part of the fusion tree [10] is a static data structure with the following properties:

Lemma 40.3

For any d , $d = O(w^{1/6})$, a static data structure containing d keys can be constructed in $O(d^4)$ time and space, such that it supports neighbour queries in $O(1)$ worst-case time.

Proof. (Sketch) The main idea behind the fusion tree is to view the keys as stored in an implicit binary trie and concentrate at the branching levels in this trie. We say that branching occurs at significant bit positions. We illustrate this view with an example, shown in Figure 40.2.

In the example, $w = 16$ and $d = 6$. We store a set Y of keys y_1, \dots, y_d . Each key in Y is represented as a path in a binary trie. In the figure, a left edge denotes a 0 and a right edge denotes a 1. For example, y_3 is $[1010010101011010]$. The significant bit positions correspond to the branching levels in the trie. In this example the levels are 4, 9, 10, and 15, marked by horizontal lines. By extracting the significant bit positions from each key, we create a set Y' of compressed keys y'_1, \dots, y'_d . In our example the compressed keys are $[0000], [0001], [0011], [0110], [1001]$, and $[1011]$. Since the trie has exactly d leaves, it contains exactly $d - 1$ binary nodes. Therefore, the number of significant bit positions, and the length of a compressed key, is at most $d - 1$. This implies that we can pack the d keys, including test bits, in d^2 bits. Since $d = O(w^{1/6})$, the packed keys fit in a constant number of words.

This extraction of bits is nontrivial; it can be done with multiplication and masking. However, the extraction is not as perfect as described here; in order to avoid problems with carry bits etc, we need to extract some more bits than just the significant ones. Here, we ignore these problems and assume that we can extract the desired bits properly. For details we refer to Fredman and Willard [10].

The d compressed keys may be used to determine the rank of a query key among the original d keys with packed computation. Assume that we search for $x = [1010011001110100]$, represented as the fat path in Figure 40.2. First, we extract the proper bits to form a compressed key $x' = [0010]$. Then, we use packed searching to determine the rank of x' among y'_1, \dots, y'_d . In this case, the packed searching will place x' between y'_2 and y'_3 , as indicated by the arrow in Figure 40.2. This is not the proper rank of the original key x , but nevertheless it is useful. The important information is obtained by finding the position of the first differing bit of x and one of the keys y_2 and y_3 . In this example, the 7th bit is the first differing bit, and, since x has a 1 at this bit position, we can conclude that it is greater than all keys in Y with the same 6-bit prefix. Furthermore, the remaining bits in x are insignificant. Therefore, we can replace x by the key $[1010011111111111]$, where all the last bits are 1s. When compressed, this new key becomes $[0111]$. Making a second packed searching with this key instead, the proper rank will be found.

Hence, in constant time we can determine the rank of a query key among our d keys. \blacksquare

The original method by Fredman and Willard is slightly different. Instead of filling the query keys with 1s (or 0s) and making a second packed searching, they use a large lookup table in each node. Fusion trees can be implemented without multiplication, using only AC⁰ instructions, provided that some simple non-standard instructions are allowed [11].

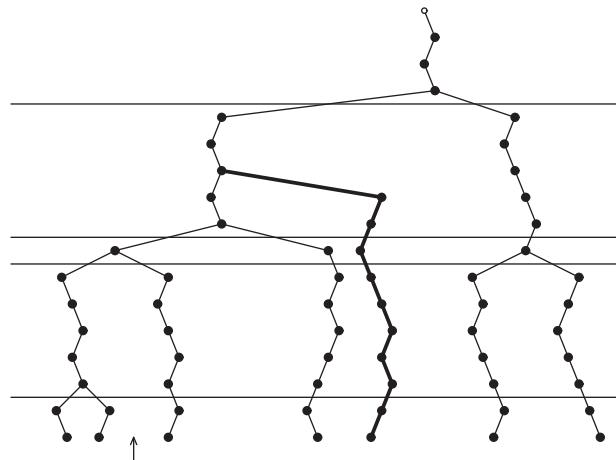

FIGURE 40.2 Searching in the internal trie in a fusion tree node. Horizontal lines represent significant bit positions. The thin paths represent the 6 keys in the trie, while the fat path represents the search key x (which is not present in the trie). The arrow marks the position of the compressed key x' among the keys in the trie.

Theorem 40.3

$$D(n) = O(\log n / \log \log n).$$

Proof. (Sketch) Based on Lemma 40.3, we use a B-tree where only the upper levels in the tree contain B-tree nodes, all having the same degree (within a constant factor). At the lower levels, traditional (i.e., comparison-based) weight-balanced trees are used. The reason for using weight-balanced trees is that the B-tree nodes are costly to reconstruct; the trees at the bottom ensure that few updates propagate to the upper levels. In this way, the amortized cost of updating a B-tree node is small.

The amortized cost of searches and updates is $O(\log n / \log d + \log d)$ for any $d = O(w^{1/6})$. The first term corresponds to the number of B-tree levels and the second term corresponds to the height of the weight-balanced trees. Since $w \geq \log n$ (otherwise a pointer would not fit in a word), the cost becomes at most $O(\log n / \log \log n)$. ■

40.5.2 Exponential Search Trees

The *exponential search tree* [12,13] allows efficient dynamization of static dictionary structures. The key feature is:

Any static data structure for searching that can be constructed in polynomial time and space can be efficiently used in a dynamic data structure.

The basic data structure is a multiway tree where the degrees of the nodes decrease doubly-exponentially down the tree. In each node, we use a static data structure for navigation. The way the tree is maintained, we can guarantee that, before an update occurs at a certain node, a polynomial number of updates will be made below it. Hence, even if an update requires a costly reconstruction of a static data structure, this will occur with large enough intervals.

Lemma 40.4

Suppose a static data structure containing d keys can be constructed in $O(d^4)$ time and space, such that it supports neighbour queries in $O(S(d))$ worst-case time. Then,

$$D(n) = O(S(n^{1/5})) + D(n^{4/5});$$

Proof. (Sketch) We use an exponential search tree. It has the following properties:

- Its root has degree $\Theta(n^{1/5})$.
- The keys of the root are stored in a local (static) data structure, with the properties stated above. During a search, the local data structure is used to determine in which subtree the search is to be continued.
- The subtrees are exponential search trees of size $\Theta(n^{4/5})$.

First, we show that, given n sorted keys, an exponential search tree can be constructed in linear time and space. The cost of constructing a node of degree d is $O(d^4)$, and the total construction cost $C(n)$ is (essentially) given by

$$C(n) = O((n^{1/5})^4) + n^{1/5} \cdot C(n^{4/5}) \Rightarrow C(n) = O(n). \quad (40.3)$$

Furthermore, with a similar equation, the space required by the data structure can be shown to be $O(n)$.

Balance is maintained by joining and splitting subtrees. The basic idea is the following: A join or split occurs when the size of a subtree has changed significantly, that is, after $\Omega(n^{4/5})$ updates. Then, a constant number of subtrees will be reconstructed; according to Equation 40.3, the cost of this is linear in the size of the subtrees $= O(n^{4/5})$. Also, some keys will be inserted or deleted from the root, causing a reconstruction of the root; the cost of this is by definition $O(n^{4/5})$. Amortizing these two costs over the $\Omega(n^{4/5})$ updates, we get $O(1)$ amortized cost for reconstructing the root. Hence, the restructuring cost is dominated by the search cost.

Finally, the search cost follows immediately from the description of the exponential search tree. ■

Exponential search trees may be combined with various other data structures, as illustrated by the following two lemmas:

Lemma 40.5

A static data structure containing d keys can be constructed in $O(d^4)$ time and space, such that it supports neighbour queries in $O\left(\frac{\log d}{\log w} + 1\right)$ worst-case time.

Proof. (Sketch) We just construct a static B-tree where each node has the largest possible degree according to Lemma 40.3. That is, it has a degree of $\min(d, w^{1/6})$. This tree satisfies the conditions of the lemma. ■

Lemma 40.6

A static data structure containing d keys and supporting neighbour queries in $O(\log w)$ worst-case time can be constructed in $O(d^4)$ time and space.

Proof. (Sketch) We study two cases.

Case 1: $w > d^{1/3}$. Lemma 40.5 gives constant query cost.

Case 2: $w \leq d^{1/3}$. The basic idea is to combine a van Emde Boas tree (Theorem 40.1) with perfect hashing. The data structure of Theorem 40.1 uses much space, which can be reduced to $O(d)$ by hash coding. Since we can afford a rather slow construction, we can use the deterministic algorithm by Fredman, Komlós, and Szemerédi [14]. With this algorithm, we can construct a perfectly hashed van Emde Boas tree in $O(d^3 w) = o(d^4)$ time. ■

Combining these two lemmas, we get a significantly improved upper bound on deterministic sorting and searching in linear space:

Theorem 40.4

$$D(n) = O(\sqrt{\log n}).$$

Proof. (Sketch) If we combine Lemmas 40.4–40.6, we obtain the following equation

$$D(n) = O\left(\min\left(1 + \frac{\log n}{\log w}, \log w\right)\right) + D(n^{4/5}) \quad (40.4)$$

which, when solved, gives the theorem. ■

Taking both n and w as parameters, $D(n)$ is $o(\sqrt{\log n})$ in many cases [12]. For example, it can be shown that $D(n) = O(\log w \log \log n)$.

The strongest possible bound is achieved by using the following result by Beame and Fich [3]

Lemma 40.7: (Beame and Fich [3])

In polynomial time and space, we can construct a deterministic data structure over d keys supporting searches in $O(\min\{\sqrt{\log d / \log \log d}, \frac{\log w}{\log \log w}\})$ time.

Combining this with the exponential search tree we get, among others, the following theorem.

Theorem 40.5

$$D(n) = O(\sqrt{\log n / \log \log n}).$$

Since a matching lower bound was also given by Beame and Fich, this bound is optimal.

40.6 From Amortized Update Cost to Worst-Case

In fact, there are worst-case efficient versions of the data structures above. Willard [15] gives a short sketch on how to make fusion trees worst-case efficient, and as shown by Andersson and Thorup [13], the exponential search tree can be modified into a worst-case data structure. Here, we give a brief description of how exponential search trees are modified.

In the above definition of exponential search trees, the criteria for when a subtree is too large or too small depend on the degree of its parent. Therefore, when a node is joined or split, the requirements on its children will change. Above, we handled that by simply rebuilding the entire subtree at each join or split, but in a worst-case setting, we need to let the children of a node remain unchanged at a join or split. In order to do this, we need to switch from a top-down definition to a bottom-up definition.

Definition 40.4: (Worst-case efficient exponential search trees)

In an exponential search tree all leaves are on the same depth. Let the height of a node to be the distance from the node to the leaves descending from it. For a non-root node v at height $i > 0$, the weight (number of descending leaves) is $|v| = \Theta(n_i)$ where $n_i = \alpha^{(1+1/(k-1))^i}$ and $\alpha = \Theta(1)$. If the root has height h , its weight is $O(n_h)$.

With the exception of the root, Definition 40.4 follows our previous definition of exponential search trees (when $k = 5$), that is, if v is a non-root node, it has $\Theta(|v|^{1/k})$ children, each of weight $\Theta(|v|^{1-1/k})$.

The worst-case efficiency is mainly based on careful scheduling: the static search structures in the nodes are rebuilt in the background so that they remain sufficiently updated as nodes get joined and split. This scheduling is developed in terms of a general theorem about rebuilding, which has some interesting properties as a tool for other de-amortization applications [13].

40.7 Sorting and Priority Queues

In the comparison-based model of computation, the cost per element is the same ($O(\log n)$) for searching and sorting. However, in the RAM model of computation, the sorting problem can be solved faster than searching. The simple intuitive explanation of this is that the bit-parallelism in packed computation can be utilized more efficiently when a number of keys are treated simultaneously, as in sorting, than when they are treated one-by-one as in searching.

Even more, it turns out that priority queues can be as implemented as efficiently as sorting. (The intuitive reason for this is that a priority queue can use sorting as a subroutine, and only keep a small part of the queue perfectly sorted.) Thorup [16] has shown the following reduction:

Theorem 40.6

If we can sort n keys in time $S(n)$ per key, then we can implement a priority queue supporting find-min in constant time and updates (insert and delete) in $S(n)$ time.

In the following, we will use $T(n, b)$ to denote the cost of sorting n b -bit keys.

40.7.1 Range Reduction

In sorting algorithms, range reduction is an often used technique. For example, we may view traditional radix sort, where we sort long strings by dividing them into shorter parts, as range reduction.

For our purposes, we will use a range reduction technique by Kirkpatrick and Reisch [17], which is similar to the van Emde Boas tree, cf. Section 40.4.1. The only difference from Section 40.4.1 is that instead of letting each trie node contain a data structure for efficient neighbour search among the outgoing edges, we just keep an unsorted list of all outgoing edges (plus the array for constant-time indexing of edges). Then, after all elements have been inserted into the trie, we create sorted lists of edges at all nodes by the following method:

1. Mark each edge with its parent node.
2. Concatenate all edge lists and sort the entire list.
3. Scan the sorted list and put each edge back in the proper node.
4. All edges lists are now sorted. By a recursive traversal of the trie we can report all leafs in sorted order.

Other details, such as the need to store one key per node to avoid space blow up, are handled in the same way as in Section 40.4.1. Altogether, we get the reduction

$$T(n, w) = O(n) + T(n, w/2). \quad (40.5)$$

Applied recursively, this gives

$$T(n, w) = O(n \log(w/k)) + T(n, k). \quad (40.6)$$

40.7.2 Packed Sorting

For the sorting problem, multiple comparisons can be utilized more efficiently than in a packed B-tree. In the packed B-tree, we used the bit-parallelism to compare one key to many keys, in this way we implemented a parallel version of a linear search, which is not the most efficient search method.

For sorting, however, we can utilize the packed computation more efficiently. It turns out that algorithms for *sorting networks* are well suited for implementation by packed computation. A sorting network is a “static” algorithm; it contains a number of

compare-and-swap operations, these are the same regardless of the outcome of the comparisons. The merging technique by Batcher [18], originally used to design *odd-even merge sort*, can be efficiently implemented with packed computation. As a sorting network, Batcher's merging algorithm has depth $\Theta(\log n)$ where each level has $O(n)$ compare-and-swap units. Based on the merging, we can sort in $\Theta(\log^2 n)$ time where the total work is $\Theta(n \log^2 n)$.

Batcher's merging technique is well suited for combination with the Paul-Simon technique, as shown by Albers and Hagerup [19].

Lemma 40.8

$$T(n, w/\log n) \leq O(n \log \log n).$$

Proof. (Sketch) The key idea is that by packing $\Theta(\log n)$ keys in a machine word, we can combine Batcher's algorithm with packed computation to merge two sorted sequences in $O(\log \log n)$ time. And, if we can merge two sequences of length $\Theta(\log n)$ in $O(\log \log n)$ time (instead of $O(\log n)$ by a comparison-based algorithm), we can use this as a subroutine to implement a variant of merge sort that sorts n keys in $O(n \log \log n)$ time (instead of $O(n \log n)$). ■

40.7.3 Combining the Techniques

First, the bound on searching from Theorem 40.1 has a corresponding theorem for sorting [17]:

Theorem 40.7

$$T(n, w) = O(n \log(w/\log n)).$$

Proof. (Sketch) Apply Eq. 40.6 with $k = \log n$. Keys of length $\log n$ can be sorted in linear time with bucket sort. ■

Secondly, we combine range reduction with packed computation. We get the following bound [20]:

Theorem 40.8

$$T(n, w) = O(n \log \log n).$$

Proof. (Sketch) If $\log w = O(\log \log n)$, Theorem 40.7 is sufficient. Otherwise, Eq. 40.6 with $k = w/\log n$ gives $T(n, w) = O(n \log \log n) + T(n, w/\log n)$. Lemma 40.8 gives the final bound. ■

40.7.4 Further Techniques and Faster Randomized Algorithms

Apart from these rather simple techniques, there are a number of more elaborate techniques that allows the complexity to be improved further. Examples of such techniques are *signature sort* [20] and *packed bucketing* [21]. Here, we give a short sketch of signature sorting.

Consider a situation where the word length w is very large, and we wish to reduce the problem of sorting w -bit keys to that of sorting k -bit keys, $k \gg \log n$. Instead of treating these k -bit keys directly, we represent each such key by a b -bit *signature*, where the b bits are a hash function of the k bits. In fact, for one w -bit key, we can in constant time replace it by a shorter key, consisting of q b -bit signatures (for details, we refer to the literature [20,21]).

1. Replace each w -bit key by a qb -bit key of concatenated signatures.
2. Sort the qb -bit keys.
3. Compute, for each qb -bit key, its first distinguishing signature. This can be done by constructing a signature-based trie of all keys.
4. If we know the first distinguishing signature in a qb -bit key, we know the first distinguishing k -bit field in the corresponding w -bit key. Finding these k -bit fields, the range reduction is completed and we can continue by sorting these shorter keys.

It should be noted that the sorted set of qb -bit keys does not correspond to a sorted set of w -bit keys. However, the ordering we get is enough to find the proper distinguishing fields. Furthermore, since we use hash coding, we might get collisions, in which case the method will not work. By choosing b large enough, the risk of failure is small enough that we can afford to redo the entire sorting in case of failure: still the expected time for the range reduction step will be linear.

As an important recent result, Han and Thorup presents a linear algorithm for splitting n integers into subsets, where each subset is of size $O(\log n)$. Combining this with techniques like signature sorting, they manage to improve the randomized complexity

of sorting to $O(n\sqrt{\log \log n})$. This, in turn, implies that a priority queue can be implemented at $O(\sqrt{\log \log n})$ time per update and find-min in constant time.

41.1 Introduction

A *functional data structure* is a data structure that is suitable for implementation in a functional programming language, or for coding in an ordinary language like C or Java using a functional style. Functional data structures are closely related to *persistent data structures* and *immutable data structures*—in fact, the three terms are often used interchangeably. However, there are subtle differences.

- The term *persistent data structures* refers to the general class of data structures in which an update does not destroy the previous version of the data structure, but rather creates a new version that co-exists with the previous version. See [Chapter 33](#) for more details about persistent data structures.
- The term *immutable data structures* emphasizes a particular implementation technique for achieving persistence, in which memory devoted to a particular version of the data structure, once initialized, is never altered.
- The term *functional data structures* emphasizes the language or coding style in which persistent data structures are implemented. Functional data structures are always immutable, except in a technical sense discussed in Section 41.4.

In this chapter, we will discuss the main issues surrounding the implementation of data structures in functional languages, and illustrate these issues with several extended examples. We will also show how to adapt functional data structures to a mainstream language such as Java, for use when a persistent data structure is required. Readers wishing more details about functional data structures should consult Okasaki [1].

41.1.1 Data Structures in Functional Languages

Functional programming languages differ in several important ways from ordinary programming languages like C or Java, and these differences can sometimes have a large effect on how data structures are implemented. The main differences (at least from the perspective of data structures) are *immutability*, *recursion*, *garbage collection*, and *pattern matching*.

41.1.1.1 Immutability

In functional languages, variables and records cannot be modified, or *mutated*, once they have been created.[†] Many textbook data structures depend critically on the ability to mutate variables and records via assignments. Such data structures can be difficult to adapt to a functional setting.

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

† Actually, many functional languages do provide mechanisms for mutation, but their use is discouraged.

41.1.1.2 Recursion

Functional languages frequently do not support looping constructs, such as for-loops or while-loops, because such loops depend on being able to mutate the loop control variable. Functional programmers use recursion instead.^{*}

41.1.1.3 Garbage Collection

Functional languages almost always depend on automatic garbage collection. Because objects are immutable in functional languages, they are shared much more widely than in ordinary languages, which makes the task of deciding when to deallocate an object very complicated. In functional languages, programmers ignore deallocation issues and allow the garbage collector to deallocate objects when it is safe to do so.

41.1.1.4 Pattern Matching

Pattern matching is a method of defining functions by cases that are essentially textual analogues of the kinds of pictures data-structure designers often draw. Pattern matching is not supported by all functional languages, but, when available, it allows many data structures to be coded very concisely and elegantly.

41.1.2 Functional Data Structures in Mainstream Languages

Even if you are programming in a mainstream language, such as C or Java, you may find it convenient to use a functional data structure. Functional data structures offer three main advantages in such a setting: *fewer bugs*, *increased sharing*, and *decreased synchronization*.

41.1.2.1 Fewer Bugs

A very common kind of bug arises when you observe a data structure in a certain state and shortly thereafter perform some action that assumes the data structure is still in that same state. Frequently, however, something has happened in the meantime to alter the state of the data structure, so that the action is no longer valid. Because functional data structures are immutable, such alterations simply cannot occur. If someone tries to change the data structure, they may produce a new version of it, but they will in no way effect the version that you are using.

41.1.2.2 Increased Sharing

Precisely to avoid the kinds of bugs described above, programmers in mainstream languages are careful to limit access to their internal data structures. When sharing is unavoidable, programmers will often clone their data structures and share the clones rather than granting access to their own internal copies. In contrast, functional data structures can be shared safely without cloning. (Actually, functional data structures typically perform a substantial amount of cloning internally, but this cloning is of individual nodes rather than entire data structures.)

41.1.2.3 Decreased Synchronization

Again, precisely to avoid the kinds of bugs described above, programmers in concurrent settings are careful to synchronize access to their data structures, so that only a single thread can access the data structure at a time. On the other hand, because functional data structures are immutable, they can often be used with little or no synchronization. Even simultaneous writes are not a problem, because each writer thread will get a new version of the data structure that reflects only its own updates. (This assumes, of course, an application where participants do not necessarily want to see changes made by all other participants.)

41.2 Stacks: A Simple Example

Stacks (see [Chapter 2](#)) represented as singly-linked lists are perhaps the simplest of all data structures to make persistent. We begin by describing functional stacks supporting four main primitives:

- `empty`: a constant representing the empty stack.
- `push(x, s)` : push the element x onto the stack s and return the new stack.
- `top(s)` : return the top element of s .
- `pop(s)` : remove the top element of s and return the new stack.

^{*} Or higher-order functions, but we will not discuss higher-order functions further because they have relatively little effect on the implementation of data structures.

We can see right away several differences between this interface and the interface for ordinary stacks. First, for ordinary stacks, `push` and `pop` would implicitly change the existing stack `s` rather than returning a new stack. However, the hallmark of functional data structures is that update operations return a new version of the data structure rather than modifying the old version. Second, ordinary stacks would support a function or constructor to *create* a fresh, new stack, rather than offering a single constant to represent all empty stacks. This highlights the increased sharing possible with functional data structures. Because pushing an element onto the empty stack will not change the empty stack, different parts of the program can use the same empty stack without interfering with each other.

[Figure 41.1](#) shows an implementation of stacks in Haskell [2], a popular functional programming language. [Figure 41.2](#) shows a similar implementation in Java. Like all code fragments in this chapter, these implementations are intended only to illustrate the relevant concepts and are not intended to be industrial strength. In particular, all error handling has been omitted. For example, the `top` and `pop` operations should check whether the stack is empty. Furthermore, programming conventions in Haskell and Java have been ignored where they would make the code harder for non-fluent readers to understand. For example, the Haskell code makes no use of currying, and the Java code makes no attempt to be object-oriented.

The Haskell code illustrates a simple use of pattern matching. The declaration

```
data Stack = Empty | Push(Element,Stack)
```

states that stacks have two possible shapes, `Empty` or `Push`, and that a stack with the `Push` shape has two fields, an element and another stack. The tags `Empty` and `Push` are called *constructors*. Later function declarations can match against these constructors. For example, the declaration

```
top(Push(x,s)) = x
```

says that when `top` is called on a stack with the `Push` shape, it returns the contents of the first field. If desired, more clauses can be added to deal with other shapes. For example, a second clause could be added to the definition of `top` to handle the error case:

```
top(Push(x,s)) = x
top(Empty) = ...signal an error...
```

How do these implementations achieve persistence? First, consider the `push` operation. Calling `push` creates a new node containing the new element and a pointer to the old top of stack, but it in no way alters the old stack. For example, if the old stack `s` contains the numbers 3, 2, 1 and we `push` 4, then the new stack `s'` contains the numbers 4, 3, 2, 1. [Figure 41.3](#) illustrates

```
data Stack = Empty | Push(Element,Stack)

empty = Empty
push(x,s) = Push(x,s)
top(Push(x,s)) = x
pop(Push(x,s)) = s
```

FIGURE 41.1 Stacks in Haskell.

```
public class Stack {
    public static final Stack empty = null;
    public static Stack push(Element x,Stack s) { return new Stack(x,s); }
    public static Element top(Stack s) { return s.element; }
    public static Stack pop(Stack s) { return s.next; }

    private Element element;
    private Stack next;
    private Stack(Element element,Stack next) {
        this.element = element;
        this.next = next;
    }
}
```

FIGURE 41.2 Stacks in Java.

$$s' = \text{push}(4, s)$$

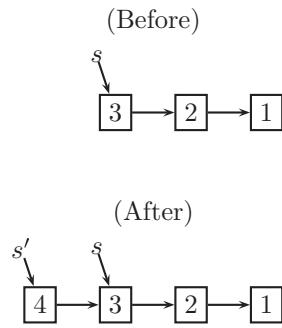

FIGURE 41.3 The push operation.

$$s'' = \text{pop}(s')$$

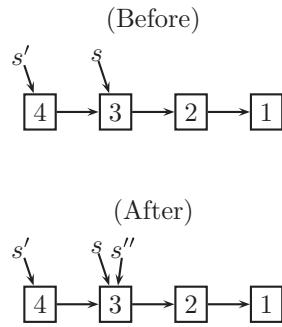

FIGURE 41.4 The pop operation.

the relationship between s and s' . Notice how the nodes containing 3, 2, and 1 are shared between both stacks. Because of this sharing, it is crucial that the nodes are immutable. Consider what would happen if nodes could be changed. If we were to change the 3 to a 5, for example, perhaps by calling an operation to update the top element of s , that change would affect not only s (which would now contain 5, 2, 1) but also s' (which would now contain 4, 5, 2, 1). Such unintended consequences would make sharing impossible.

Next, consider the `pop` operation, which simply returns the *next* pointer of the current node without changing the current node in any way. For example, Figure 41.4 illustrates the result of popping the stack s' to get the stack s'' (which shares its entire representation with the original stack s). Notice that, after popping s' , the node containing 4 may or may not be garbage. It depends on whether any part of the program is still using the s' stack. If not, then automatic garbage collection will eventually deallocate that node.

41.3 Binary Search Trees: Path Copying

Stacks are unusual in that there is never a need to update an existing node. However, for most data structures, there is such a need. For example, consider inserting an element into a binary search tree (see Chapter 3). At the very least, we need to update the new node's parent to point to the new node. But how can we do this if nodes are immutable? The solution is a technique called *path copying*. To update an existing node, we copy the node and make the necessary changes in the copy. However, we then have to update the existing node's parent in a similar fashion to point to the copy. In this way, changes propagate all the way from the site of the update to the root, and we end up copying that entire path. That may seem like a lot of copying, but notice that all nodes not on that path are shared between the old and new versions.

To see how path copying works in practice, consider a simple implementation of integer sets as unbalanced binary search trees. Figure 41.5 shows an implementation in Haskell and Figure 41.6 shows the same implementation in Java.

```

data Tree = Empty | Node(Tree, Int, Tree)

empty = Empty
insert(x, Empty) = Node(Empty, x, Empty)
insert(x, Node(t1, y, t2)) = if x < y then Node(insert(x, t1), y, t2)
                           else if x > y then Node(t1, y, insert(x, t2))
                           else Node(t1, y, t2)
search(x, Empty) = False
search(x, Node(t1, y, t2)) = if x < y then search(x, t1)
                           else if x > y then search(x, t2)
                           else True

```

FIGURE 41.5 Binary search trees in Haskell.

```

public class Tree {
    public static final Tree empty = null;
    public static Tree insert(int x, Tree t) {
        if (t == null) return new Tree(null, x, null);
        else if (x < t.element)
            return new Tree(insert(x, t.left), t.element, t.right);
        else if (x > t.element)
            return new Tree(t.left, t.element, insert(x, t.right));
        else return t;
    }
    public static boolean search(int x, Tree t) {
        if (t == null) return false;
        else if (x < t.element) return search(x, t.left);
        else if (x > t.element) return search(x, t.right);
        else return true;
    }
    private int element;
    private Tree left, right;
    private Tree(Tree left, int element, Tree right) {
        this.left = left;
        this.element = element;
        this.right = right;
    }
}

```

FIGURE 41.6 Binary search trees in Java.

The key to understanding path copying lies in the `insert` operation. Consider the case where the element being inserted is larger than the element at the current node. In the Java implementation, this case executes the code

```
return new Tree(t.left, t.element, insert(x, t.right));
```

First, `insert` calls itself recursively on the right subtree, returning a pointer to the new right subtree. It then allocates a new tree node, copying the `left` and `element` fields from the old node, and installing the new pointer in the `right` field. Finally, it returns a pointer to the new node. This process continues until it terminates at the root. Figure 41.7 illustrates a sample insertion. Notice how the parts of the tree not on the path from the root to the site of the update are shared between the old and new trees.

This functional implementation of binary search trees has exactly the same time complexity as an ordinary non-persistent implementation. The running time of `insert` is still proportional to the length of the search path. Of course, the functional implementation allocates more space, but even that issue is not clear cut. If the old tree is no longer needed, then the just-copied nodes can immediately be garbage collected, leaving a net space increase of one node—exactly the same space required by a non-persistent implementation. On the other hand, if the old tree is still needed, then the just-copied nodes cannot be garbage collected, but in that case we are actively taking advantage of functionality not supported by ordinary binary search trees.

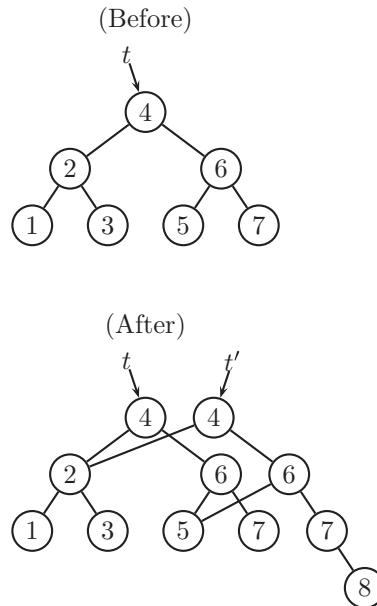

$$t' = \text{insert}(8, t)$$

FIGURE 41.7 The insert operation.

Of course, the binary search trees described above suffer from the same limitations as ordinary unbalanced binary search trees, namely a linear time complexity in the worst case. Whether the implementation is functional or not has no effect in this regard. However, we can easily apply the ideas of path copying to most kinds of *balanced* binary search trees (see [Chapter 11](#)), such as AVL trees [3,4], red-black trees [5], 2-3 trees [6], and weight-balanced trees [7]. Such a functional implementation retains the logarithmic time complexity of the underlying design, but makes it persistent.

Path copying is sufficient for implementing many tree-based data structures besides binary search trees, including binomial queues [8,9] ([Chapter 7](#)), leftist heaps [1,10] ([Chapter 5](#)), Patricia tries [11] ([Chapter 29](#)), and many others.

41.4 Skew Heaps: Amortization and Lazy Evaluation

Next, we turn to priority queues, or *heaps*, supporting the following primitives:

- `empty`: a constant representing the empty heap.
- `insert(x, h)`: insert the element x into the heap h and return the new heap.
- `findMin(h)`: return the minimum element of h .
- `deleteMin(h)`: delete the minimum element of h and return the new heap.
- `merge(h1, h2)`: combine the heaps h_1 and h_2 into a single heap and return the new heap.

Many of the standard heap data structures can easily be adapted to a functional setting, including binomial queues [8,9] and leftist heaps [1,10]. In this section, we describe a simple, yet interesting, design known as *skew heaps* [12]. (Non-persistent skew heaps are described in detail in [Chapter 6](#).)

A skew heap is a heap-ordered binary tree. Each node contains a single element, and the nodes are ordered such that the element at each node is no larger than the elements at the node's children. Because of this ordering, the minimum element in a tree is always at the root. Therefore, the `findMin` operation simply returns the element at the root. The `insert` and `deleteMin` operations are defined in terms of `merge`: `insert` creates a new node and merges it with the existing heap, and `deleteMin` discards the root and merges its children.

The interesting operation is `merge`. Assuming both heaps are non-empty, `merge` compares their roots. The smaller root (that is, the root with the smaller element) becomes the new overall root and its children are swapped. Then the larger root is merged with the new left child of the smaller root (which used to be the right child). The net effect of a `merge` is to interleave the rightmost paths of the two trees in sorted order, swapping the children of nodes along the way. This process is illustrated in [Figure 41.8](#).

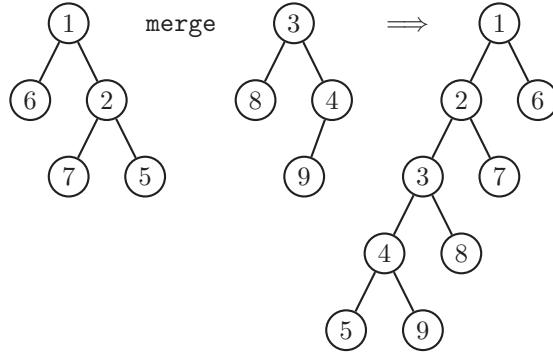

FIGURE 41.8 Merging two skew heaps.

```

data Skew = Empty | Node(Int,Skew,Skew)

empty = Empty
insert(x,s) = merge(Node(x,Empty,Empty),s)
findMin(Node(x,s1,s2)) = x
deleteMin(Node(x,s1,s2)) = merge(s1,s2)

merge(s1,Empty) = s1
merge(Empty,s2) = s2
merge(Node(x,s1,s2),Node(y,t1,t2)) =
  if x < y then Node(x,merge(Node(y,t1,t2),s2),s1)
  else Node(y,merge(Node(x,s1,s2),t2),t1)
  
```

FIGURE 41.9 Skew heaps in Haskell.

Notice how the nodes on the rightmost paths of the arguments end up on the leftmost path of the result. A Haskell implementation of skew heaps incorporating path copying is shown in Figure 41.9. A naive Java implementation is shown in Figure 41.10.

Skew heaps are not balanced, and individual operations can take linear time in the worst case. For example, Figure 41.11 shows an unbalanced skew heap generated by inserting the elements

5, 6, 4, 6, 3, 6, 2, 6, 1, 6

into an initially empty heap. Inserting a new element such as 7 into this unbalanced skew heap would take linear time. However, in spite of the fact that any one operation can be inefficient, the way that children are regularly swapped keeps the operations efficient in the amortized sense—`insert`, `deleteMin`, and `merge` run in logarithmic amortized time [12].

Or, at least, those would be the bounds for non-persistent skew heaps. When we analyze skew heaps in a persistent setting, we receive a nasty shock. Making an amortized data structure such as skew heaps persistent using path copying breaks its amortized bounds! In the case of skew heaps, naively incorporating path copying causes the logarithmic amortized bounds to degrade to the linear worst-case bounds.

Consider, for example, the unbalanced skew heap s in Figure 41.11, for which `insert` takes linear time for large elements. The result of the `insert` is a new skew heap s' . Performing another `insert` on s' would actually be quite efficient, but because these structures are persistent, we are free to ignore s' and perform the next `insert` on the old skew heap s instead. This `insert` again takes linear time. We can continue performing operations on the old skew heap as often as we want. The average cost per operation over a sequence of such operations is linear, which means that the amortized cost per operation is now linear, rather than logarithmic. Simple experiments on the Java implementation from Figure 41.10 confirm this analysis.

However, if we repeat those experiments on the Haskell implementation from Figure 41.9, we do not observe linear behavior. Instead, the operations appear to retain their logarithmic amortized bounds, even under persistent usage. This pleasant result is a consequence of a fortuitous interaction between path copying and a property of the Haskell language called *lazy evaluation*. (Many other functional programming languages also support lazy evaluation).

Under lazy evaluation, operations such as `merge` are not actually executed until their results are needed. Instead, a new kind of node that we might call a *pending merge* is automatically created. The pending merge lays dormant until some other operation

```

public class Skew {
    public static final Skew empty = null;
    public static Skew insert(int x, Skew s) { return merge(new Skew(x,null,null),s); }
    public static int findMin(Skew s) { return s.element; }
    public static Skew deleteMin(Skew s) { return merge(s.left,s.right); }

    public static Skew merge(Skew s,Skew t) {
        if (t == null) return s;
        else if (s == null) return t;
        else if (s.element < t.element)
            return new Skew(s.element,merge(t,s.right),s.left);
        else
            return new Skew(t.element,merge(s,t.right),t.left);
    }

    private int element;
    private Skew left,right;
    private Skew(int element, Skew left, Skew right) {
        this.element = element;
        this.left = left;
        this.right = right;
    }
}

```

FIGURE 41.10 First attempt at skew heaps in Java

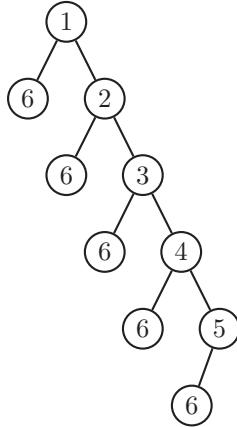

FIGURE 41.11 An unbalanced skew heap.

such as `findMin` needs to know the result. Then and only then is the pending merge executed. The node representing the pending merge is overwritten with the result so that it cannot be executed twice.

Although Java does not directly support lazy evaluation, it is easy to simulate, as shown in Figure 41.12. A minor difference between the lazy Java implementation and the Haskell implementation is that the Java implementation avoids creating pending merge nodes when one of the arguments is `null`.

A crucial aspect of lazy evaluation is that a pending computation, once triggered, is executed only far enough to produce the part of the result that is needed. The remaining parts of the computation may be delayed further by creating new pending nodes. In the case of the `merge` operation, this means that when a pending merge is executed, the two roots are compared and the children of the smaller root are swapped as normal, but the recursive `merge` of the larger root with the former right child of the smaller root is *not* performed. Instead, a new pending merge is created and installed as the left child of the new root node. This process is illustrated in Figure 41.13, with the pending merges drawn as diamonds.

Figure 41.14 illustrates the propagation of pending merges through a sequence of operations. First, the initial tree is built via a series of `inserts`. Then `findMin` executes those pending merges to find the value of the root. Next, `deleteMin` deletes the

```

public class Skew {
    public static final Skew empty = null;
    public static Skew insert(int x, Skew s) { return merge(new Skew(x,null,null),s); }
    public static int findMin(Skew s) {
        executePendingMerge(s);
        return s.element;
    }
    public static Skew deleteMin(Skew s) {
        executePendingMerge(s);
        return merge(s.left,s.right);
    }

    public static Skew merge(Skew s,Skew t) {
        if (t == null) return s;
        else if (s == null) return t;
        else return new Skew(s,t); // create a pending merge
    }

    private static void executePendingMerge(Skew s) {
        if (s != null && s.pendingMerge) {
            Skew s1 = s.left, s2 = s.right;
            executePendingMerge(s1);
            executePendingMerge(s2);
            if (s2.element < s1.element) { Skew tmp = s1; s1 = s2; s2 = tmp; }
            s.element = s1.element;
            s.left = merge(s2,s1.right);
            s.right = s1.left;
            s.pendingMerge = false;
        }
    }
}

private boolean pendingMerge;
private int element;
private Skew left,right;
private Skew(int element, Skew left, Skew right) {
    this.element = element;
    this.left = left;
    this.right = right;
    pendingMerge = false;
}
private Skew(Skew left,Skew right) { // create a pending merge
    this.left = left;
    this.right = right;
    pendingMerge = true;
}
}

```

FIGURE 41.12 Skew heaps with lazy evaluation in Java.

root and creates a new pending merge of the two children. Finally, `findMin` again executes the pending merges to find the new value of the root.

Notice that pending nodes and lazy evaluation affect *when* the various steps of a merge are carried out, but that they do not affect the end results of those steps. After all the pending merges have been executed, the final tree is identical to the one produced by skew heaps without lazy evaluation.

Strictly speaking, the nodes of a lazy skew heap can no longer be called immutable. In particular, when a pending merge is executed, the node representing the pending merge is updated with the result so that it cannot be executed twice. Functional languages typically allow this kind of mutation, known as *memoization*, because it is invisible to the user, except in terms of efficiency. Suppose that memoization was not performed. Then pending merges might be executed multiple times. However,

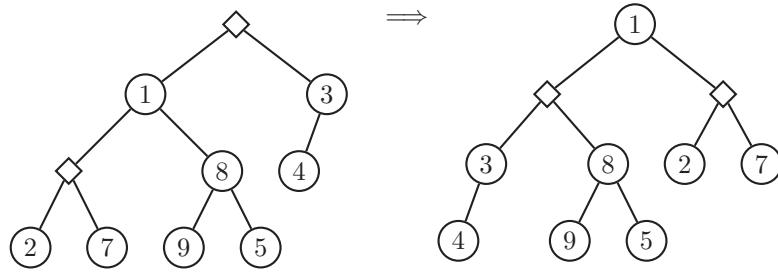

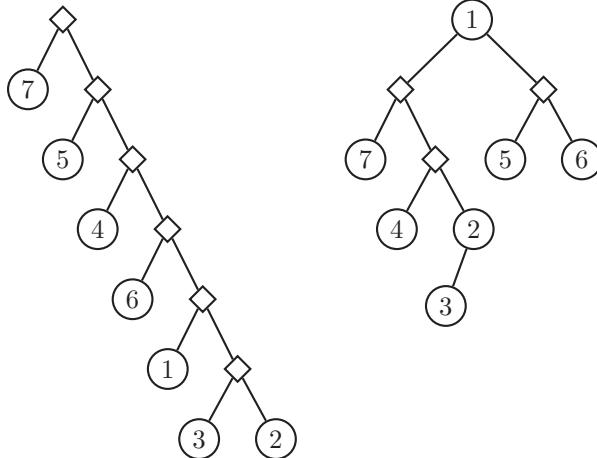

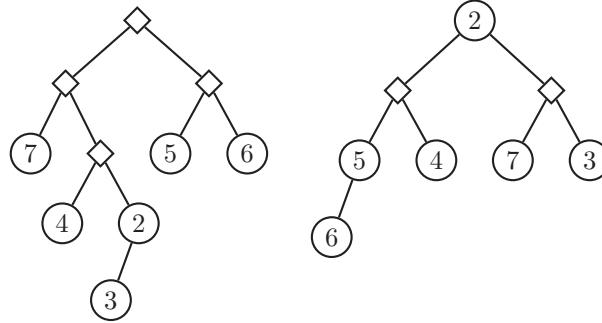

FIGURE 41.13 Executing a pending merge.

(a) insert 2,3,1,6,4,5,7 (b) findMin (returns 1)

(c) deleteMin

(d) findMin (returns 2)

FIGURE 41.14 A sequence of operations on skew heaps.

every time a given pending merge was executed, it would produce the same result. Therefore, memoization is an optimization that makes lazy evaluation run faster, but that has no effect on the output of any computation.

41.4.1 Analysis of Lazy Skew Heaps

Next, we prove that `merge` on lazy skew heaps runs in logarithmic amortized time. We use the banker's method, associating a certain number of credits with each pending merge.

We begin with a few definitions. The *logical view* of a tree is what the tree would look like if all of its pending merges were executed. The *logical left spine* of a tree is the leftmost path from the root in the logical view. Similarly, the *logical right spine* of a tree is the rightmost path from the root in the logical view. A pending node is called *left-heavy* if its left subtree is at least as large as its right subtree in the logical view, or *right-heavy* if its right subtree is larger than its left subtree in the logical view. The

successor of a pending node is the new pending node that is created as the new left child of the existing node when the existing node is executed.

Now, we charge one credit to execute a single pending merge. This credit pays for the comparison, the allocation of the successor node, and all necessary pointer manipulations, but it does not pay for executing the child nodes if they happen to be pending merges as well. When a right-heavy pending node is executed, it spends one of its own credits. When a left-heavy pending node is executed, the credit must be supplied either by its parent node, if it has one, or by the heap operation that originated the request, if the node is a root. This adds a single credit to the costs of the `insert` and `deleteMin` operations. After a pending node is executed, it passes any remaining credits to its successor node.

When we create a pending node, we must provide it with all the credits it will ever need. This includes

- One credit for itself, if it is right-heavy,
- One credit for each child that is a left-heavy pending node, and
- Any credits needed by its successors.

Notice that a pending node and its successors all lay on the logical left spine of the resulting tree in the logical view. Similarly, the physical children of a pending node and its successors all lay on the logical right spines of the argument trees to the original merge. Therefore, the number of credits that we must create during a `merge` is bounded by the number of right-heavy nodes in the logical left spine of the resulting tree plus the numbers of left-heavy nodes in the logical right spines of the argument trees.

It is easy to see that the number of right-heavy nodes in a logical left spine is at most logarithmic in the size of the logical view. Similarly, the number of left-heavy nodes in a logical right spine is at most logarithmic in the size of the logical view. The total number of credits created by `merge` is therefore bounded by the sum of three logarithmic values, and thus is logarithmic itself.

41.5 Difficulties

As this chapter has shown, many data structures work quite nicely in a functional setting. However, some do not. We close with a description of several warning signs to watch for.

- *Random access*: All of the data structures described in this chapter have been pointer-based. Unfortunately, data structures that depend on arrays—such as hash tables—are more difficult to handle. No entirely satisfactory approach is known for making arrays persistent. The best known approach from a theoretical point of view is that of Dietz [13], in which array accesses run in $O(\log \log n)$ expected amortized time. However, his approach is quite complicated and difficult to implement. Competing approaches, such as [14–16], degrade to logarithmic (or worse!) time per access in common cases.
- *Cycles*: Not all pointer-based data structures are suitable for implementation in a functional setting. The most common problem is the presence of cycles, such as those found in doubly-linked lists or in binary search trees with parent pointers. Path copying requires copying *all* paths from the root to the site of the update. In the presence of cycles, this frequently means copying the entire data structure.
- *Multiple entrypoints*: Even without cycles, a pointer-based data structure can run into difficulties if it has multiple entrypoints. For example, consider a pointer-based implementation of the union-find data structure [17]. All the pointers go from children to parents, so there are no cycles (except sometimes trivial ones at the roots). However, it is common for every node of the union-find data structure to be a potential entrypoint, rather than just the root(s). Path copying requires copying all paths from *any entrypoint* to the site of the update. With multiple entrypoints, this again frequently degrades into copying the entire data structure.
- *Unpredictable access patterns*: Section 41.4 described how to use lazy evaluation to make an amortized data structure persistent. Although this works for many amortized data structures, such as skew heaps [12], it does not work for all amortized data structures. In particular, data structures with highly unpredictable access patterns, such as splay trees [18] (see Chapter 13), are difficult to make persistent in this fashion.

41.6 Further Reading

The most complete general reference on functional data structures is Okasaki [1]. For more information on specific data structures, consult the following sources:

- Queues and deques [19–22]
- Priority queues and priority search queues [23,24]
- Random-access lists and flexible arrays [25–30]
- Catenable lists and deques [31–33]

University of Trier

42.1 Introduction

LEDA, the Library of Efficient Data Types and Algorithms, aims at being a comprehensive software platform for the area of combinatorial and geometric computing. It provides a sizable collection of data types and algorithms in C++. This collection includes most of the data types and algorithms described in the text books of the area [1–10]. LEDA supports a broad range of applications. It has already been used in such diverse areas as code optimization, VLSI design, graph drawing, graphics, robot motion planning, traffic scheduling, geographic information systems, machine learning and computational biology.

The LEDA project was started in 1988 by Kurt Mehlhorn and Stefan Näher. The first months they spent on the specification of different data types and on selecting the implementation language. At that time the item concept came up as an abstraction of the notion “pointer into a data structure.” Items provide direct and efficient access to data and are similar to iterators in the standard template library. The item concept worked successfully for all test cases and is now used for most data types in LEDA. Concurrently with searching for the correct specifications several languages were investigated for their suitability as an implementation platform. Among the candidates were Smalltalk, Modula, Ada, Eiffel, and C++. The language had to support abstract data types and type parameters (genericity) and should be widely available. Based on the experiences with different example programs C++ was selected because of its flexibility, expressive power, and availability.

We discuss some of the general aspects of the LEDA system.

42.1.1 Ease of Use

The library is easy to use. In fact, only a small fraction of the users are algorithms experts and many users are not even computer scientists. For these users the broad scope of the library, its ease of use, and the correctness and efficiency of the algorithms in the library are crucial. The LEDA manual [11] gives precise and readable specifications for the data types and algorithms mentioned

^{*} This chapter has been reprinted from first edition of this Handbook, without any content updates.

above. The specifications are short (typically not more than a page), general (so as to allow several implementations) and abstract (so as to hide all details of the implementation).

42.1.2 Extensibility

Combinatorial and geometric computing is a diverse area and hence it is impossible for a library to provide ready-made solutions for all application problems. For this reason it is important that LEDA is easily extendible and can be used as a platform for further software development. In many cases LEDA programs are very close to the typical text book presentation of the underlying algorithms. The goal is the equation *Algorithm + LEDA = Program*.

LEDA extension packages (LEPs) extend LEDA into particular application domains and areas of algorithmics not covered by the core system. LEDA extension packages satisfy requirements, which guarantee compatibility with the LEDA philosophy. LEPs have a LEDA-style documentation, they are implemented as platform independent as possible and the installation process allows a close integration into the LEDA core library. Currently, the following LEPs are available: PQ-trees, dynamic graph algorithms, a homogeneous d -dimensional geometry kernel, and a library for graph drawing.

42.1.3 Correctness

Programming is a notoriously error-prone task; this is even true when programming is interpreted in a narrow sense: going from a (correct) algorithm to a program. The standard way to guard against coding errors is program testing. The program is exercised on inputs for which the output is known by other means, typically as the output of an alternative program for the same task. Program testing has severe limitations. It is usually only done during the testing phase of a program. Also, it is difficult to determine the “correct” suite of test inputs. Even if appropriate test inputs are known it is usually difficult to determine the correct outputs for these inputs: alternative programs may have different input and output conventions or may be too inefficient to solve the test cases.

Given that program verification, that is, formal proof of correctness of an implementation, will not be available on a practical scale for some years to come, *program checking* has been proposed as an extension to testing [12,13]. The cited papers explored program checking in the area of algebraic, numerical, and combinatorial computing. In References 14–16 program checkers are presented for planarity testing and a variety of geometric tasks. LEDA uses program checkers for many of its implementations.

In computational geometry the correctness problem is even more difficult because geometric algorithms are frequently formulated under two unrealistic assumptions: computers are assumed to use exact real arithmetic (in the sense of mathematics) and inputs are assumed to be in general position. The naive use of floating point arithmetic as an approximation to exact real arithmetic very rarely leads to correct implementations. In a sequence of papers [17–21] the degeneracy and precision issues have been investigated and LEDA was extended based on this theoretical work. It now provides exact geometric kernels for two-dimensional and higher dimensional computational geometry [22] and also correct implementations for basic geometric tasks, for example, two-dimensional convex hulls, Delaunay diagrams, Voronoi diagrams, point location, line segment intersection, and higher-dimensional convex hulls and Delaunay triangulations.

An elegant (theoretical) approach to the degeneracy problem is *symbolic perturbation*. However, this method of forcing input data into general position can cause some serious problems in practice. In many cases, it increases the complexity of (intermediate) results considerably and furthermore, the final limit process turns out to be very difficult in particular in the presence of combinatorial structures. For this reason, LEDA follows a different approach. It copes with degeneracies directly by treating the degenerate case as the “normal” case. This approach proved to be very effective for many geometric problems.

42.1.4 Availability and Usage

LEDA is realized in C++ and can be used on many different platforms with many different compilers. LEDA is now used at many academic sites. A commercial version of LEDA is marketed by Algorithmic Solutions Software GmbH (<www.algorithmic-solutions.com>).

42.2 The Structure of LEDA

LEDA uses templates for the implementation of parameterized data types and for generic algorithms. However, it is not a pure template library and therefore is based on a number of object code libraries of precompiled code. Programs using LEDA data types or algorithms have to include the appropriate LEDA header files into their source code and have to be linked with one or more of these libraries. The four object code libraries are built on top of each other. Here, we only give a short overview. Consult the LEDA user manual [11] or the LEDA book [23] for a detailed description.

- The Basic Library (*libL*) contains system dependent code, basic data structures, numbers and types for linear algebra, dictionaries, priority queues, partitions, and many more basic data structures and algorithms.

- The Graph Library (*libG*) contains different types of graphs and a large collection of graph and network algorithms
- The 2D Geometry Library (*libP*) contains the two-dimensional geometric kernels advanced geometric data structures, and a large number of algorithms for two-dimensional geometric problems.
- The 3D Geometry Library (*libP*) contains the three-dimensional kernels and some algorithms for three-dimensional problems.
- The Window Library(*libW*) supports graphical output and user interaction for both the X11 platform (Unix) and Microsoft Windows systems. It also contains animation support: GraphWin, a powerful graph editor, and GeoWin, a interactive tool for the visualization of geometric algorithms. See Section 42.5 for details.

42.3 Data Structures and Data Types

LEDA contains a large number of data structures from the different areas of combinatorial and geometric computing. However, as indicated in the name of the library, LEDA was not designed as a collection of *data structures* but as a library of (parameterized) *data types*. For each (abstract) data type in the library there is at least one data structure which implements this type. This separation of specification (by an abstract data type) and implementation (by an actual data structure) is crucial for a software component library. It allows to change the underlying implementation or to choose between different implementations without having to change the application program. In general, there is one default data structure for each of the advanced data types, for example, avl-trees for dictionaries, skiplists for sorted sequences, binary heaps for priority queues, and a union-find structure for partitions. For most of these data types a number of additional data structures are available and can be specified by an optional template argument. For instance `dictionary<string, int, skiplist>` specifies a dictionary type with key type *string* and information type *int* which is implemented by the *skiplist* data structure (see Reference 23 for more details and Section 42.6.1 for an example).

42.3.1 Basic Data Types

Of course, LEDA contains a complete collection of all basic data types, such as strings, stacks, queues, lists, arrays, tuples . . . which are ubiquitous in all areas of computing.

42.3.2 Numbers and Matrices

Numbers are at the origin of computing. We all learn about integers, rationals, and real numbers during our education. Unfortunately, the number types *int*, *float*, and *double* provided by C++ are only crude approximations of their mathematical counterparts: there are only finitely many numbers of each type and for floats and doubles the arithmetic incurs rounding errors. LEDA offers the additional number types *integer*, *rational*, *bigfloat*, and *real*. The first two are the exact realization of the corresponding mathematical types and the latter two are better approximations of the real numbers. Vectors and matrices are one- and two-dimensional arrays of numbers, respectively. They provide the basic operations of linear algebra.

42.3.3 Advanced Data Types

A collection of parameterized data types representing sets, partitions, dictionaries, priority queues, sorted sequences, partitions and sparse arrays (maps, dictionary and hashing arrays). Type parameters include the key, information, priority, or element type and (optional) the data structure used for the implementation of the type. The list of data structures includes skiplists (see Chapter 14), (a, b) -trees, avl-trees, red-black trees, $bb[\alpha]$ -trees (see Chapter 11), randomized search trees (see Chapter 14), Fibonacci heaps, binary heaps, pairing heaps (see Chapter 7), redistributive heaps, union find with path compression (Chapter 34), dynamic perfect hashing, cuckoo hashing (see Chapter 9), Emde-Boas trees, This list of data structures is continuously growing and adapted to new results from the area for data structures and algorithms.

42.3.4 Graph Data Structures

The graph data type (Chapter 4) is one of the central data types in LEDA. It offers the standard iterations such as “for all nodes v of a graph G do” (written `forall_nodes(v, G)`) or “for all edges e incident to a node v do” (written `forall_out_edges(e, v)`), it allows to add and delete vertices and edges and it offers arrays and matrices indexed by nodes and edges, (see Reference 23 Chapter 6 for details and Section 42.6.2 for an example program). The data type *graph* allows to write programs for graph problems in a form very close to the typical text book presentation.

42.3.5 Geometry Kernels

LEDA offers kernels for two- and three-dimensional geometry, a kernel of arbitrary dimension is available as an extension package. In either case there exists a version of the kernel based on floating point Cartesian coordinates (called *float-kernel*) as well as a kernel based on rational homogeneous coordinates (called *rat-kernel*). All kernels provide a complete collection of geometric objects (points, segments, rays, lines, circles, simplices, polygons, planes, etc.) together with a large set of geometric primitives and predicates (orientation of points, side-of-circle tests, side-of-hyperplane, intersection tests and computation, etc.). For a detailed discussion and the precise specification see [Chapter 9](#) of the LEDA book [23]. Note that only for the rational kernel, which is based on exact arithmetic and floating-point filters, all operations and primitives are guaranteed to compute the correct result.

42.3.6 Advanced Geometric Data Structures

In addition to the basic kernel data structures LEDA provides many advanced data types for computational geometry. Examples are

- A general polygon type (`gen_polygon` or `rat_gen_polygon`) with a complete set of boolean operations. Its implementation is based on an efficient and robust plane sweep algorithms for the construction of the arrangement of a set of straight line segments (see References 23 and 24 [Chapter 11.7](#) for a detailed description).
- Two- and higher-dimensional geometric tree structures, such as range, segment, interval and priority search trees (see [Chapter 19](#)).
- Partially and fully persistent search trees ([Chapter 33](#)).
- Different kinds of geometric graphs (triangulations, Voronoi diagrams, and arrangements)
- A dynamic `point_set` data type supporting update, search, closest point, and different types of range query operations on one single representation which is based on a dynamic Delaunay triangulation (see Reference 23 [Chapter 11.6](#)).

42.4 Algorithms

The LEDA project had never the goal to provide a complete collection of all algorithms. LEDA was designed and implemented to establish a *platform* for combinatorial and geometric computing enabling programmers to implement these algorithms themselves more easily and customized to their particular needs. But of course the library already contains a considerable number of standard algorithms.

Here we give a brief overview and refer the reader to the user manual for precise specifications and to [Chapter 10](#) of the LEDA-book [23] for a detailed description and analysis of the corresponding implementations. In the current version LEDA offers different implementation of algorithms for the following problems:

- Sorting and searching
- Basic graph properties
- Graph traversals
- Different kinds of connected components
- Planarity test and embeddings
- Minimum spanning trees
- Shortest paths
- Network flows
- Maximum weight and cardinality matchings
- Graph drawing
- Convex hulls (also three-dimensional)
- Half-plane intersections
- (Constraint) triangulations
- Closest and farthest Delaunay and Voronoi diagrams
- Euclidean minimum spanning trees
- Closest pairs
- Boolean operations on generalized polygons
- Segment intersection and construction of line arrangements
- Minkowski sums and differences
- Nearest neighbors and closest points
- Minimum enclosing circles and annuli
- Curve reconstruction

42.5 Visualization

Visualization and animation of programs is very important for the understanding, presentation, and debugging of algorithms (see [Chapter 45](#)). LEDA provides two powerful tools for interactive visualization and animation of data structures and algorithms:

42.5.1 GraphWin

The *GraphWin* data type (see Reference 23, [Chapter 12](#)) combines the *graph* and the *window* data type. An object of type *GraphWin* (short: a *GraphWin*) is a window, a graph, and a drawing of the graph, all at once. The graph and its drawing can be modified either by mouse operations or by running a graph algorithm on the graph. The *GraphWin* data type can be used to:

- Construct and display graphs,
- Visualize graphs and the results of graph algorithms,
- Write interactive demos for graph algorithms,
- Animate graph algorithms.

All demos and animations of graph algorithms in LEDA are based on *GraphWin*, many of the drawings in the LEDA book [23] have been made with *GraphWin*, and many of the geometry demos in LEDA have a *GraphWin* button that allows us to view the graph structure underlying a geometric object.

GraphWin can easily be used in programs for constructing, displaying and manipulating graphs and for animating and debugging graph algorithms. It offers both a programming and an interactive interface, most applications use both of them. [Figure 42.1](#) shows a screenshot of a typical *GraphWin* window.

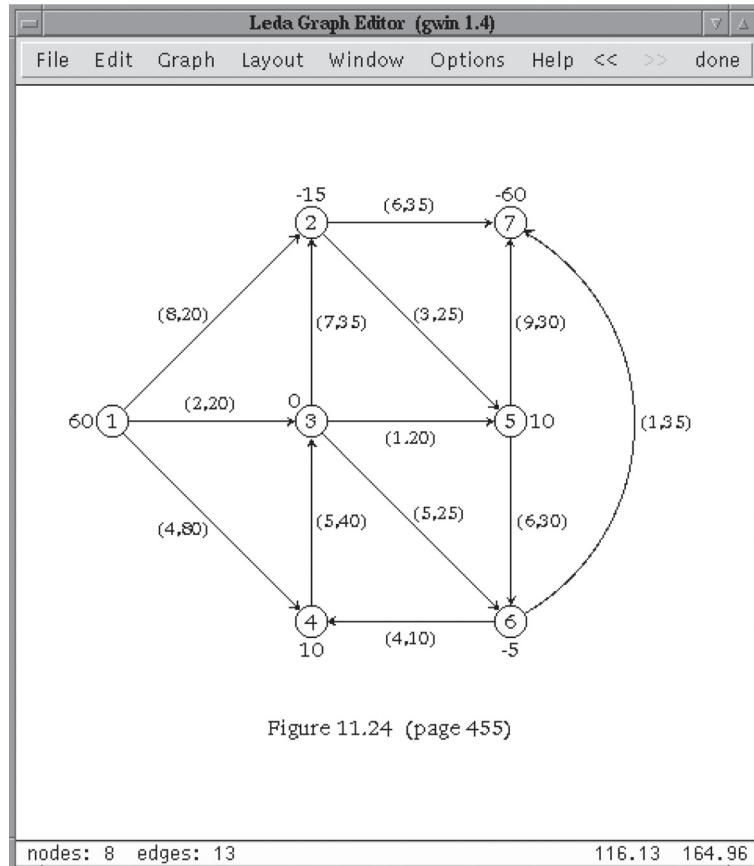

Figure 11.24 (page 455)

FIGURE 42.1 A *GraphWin*. The display part of the window shows a graph G and the panel part of the window features the default menu of a *GraphWin*. G can be edited interactively, e.g., nodes and edges can be added, deleted, and moved around. It is also possible to run graph algorithms on G and to display their result or to animate their execution.

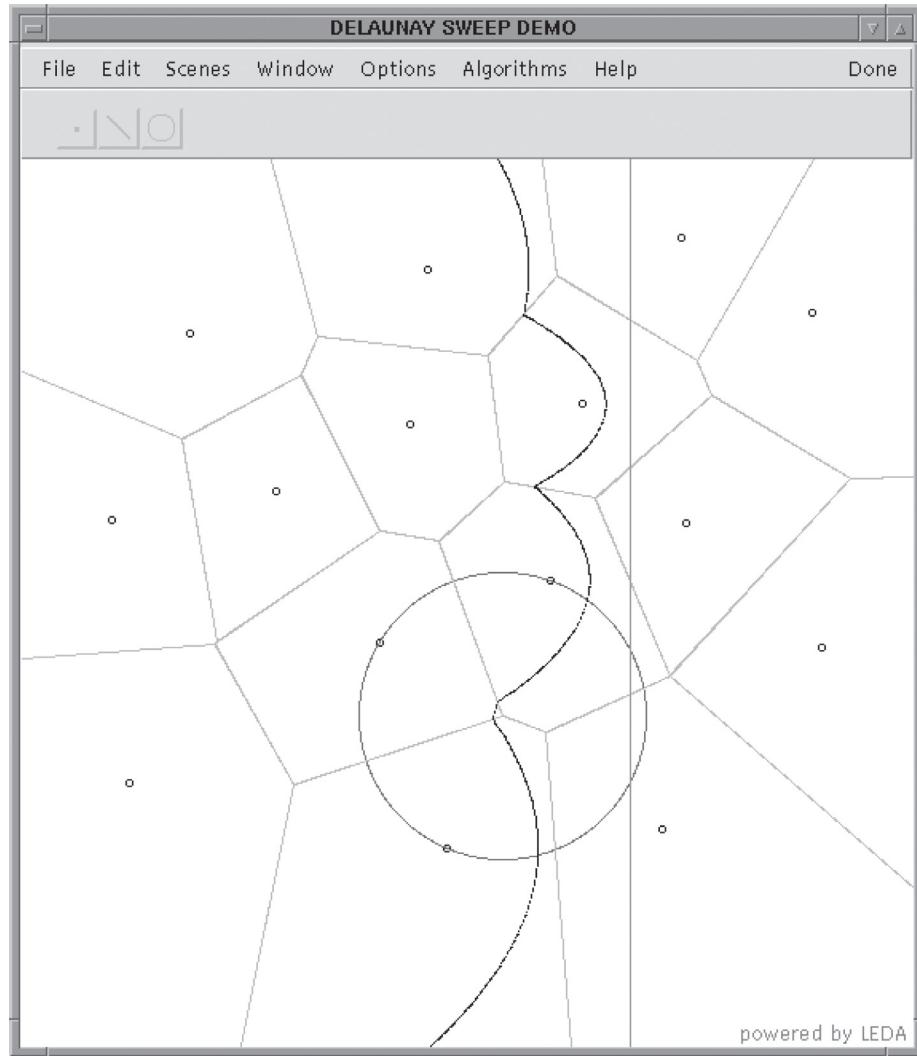

FIGURE 42.2 GeoWin animating Fortune’s Sweep Algorithm.

42.5.2 GeoWin

GeoWin [25] is a generic tool for the interactive visualization of geometric algorithms. *GeoWin* is implemented as a C++ data type. It provides support for a number of programming techniques which have shown to be very useful for the visualization and animation of algorithms. The animations use *smooth transitions* to show the result of geometric algorithms on dynamic user-manipulated input objects, for example, the Voronoi diagram of a set of moving points or the result of a sweep algorithm that is controlled by dragging the sweep line with the mouse (see Figure 42.2).

A GeoWin maintains one or more geometric scenes. A geometric *scene* is a collection of geometric objects of the same type. A collection is simply either a standard C++-list (STL-list) or a LEDA-list of objects. GeoWin requires that the objects provide a certain functionality, such as stream input and output, basic geometric transformations, drawing and input in a LEDA window. A precise definition of the required operations can be found in the manual pages [11]. GeoWin can be used for any collection of basic geometric objects (geometry kernel) fulfilling these requirements.

The visualization of a scene is controlled by a number of attributes, such as color, line width, line style, etc. A scene can be subject to user interaction and it may be defined from other scenes by means of an algorithm (a C++ function). In the latter case the scene (also called *result scene*) may be recomputed whenever one of the scenes on which it depends is modified. There are three main modes for re-computation: user-driven, continuous, and event-driven.

GeoWin has both an interactive and a programming interface. The interactive interface supports the interactive manipulation of input scenes, the change of geometric attributes, and the selection of scenes for visualization.

42.6 Example Programs

In this section we give several programming examples showing how LEDA can be used to implement combinatorial and geometric algorithms in a very elegant and readable way. In each case we will first state the algorithm and then show the program. It is not essential to understand the algorithms in full detail; our goal is to show:

- How easily the algorithms are transferred into programs and
- How natural and elegant the programs are.

In other words, Algorithm + LEDA = Program.

42.6.1 Word Count

We start with a very simple program. The task is to read a sequence of strings from standard input, to count the number of occurrences of each string in the input, and to print a list of all occurring strings together with their frequencies on standard output.

The program uses the LEDA types *string* and *d_array* (dictionary arrays). The parameterized data type *d_array* $\langle I, E \rangle$ realizes arrays with index type *I* and element type *E*. We use it with index type *string* and element type *int*.

```
#include <LEDA/d_array.h>
#include <LEDA/impl/skiplist.h>
int main()
{ d_array<string,int,skiplist> N(0);
  string s;
  while (cin >> s) N[s]++;
  forall_defined(s,N) cout << s << " " << N[s] << endl;
}
```

We give some more explanations. The program starts with the include statement for dictionary arrays and skiplists. In the first line of the main program we define a dictionary array *N* with index type *string*, element type *int* and implementation *skiplist* and initialize all entries of the array to zero. Conceptually, this creates an infinite array with one entry for each conceivable string and sets all entries to zero; the implementation of *d_arrays* stores the non-zero entries in a balanced search tree with key type *string*. In the second line we define a string *s*. The while-loop does most of the work. We read strings from the standard input until the end of the input stream is reached. For every string *s* we increment the entry *N[s]* of the array *N* by one. The iteration *forall_defined(s,N)* in the last line successively assigns all strings to *s* for which the corresponding entry of *N* was touched during execution. For each such string, the string and its frequency are printed on the standard output.

42.6.2 Shortest Paths

Dijkstra's shortest path algorithm [26] takes a directed graph $G = (V, E)$, a node $s \in V$, called the source, and a non-negative cost function on the edges $cost : E \rightarrow R_{\geq 0}$. It computes for each node $v \in V$ the distance from s , see Figure 42.3. A typical text book presentation of the algorithm is as follows:

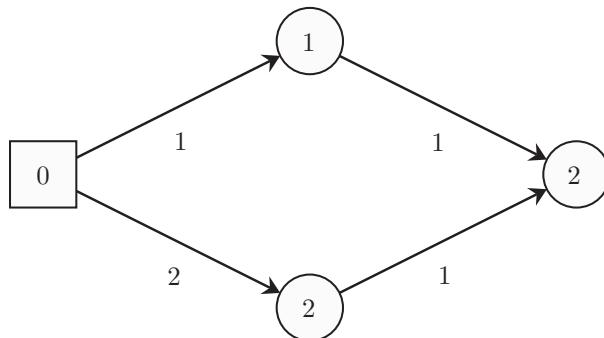

FIGURE 42.3 A shortest path in a graph. Each edge has a non-negative cost. The cost of a path is the sum of the cost of its edges. The source node s is indicated as a square. For each node the length of the shortest path from s is shown.

```

forall nodes  $v$  do
    set  $dist(v)$  to infinity.
    declare  $v$  unreached.
od
set  $dist(s)$  to 0.

while there is an unreached node do
    let  $u$  be an unreached node with minimal dist-value. (*)
    declare  $u$  reached.
    forall edges  $e = (u, v)$  out of  $u$  do
        set  $dist(v) = \min(dist(v), dist(u) + cost(e))$ .
    od
od

```

The text book presentation will then continue to discuss the implementation of line (*). It will state that the pairs $\{(v, dist(v)); v \text{ unreached}\}$ should be stored in a priority queue, for example, a Fibonacci heap, because this will allow the selection of an unreached node with minimal distance value in logarithmic time. It will probably refer to some other chapter of the book for a discussion of priority queues.

We next give the corresponding LEDA program; it is very similar to the pseudo-code above. In fact, after some experience with LEDA you should be able to turn the pseudo-code into code within a few minutes.

```

#include <LEDA/graph.h>
#include <LEDA/node_pq.h>
void DIJKSTRA(const graph& G, node s, const edge_array<double>& cost,
               node_array<double>& dist)
{
    node_pq<double> PQ(G);
    node v;
    dist[s] = 0;
    forall_nodes(v, G)
    {
        if (v != s) dist[v] = MAXDOUBLE;
        PQ.insert(v, dist[v]);
    }

    while (!PQ.empty())
    {
        node u = PQ.del_min();
        edge e;
        forall_out_edges(e, u)
        {
            v = target(e);
            double c = dist[u] + cost[e];
            if (c < dist[v])
            {
                PQ.decrease_p(v, c);
                dist[v] = c;
            }
        }
    }
}
}

```

We start by including the graph and the node priority queue data types. The function *DIJKSTRA* takes a graph G , a node s , an *edge_array* $cost$, and a *node_array* $dist$. Edge arrays and node arrays are arrays indexed by edges and nodes, respectively. We declare a priority queue PQ for the nodes of graph G . It stores pairs $(v, dist[v])$ and is initially empty. The *forall_nodes*-loop initializes $dist$ and PQ . In the main loop we repeatedly select a pair $(u, dist[u])$ with minimal distance value and then iterate over all out-going edges to update distance values of neighboring vertices.

We next incorporate the shortest path program into a small demo. We generate a random graph with n nodes and m edges and choose the edge costs as random number in the range $[0, 100]$. We call the function above and report the running time.

```

int main()
{
    int n = read_int("number of nodes = ");
    int m = read_int("number of edges = ");
    graph G;
}

```

```

random_graph(G,n,m);
edge_array<double> cost(G);
node_array<double> dist(G);
edge e;
forall_edges(e,G) cost[e] = rand_int(0,100);

float T = used_time();
DIJKSTRA(G,G.first_node(),cost,dist);
cout << "The computation took" << used_time(T) << "seconds." << endl;
}

```

On a graph with 10,000 nodes and 100,000 edges the computation takes less than a second.

42.6.3 Curve Reconstruction

The reconstruction of a curve from a set of sample points is an important problem in computer vision. Amenta, Bern, and Eppstein [27] introduced a reconstruction algorithm which they called CRUST. Figure 42.4 shows a point set and the curves reconstructed by their algorithm. The algorithm CRUST takes a list S of points and returns a graph G . CRUST makes use of Delaunay diagrams and Voronoi diagrams and proceeds in three steps:

- It first constructs the Voronoi diagram VD of the points in S .
- It then constructs a set $L = S \cup V$, where V is the set of vertices of VD .
- Finally, it constructs the Delaunay triangulation DT of L and makes G the graph of all edges of DT that connect points in S .

The algorithm is very simple to implement

```

#include <LEDA/graph.h>
#include <LEDA/map.h>
#include <LEDA/float_kernel.h>
#include <LEDA/geo_alg.h>
void CRUST(const list<point>& S, GRAPH<point,int>& G)
{
list<point> L = S;
GRAPH<circle,point> VD;
VORONOI(L,VD);
// add Voronoi vertices and mark them
map<point,bool> voronoi_vertex(false);
node v;
forall_nodes(v,VD)
{ if (VD.outdeg(v) < 2) continue;
  point p = VD[v].center();
  voronoi_vertex[p] = true;
  L.append(p);
}
DELAUNAY_TRIANG(L,G);

```

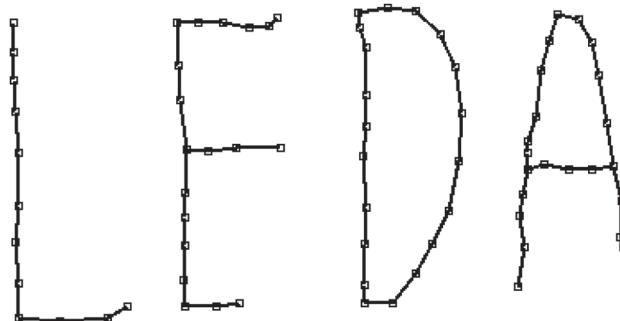

FIGURE 42.4 A set of points in the plane and the curve reconstructed by CRUST. The figure was generated by the program presented in Section 42.6.3.

```

forall_nodes(v,G)
if (voronoi_vertex[G[v]]) G.del_node(v);
}

```

We give some explanations. We start by including graphs, maps, the floating point geometry kernel, and the geometry algorithms. In CRUST we first make a copy of S in L . Next we compute the Voronoi diagram VD of the points in L . In LEDA we represent Voronoi diagrams by graphs whose nodes are labeled with circles. A node v is labeled by a circle passing through the defining sites of the vertex. In particular, $VD[v].center()$ is the position of the node v in the plane. Having computed VD we iterate over all nodes of VD and add all finite vertices (a Voronoi diagram also has nodes at infinity, they have degree one in our graph representation of Voronoi diagrams) to L . We also mark all added points as vertices of the Voronoi diagram. Next we compute the Delaunay triangulation of the extended point set in G . Having computed the Delaunay triangulation, we collect all nodes of G that correspond to vertices of the Voronoi diagram in a list $vlist$ and delete all nodes in $vlist$ from G . The resulting graph is the result of the reconstruction.

We next incorporate CRUST into a small demo which illustrates its speed. We generate n random points in the plane and construct their crust. We are aware that it does really make sense to apply CRUST to a random set of points, but the goal of the demo is to illustrate the running time.

```

int main()
{ int n = read_int("number of points = ");
  list<point> S;
  random_points_in_unit_square(n,S);
  GRAPH<point,int> G;

  float T = used_time();
  CRUST(S,G);
  cout << "The crust computation took" << used_time(T) << "seconds." ;
  cout << endl;
}

```

For 3000 points the computation takes less than a second. We can now use the preceding program for a small interactive demo.

```

#include <LEDA/window.h>
int main()
{ window W;
  W.display();
  W.set_node_width(2);
  W.set_line_width(2);
  point p;
  list<point> S;
  GRAPH<point,int> G;
  while (W >> p)
  { S.append(p);
    CRUST(S,G);
    W.clear();
    node v;
    forall_nodes(v,G) W.draw_node(G[v]);
    edge e;
    forall_edges(e,G) W.draw_segment(G[source(e)], G[target(e)]);
  }
}

```

We give some more explanations. We start by including the window type. In the main program we define a window and open its display. A window will pop up. We state that we want nodes and edges to be drawn with width two. We define the list S and the graph G required for CRUST. In each iteration of the while-loop we read a point in W (each click of the left mouse button enters a point), append it to S and compute the crust of S in G . We then draw G by drawing its vertices and its edges. Each edge is drawn as a line segment connecting its endpoints. [Figure 42.4](#) was generated with the program above.

42.6.4 Upper Convex Hull

In the next example we show how to use LEDA for computing the upper convex hull of a given set of points. The following function `UPPER_HULL` takes a list L of rational points (type `rat_point`) as input and returns the list of points of the upper convex hull of L in clockwise ordering. The algorithm is a variant of Graham's Scan [28]. First we sort L according to the lexicographic ordering of the Cartesian coordinates and remove multiple points. If the list contains not more than two points after this step we stop. Before starting the actual Graham Scan we first skip all initial points lying on or below the line connecting the two extreme points. Then we scan the remaining points from left to right and maintain the upper hull of all points seen so far in a list called $hull$. Note however that the last point of the hull is not stored in this list but in a separate variable p . This makes it easier to access the last two hull points as required by the algorithm. Note also that we use the rightmost point as a sentinel avoiding the special case that $hull$ becomes empty.

```
using namespace leda;
list<rat_point> UPPER_HULL(list<rat_point> L)
{ L.sort();
  L.unique();
  if (L.length() <= 2) return L;

  rat_point p_min = L.front(); // leftmost point
  rat_point p_max = L.back(); // rightmost point

  list<rat_point> hull;
  hull.append(p_max); // use rightmost point as sentinel
  hull.append(p_min); // first hull point

  // goto first point p above (p_min,p_max)
  while (!L.empty() && !left_turn(p_min,p_max,L.front())) L.pop();
  if (L.empty()) return hull;

  rat_point p = L.pop(); // second (potential) hull point
  rat_point q;
  forall(q,L)
  { while (!right_turn(hull.back(),p,q)) p = hull.pop_back();
    hull.append(p);
    p = q;
  }

  hull.append(p); // add last hull point
  hull.pop(); // remove sentinel
  return hull;
}
```

42.6.5 Delaunay Flipping

LEDA represents triangulations by bidirected plane graphs (from the graph library) whose nodes are labeled with points and whose edges may carry additional information, for example, integer flags indicating the type of edge (hull edge, triangulation edge, etc.). All edges incident to a node v are ordered in counter-clockwise ordering and every edge has a reversal edge. In this way the faces of the graph represent the triangles of the triangulation. The graph type offers methods for iterating over the nodes, edges, and adjacency lists of the graph. In the case of plane graphs there are also operations for retrieving the reverse edge and for iterating over the edges of a face. Furthermore, edges can be moved to new nodes. This graph operation is used in the following program to implement edge flips.

Function `DELAUNAY_FLIPPING` takes as input an arbitrary triangulation and turns into a Delaunay triangulation by the well-known flipping algorithm. This algorithm performs a sequence of local transformations as shown in Figure 42.5 to establish the Delaunay property: for every triangle the circumscribing sphere does not contain any vertex of the triangulation in its interior. The test whether an edge has to be flipped or not can be realized by a so-called `side_of_circle` test. This test takes four points a , b , c , d and decides on which side of the oriented circle through the first three points a , b , and c the last point d lies. The result is positive or negative if d lies on the left or on the right side of the circle, respectively, and the result is zero if all four points lie on one common circle. The algorithms uses a list of candidates which might have to be flipped (initially all edges). After a flip the

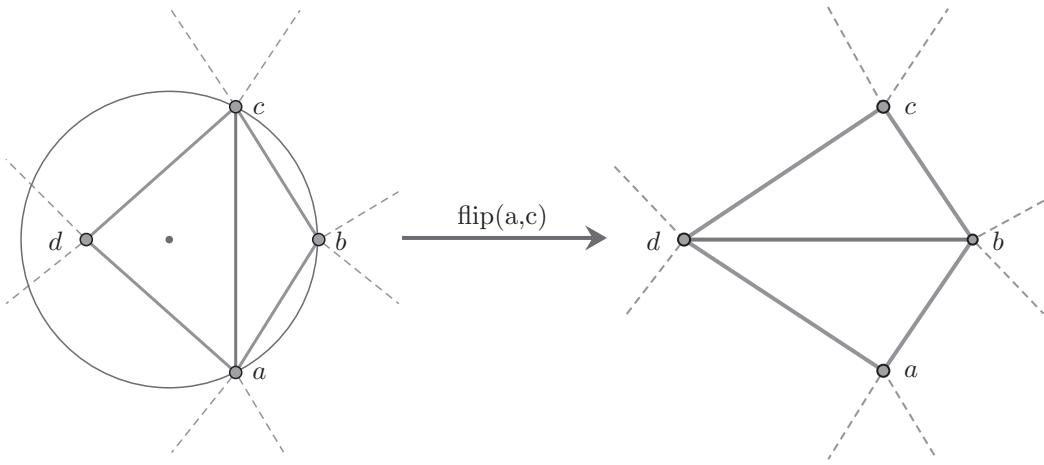

FIGURE 42.5 Delaunay Flipping.

four edges of the corresponding quadrilateral are pushed onto this candidate list. Note that $G[v]$ returns the position of node v in the triangulation graph G . A detailed description of the algorithm and its implementation can be found in the LEDA book ([23]).

```
void DELAUNAY_FLIPPING(GRAPH<POINT, int>& G)
{
    list<edge> S = G.all_edges();

    while ( !S.empty() )
    { edge e = S.pop();
      edge r = G.rev_edge(e);

      // e1,e2,e3,e4: edges of quadrilateral with diagonal e
      edge e1 = G.face_cycle_succ(r);
      edge e2 = G.face_cycle_succ(e1);
      edge e3 = G.face_cycle_succ(e);
      edge e4 = G.face_cycle_succ(e3);

      // a,b,c,d: corners of quadrilateral
      POINT a = G[G.source(e1)];
      POINT b = G[G.target(e1)];
      POINT c = G[G.source(e3)];
      POINT d = G[G.target(e3)];

      if (side_of_circle(a,b,c,d) > 0)
      { S.push(e1); S.push(e2); S.push(e3); S.push(e4);
        // flip diagonal
        G.move_edge(e,e2,source(e4));
        G.move_edge(r,e4,source(e2));
      }
    }
}
```

42.6.6 Discussion

In each of the above examples only a few lines of code were necessary to achieve complex functionality and, moreover, the code is elegant and readable. The data structures and algorithms in LEDA are efficient. For example, the computation of shortest paths in a graph with 10,000 nodes and 100,000 edges and the computation of the crust of 5000 points takes less than a second each. We conclude that LEDA is ideally suited for rapid prototyping as summarized in the equation

$$\text{Algorithm} + \text{LEDA} = \text{Efficient Program.}$$

42.7 Projects Enabled by LEDA

A large number academic and industrial projects from almost every area of combinatorial and geometric computing have been enabled by LEDA. Examples are graph drawing, algorithm visualization, geographic information systems, location problems, visibility algorithms, DNA sequencing, dynamic graph algorithms, map labeling, covering problems, railway optimization, route planning and many more. A detailed list of academic LEDA projects can be found on <<http://www.mpi-sb.mpg.de/LEDA/friends>> and a selection of industrial projects is shown on <<http://www.algorithmic-solutions.com/enreferenzen.htm>>.

43.1 Introduction

In C++, several classic data structures are implemented as a part of the standard library, commonly known as the *Standard Template Library*. The Standard Template Library (or simply, the STL) consists of a set of *container classes*, such as lists, sets, and maps; *iterator classes* that are used to traverse the container classes; and *generic algorithms*, such as sorting and searching. As its name implies, the library consists of (both function and class) templates. The STL is very powerful and makes some use of advanced C++ features. Our discussion is focused on the most basic uses of the STL, but does include some features found only in C++11 or later.

We partition our discussion of the Standard Template Library into the following sections:

1. Containers
2. Iterators
3. Generic Algorithms

See References 1–7 for additional material on the Standard Template Library.

43.2 Basic Containers

The STL defines several container templates that store collections of objects. Some collections are unordered, while others are ordered. Some collections allow duplicates, while others do not. All containers support the following operations:

- `int size() const`: returns the number of elements in the container.
- `void clear()`: removes all elements from the container.
- `bool empty() const`: returns `true` if the container contains no elements and `false` otherwise.

There is no universal `add` or `insert` member function; different containers use different names.

The container classes can be split into three broad categories:

1. *Sequence containers* maintain items with a notion of a position in the collection. Examples include `vector`, `list`, and `deque`.
2. *Associative containers* maintain items in a manner that allows efficient searching, insertion, and deletion (using balanced search trees, and starting in C++11, hash tables). Examples include `set`, `multiset`, `map`, and `multimap`.
3. *Container adapters* built on top of other containers to yield classic data structures. Examples include `stack`, `queue`, and `priority_queue`.

Associated with all containers is an *iterator*. An iterator represents the notion of a position in the container and is used to step through the container. All containers support the following operations:

- `iterator begin()`: returns an appropriate iterator representing the first item in the container.
- `iterator end()`: returns an appropriate iterator representing the end marker in the container (i.e., the position after the last item in the container).

We defer the discussion of iterators to Section 43.3.

43.2.1 Sequence Containers

The three basic sequence containers in the STL are the `vector`, `list`, and `deque`.

`vector` is a growable array. The `vector` wraps an internal array, maintaining a notion of its size, and internally its current capacity. If a sequence of additions would cause the size to exceed capacity, the capacity is automatically doubled. This makes additions at the end of the `vector` take constant amortized time. `list` is a doubly linked list, in which pointers to both ends are maintained. `deque` is, in effect, a growable array that grows at both ends. There are several well-known ways to implement `deque` efficiently, but the standard is silent about which implementation must be used.

For `vector`, an insertion or deletion takes *amortized time* that is proportional to the distance from the back, while for a `deque`, these operations take amortized time that is proportional to the smaller of the distances from the front and back. For a `list`, these operations take worst-case time that is proportional to the smaller of the distances from the front and back if an index is specified, but constant worst-case time if the position is specified by an existing iterator. `vector` and `deque` support indexing in constant worst-case time; `list` does not.

The basic operations that are supported by both containers are:

- `void push_back(const Object & x)`: adds `x` to the end of the container.
- `Object & back()`: returns the object at the end of the container (an accessor that returns a constant reference is also provided).
- `void pop_back()`: removes the object at the end of the container.
- `Object & front()`: returns the object at the front of the container (an accessor that returns a constant reference is also provided).
- `iterator insert(iterator pos, const Object & x)`: adds `x` into the container, prior to the position given by the iterator `pos`. This is a constant-time operation for `list`, but not for `vector` or `deque`. The return value is an iterator representing the position of the inserted item.
- `iterator erase(iterator pos)`: removes the object at the position given by the iterator. This is a constant-time operation for `list`, but not `vector` or `deque`. The return value is the position of the element that followed `pos` prior to the call. This operation invalidates `pos`, which is now stale.
- `iterator erase(iterator start, iterator end)`: removes all items beginning at position `start`, up to but not including `end`. Observe that an entire container can be erased by the call: `c.erase(c.begin(), c.end())`.

For `deque` and `list`, two additional operations are available with expected semantics:

- `void push_front(const Object & x)`: adds `x` to the front of the container.
- `void pop_front()`: removes the object at the front of the container.

The `list` also provides a `splice` operation that allows the transfer of a sublist to somewhere else.

- `void splice(iterator pos, list & l, iterator start, iterator end)`: moves all items beginning at position `start`, up to but not including `end` to after `pos`. The moved items are assumed to have come from list `l`. The running time of this operation is proportional to the number of items moved, unless the items are moved within the same list (i.e., `&l==this`), in which case the running time is constant time.

For `vector` and `deque`, additional operations include:

- `Object & operator[](int idx)`: returns the object at index `idx` in the container, with no bounds-checking (an accessor that returns a constant reference is also provided).
- `Object & at(int idx)`: returns the object at index `idx` in the container, with bounds-checking (an accessor that returns a constant reference is also provided).
- `int capacity() const`: returns the internal capacity.
- `void reserve(int newCapacity)`: for `vector` only, sets the new capacity. If a good estimate is available, it can be used to avoid array expansion.

C++11 adds an array container that represents a fixed size array with no space overhead, and which is instantiated with a type and size (e.g., `array<int, 6>`). `array` is useful for embedded systems as a safer replacement for built-in arrays, but does not support insertion or deletion. Generally speaking, the non-modifying operations discussed earlier, such as `at`, `begin` and `end`, and `size` work for `array` also.

C++11 also adds a `forward_list`, which is a singly linked list. Because in a standard `list`, `insert` and `erase` add and remove prior to the position given in the iterator, those operations would be linear time in a singly linked list. Accordingly, in a `forward_list` you'll find additional member functions `insert_after` and `erase_after` that provide constant-time performance.

43.2.2 Associative Containers

The STL provides two basic types of associative containers. Sets are used to store items. The `multiset` allows duplicates, while the `set` does not. Maps are used to store key/value pairs. The `multimap` allows duplicate keys, while the `map` does not. In classic C++, for sets, the items are logically maintained in sorted order, so an iterator to the “beginning item” represents the smallest item in the collection. For maps, the keys are logically maintained in sorted order. As a result, the most natural implementation of sets and maps makes use of balanced binary search trees; typically a top-down red black tree (see [Chapter 11](#)) is used. The significant liability is that basic operations take logarithmic worst-case time.

Historically, STL implementations (such as SGI's version) provided `hash_set` and `hash_map`, which make use of hash tables (see [Chapter 9](#)) and provided constant average time per basic operation, but were non-standard. Finally, C++11 added four additional classes that maintain the sets and maps without order, using separate chaining hash tables. These classes are `unordered_set`, `unordered_multiset`, `unordered_map`, and `unordered_multimap`; the class names are chosen to avoid conflicting with various preexisting nonstandard classes.

C++ ordered sets and maps use either a default ordering (`operator<`) or one provided by a function object. In C++, a function object is implemented by providing a class that contains an overloaded `operator()` and then instantiating a template with the class name as a template parameter; similarly, unordered sets and maps use either a default hash function and equality operator (for instance, with strings), or ones provided by function objects (an example of this is shown later in [Figures 43.1](#) and [43.2](#)).

Both sets and maps make use of the `pair` class template. The `pair` class template stores two data members `first` and `second`, which can be directly accessed, without invoking member functions. Internally, maps store items of type `pair`. Additionally, several `set` member functions need to return two things; this is done by returning an appropriately instantiated `pair`.

43.2.2.1 Sets and Multisets

The `set` and `unordered_set` provide several member functions in addition to the usual suspects, including:

- `pair<iterator, bool> insert(const Object & x)`: adds `x` to the set. If `x` is not already present, the returned `pair` will contain the iterator representing the already contained `x`, and `false`. Otherwise, it will contain the iterator representing the newly inserted `x`, and `true`.
- `pair<iterator, bool> insert(iterator hint, const Object & x)`: same behavior as the one-parameter `insert`, but allows specification of a hint, representing the position where `x` should go. If the underlying implementation is a finger search tree (see [Chapter 12](#)), or equivalent, the performance could be better than using the one-parameter `insert`.
- `iterator find(const Object & x) const`: returns an iterator representing the position of `x` in the set. If `x` is not found, the endmarker is returned.
- `int erase(const Object & x)`: removes `x` (if present) and returns the number of items removed, which is either 0 or 1 in a `set`, and perhaps larger in a `multiset`.
- `iterator erase(iterator pos)`: same behavior as the sequence container version.
- `iterator erase(iterator start, iterator end)`: same behavior as the sequence container version.
- `iterator lower_bound(const Object & x)`: returns an iterator to the first element in the set with a key that is greater than or equal to `x` (only for `set`).
- `iterator upper_bound(const Object & x)`: returns an iterator to the first element in the set with a key that is greater than `x` (only for `set`).
- `pair<iterator, iterator> equal_range(const Object & x)`: returns a pair of iterators representing `lower_bound` and `upper_bound`.

A `multiset` is like a `set` except that duplicates are allowed. The return type of `insert` is modified to indicate that the `insert` always succeeds:

```

#include <set>
#include <string>
#include <cstring>
#include <iostream>
using namespace std;

class CaseInsensitive
{
public:
    bool operator() ( const string & lhs, const string & rhs ) const
    { return strcasecmp( lhs.c_str( ), rhs.c_str( ) ) > 0; }
};

template <typename Set1, typename Set2>
void testSets( Set1 & s1, Set2 & s2 )
{
    s1.clear( ); s2.clear( );
    s1.insert( "hello" ); s1.insert( "world" ); s1.insert( "HELLO" );
    s2.insert( "hello" ); s2.insert( "world" ); s2.insert( "HELLO" );

    cout << s1.size( ) << " " << s2.size( ) << endl;      // prints 3 2
    cout << (s1.find( "HeLLO" ) == s1.end( )) << endl; // returns true
    cout << (s2.find( "HeLLO" ) == s2.end( )) << endl; // returns false
}

int main( )
{
    set<string>           s1;
    set<string,CaseInsensitive> s2;
    testSets( s1, s2 );

    return 0;
}

```

FIGURE 43.1 Using the `set` class template.

- `iterator insert(const Object & x)`: adds `x` to the multiset; returns an iterator representing the newly inserted `x`.
- `iterator insert(iterator hint, const Object & x)`: adds `x` to the multiset; returns an iterator representing the newly inserted `x`. Performance might be enhanced if `x` is inserted close to the position given by `hint`.

For the `multiset`, the `erase` member function that takes an `Object x` removes all occurrences of `x`. To simply remove one occurrence, first call `find` to obtain an iterator, and then use the `erase` member function that takes an iterator.

In a multiset, to find all occurrences of `x`, we cannot simply call `find`; that returns an iterator referencing one occurrence (if there is one), but which specific occurrence is returned is not guaranteed. Instead, the range returned by a call to `equal_range` is used.

[Figure 43.1](#) illustrates two sets: `s1` which stores strings using the normal case-sensitive ordering and `s2` which stores strings using case-insensitive comparisons. `s2` is instantiated by providing the class of a function object as a template parameter. As a result, `s1` contains three strings, but `s2` considers "hello" and "HELLO" to be identical, and thus only stores one of them. [Figure 43.2](#) shows a `main` that implements identical logic for `unordered_sets`.

43.2.2.2 Maps and Multimaps

A `map` behaves like a `set` instantiated with a `pair` representing a key and value, with a comparison function that refers only to the key. Thus it supports all of the `set` operations. Similarly, an `unordered_map` behaves like a `map`, with hash function and equality test refers only to the key.

```

#include <unordered_set>
#include <string>
#include <cstring>
using namespace std;

class CaseInsensitiveHash
{
public:
    bool operator() ( const string & lhs, const string & rhs ) const
    { return strcasecmp( lhs.c_str( ), rhs.c_str( ) ) == 0; }

    size_t operator() ( const string & str ) const
    {
        size_t hashVal = 0;

        for( char ch : str )
            hashVal = 37 * hashVal + tolower( ch );

        return hashVal;
    }
};

int main( )
{
    unordered_set<string>                                h1;
    unordered_set<string,CaseInsensitiveHash,CaseInsensitiveHash> h2;
    testSets( h1, h2 );

    return 0;
}

```

FIGURE 43.2 Using the `set` class template.

The `find` operation for maps requires only a key, but the iterator that it returns references a pair. Similarly, `erase` requires only a key and otherwise behaves like the `set`'s `erase`. `insert` is supported, but to use `insert`, we must insert a properly instantiated pair, which is cumbersome, and thus rarely done. Instead, the `map` overloads the array indexing `operator[]`:

- `ValueType & operator[] (const KeyType & key)`: if the key is present in the map, a reference to the value is returned. If the key is not present in the map, it is inserted with a default value into the map, and then a reference to the inserted default value is returned. The default value is obtained by applying a zero-parameter constructor or is zero for the primitive types.

The semantics of `operator[]` do not allow an accessor version of `operator[]`, and so `operator[]` cannot be used on an immutable `map`. For instance, if a `map` is passed by constant reference, inside the routine, `operator[]` is unusable. In such a case, we can use `find` to obtain an iterator, test if the iterator represents the endmarker (in which case the `find` has failed), and if the iterator is valid, we can use it to access the pair's second component, which is the value.

A `mymap` is a `map` in which duplicate keys are allowed. `mymaps` behave like `maps` but do not support `operator[]`.

[Figure 43.3](#) illustrates a combination of `map` and `vector` in which the keys are email aliases, and the values are the email addresses corresponding to each alias. Since there can be several addresses for each alias, the values are themselves vectors of strings. The trickiest part (other than the various parameter-passing modes) concerns the one-line implementation of `addAlias`. There, we see that `aliasMap[name]` refers to the `vector` value in the `map` for the `name` key. If `name` is not in the `map`, then the call to `operator[]` causes it to be placed into the `map`, with a default value being a zero-sized `vector`. Thus whether or not `name` was in the `map` prior to calling `addAlias`, after the access of the `map`, the call to `push_back` updates the `vector` value correctly.

```

#include <unordered_map>
#include <string>
#include <vector>
#include <iostream>
using namespace std;

template <typename Map, typename NameType, typename AliasType>
void addAlias( Map & aliasMap, const NameType & name, const AliasType & alias )
{
    aliasMap[ name ].push_back( alias );
}

template <typename Map, typename NameType>
auto getAliases( Map & aliasMap, const NameType & name ) -> decltype( aliasMap[ name ] )
{
    return aliasMap[ name ];
}

int main( )
{
    unordered_map<string,vector<string>> aliasMap;

    addAlias( aliasMap, "john", "john.doe@sillymail.com" );
    addAlias( aliasMap, "authors", "sahni@cise.ufl.edu" );
    addAlias( aliasMap, "authors", "dmehta@mines.edu" );
    addAlias( aliasMap, "authors", "weiss@fiu.edu" );

    cout << "authors is aliased to: ";
    auto & authors = getAliases( aliasMap, "authors" );
    for( auto email : authors )
        cout << email << " ";
    cout << endl;

    return 0;
}

```

FIGURE 43.3 Using the `map` class template.

43.2.3 Container Adapters

The STL provides adapter class templates to implement stacks, queues, and priority queues. These class templates are instantiated with the type of object to be stored and (optionally, if the default is unacceptable) the container class (such as `vector`, `list`, or `deque`) that is used to store the objects. Thus we can specify a linked list or array implementation for a stack, though in reality, this feature does little more than add nicer names than `push_back` to the (existing `list` or `vector`, respectively) interface.

43.2.3.1 stack and queue

For `stack`, the member functions are `push`, `pop`, and `top`. For `queue`, we get `push`, `front`, and `pop`. By default, a `vector` is used for `stack` and a `deque` for `queue`. [Figure 43.4](#) shows how to use the `queue` adapter, implemented with a doubly linked list.

43.2.3.2 priority_queue

The `priority_queue` template contains member functions named `push`, `top`, and `pop`, that mirror `insert`, `findmax`, and `deletemax` in a classic max-heap.

The priority queue template is instantiated with an item type, the container type (as in `stack` and `queue`), and the comparator, with defaults allowed for the last two parameters. Sometimes priority queues are set up to remove and access the smallest item instead of the largest item. In such a case, the priority queue can be instantiated with an appropriate `greater` function object to reverse the comparison order and allow access to the smallest item.

[Figure 43.5](#) illustrates both a max-heap and a min-heap.

```
#include <queue>
#include <iostream>
#include <list>
using namespace std;

int main( )
{
    queue<int,list<int>> q;
    q.push( 3 ); q.push( 7 );

    for( ; !q.empty( ); q.pop( ) )
        cout << q.front( ) << endl;

    return 0;
}
```

FIGURE 43.4 Using the `queue` adapter.

```
#include <vector>
#include <queue>
#include <functional>
#include <string>
#include <iostream>
using namespace std;

// Empty the priority queue and print its contents.
template <typename PQueue>
void dumpPQ( const string & msg, PQueue & pq )
{
    if( pq.empty( ) )
        cout << msg << " is empty" << endl;
    else
    {
        cout << msg << ":" << pq.top( );
        pq.pop( );
        while( !pq.empty( ) )
        {
            cout << " " << pq.top( );
            pq.pop( );
        }
        cout << endl;
    }
}

int main( )
{
    priority_queue<int>                         maxpq;
    priority_queue<int,vector<int>,greater<int>> minpq;

    minpq.push( 3 ); minpq.push( 7 ); minpq.push( 3 );
    maxpq.push( 3 ); maxpq.push( 7 ); maxpq.push( 3 );

    dumpPQ( "minpq", minpq );      // minpq: 3 3 7
    dumpPQ( "maxpq", maxpq );      // maxpq: 7 3 3

    return 0;
}
```

FIGURE 43.5 Using the `priority_queue` adapter.

43.3 Iterators

The `iterator` in C++ abstracts the notion of a position in the container. As we have already seen, there are several ways to obtain such a position. All containers provide `begin` and `end` member functions that return iterators representing the first item and end-marker, respectively. Many containers provide a searching member function (e.g., `set::find`) that returns an iterator viewing the found item or the endmarker if the item is not found.

43.3.1 Basics

Throughout our discussion, we have used `iterator` as a type. In reality, in C++, each container defines several iterator types, nested in the scope of the container, and these specific iterator types are used by the programmer instead of simply using the word `iterator`. For instance, if we have a `vector<int>`, the basic iterator type is `vector<int>::iterator`. The basic iterator can be used to traverse and change the contents of the container.

Another iterator type, `vector<int>::const_iterator`, does not allow changes to the container on which the iterator is operating. All iterators are guaranteed to have at least the following set of operations:

- `++itr` and `itr++`: advance the iterator `itr` to the next location. Both the prefix and postfix forms are available. This does not cause any change to the container.
- `*itr`: returns a reference to the container object that `itr` is currently representing. The reference that is returned is modifiable for basic iterators, but is not modifiable (i.e., a constant reference) for `const_iterators`.
- `itr1==itr2`: returns `true` if iterators `itr1` and `itr2` refer to the same position in the same container and `false` otherwise.
- `itr1!=itr2`: returns `true` if iterators `itr1` and `itr2` refer to different positions or different containers and `false` otherwise.

Some iterators efficiently support `--itr` and `itr--`. Those iterators are called *bidirectional iterators*. All of the iterators for the common containers `vector`, `list`, `deque`, `set`, and `map` are bidirectional.

Some iterators efficiently support both `itr+=k` and `itr+k`. Those iterators are called *random-access iterators*. `itr+=k` advances the iterator `k` positions. `itr+k` returns a new iterator that is `k` positions ahead of `itr`. Also supported by random access iterators are `itr-=k` and `itr-k`, with obvious semantics, and `itr1-itr2` which yields a separation distance as an integer. The iterators for `vector` and `deque` support random access.

All C++ containers have two member functions: `begin` and `end` that return iterators. Each collection defines four member functions:

- `iterator begin()`
- `const_iterator begin() const`
- `iterator end()`
- `const_iterator end() const`

`begin` returns an iterator that is positioned at the first item in the container. `end` returns an iterator that is positioned at the endmarker, which represents a position one past the last element in the container. On an empty container, `begin` and `end` return the same position. For random access iterators, the result of subtracting the return values of `end` and `begin` is always the size of the container.

A common use of an iterator is to sequentially scan through a container. In classic C++, this is done by initializing a local iterator to be a copy of the `begin` iterator, and have it step through the container, stopping as soon as it hits the endmarker.

As an example, [Figure 43.6](#) shows a `print` function that prints the elements of any container, provided that the elements in the container have implemented an `operator<<`. Note that we must use a `const_iterator` to traverse the container, because the container is itself immutable in the scope of `print`. The test program illustrates five different containers that invoke the `print` function, along with the expected output (in comments). Observe that both `set` and `multiset` output in sorted order, with `multiset` allowing the second insertion of `beta`. Additionally, for `map` to be compatible with the `print` routine, we must provide an `operator<<` that works for the elements of the `map`, namely the appropriate pairs.

In C++11, the *range for* loop can be used to simplify this idiom, for any container that provides an appropriate iteration mechanism. The code to implement `print` in [Figure 43.7](#) is mechanically converted by the compiler into the equivalent code, shown in [Figure 43.6](#). Note that since C++11 allows the compiler to deduce the needed type when `auto` is appropriately used, in many instances the details of whether `iterator` or `const_iterator` is needed are no longer something the programmer needs to worry about.

```

#include <iostream>
#include <vector>
#include <list>
#include <set>
#include <string>
#include <map>
using namespace std;

43.3.2 Reverse Iterators

Sometimes it is important to be able to traverse a container in the reverse direction. Because of the asymmetric nature of `begin` and `end` (representing the first element and the endmarker, rather than the last element, respectively) this is cumbersome to do, even for bidirectional iterators. As a result, containers that support bidirectional iterators typically also provide a *reverse iterator*. The reverse iterator comes in two flavors: `reverse_iterator` and `const_reverse_iterator`. For reverse iterators, `++` retreats one position toward the beginning, while `--` advances one position toward the end. Container member functions `rbegin` and `rend` are used to obtain iterators representing the last element and the beginmarker, respectively. The code in [Figure 43.8](#) prints any container in reverse order. Once again, the use of `auto` in C++11 removes from the programmer the burden of deciding whether `reverse_iterator` or `const_reverse_iterator` is needed.

43.4 Additional Components of the STL

43.4.1 Sorting, Searching, and Selection

The Standard Library includes a rich set of functions that can be applied to the standard containers. Some of the algorithms include routines for sorting, searching, copying (possibly with substitutions), shuffling, reversing, rotating, merging, and so on. In all there are over 60 generic algorithms. In this section, we highlight those related to efficient sorting, selection, and binary search.

43.4.1.1 Sorting

Sorting in C++ is accomplished by use of function template `sort`. The parameters to `sort` represent the start and endmarker of a (half-open range in a) container and an optional comparator:

- `void sort(iterator begin, iterator end)`
- `void sort(iterator begin, iterator end, Comparator cmp)`

The iterators must support random access. As an example, in

```

sort( v.begin( ), v.end( ) );
sort( v.begin( ), v.end( ), greater<int>( ) );
sort( v.begin( ), v.begin( ) + min( v.size( ), 5 ) );

```

the first call sorts the entire container, `v`, in nondecreasing order. The second call sorts the entire container in nonincreasing order. The third call sorts the first five elements of the container in nondecreasing order. C++11 requires that `sort` provides

$O(N \log N)$ worst-case performance; recent implementations have used a quicksort/heapsort hybrid algorithm (*introsort*) [8], but no specific implementation is mandated.

The C++ library inherits the sorting routine `qsort` from C. `qsort` uses pointers to functions to perform its comparison making it significantly slower on average than the `sort` routine. Furthermore, many implementations use a version of quicksort that has been shown to provide quadratic behavior on some commonly occurring inputs [9]. Avoid using `qsort`.

43.4.1.2 Selection

The function template `nth_element` is used for selection, and as expected has $O(N)$ average-case running time. The parameters include a pair of iterators, and k :

- `void nth_element(iterator begin, int k, iterator end)`
- `void nth_element(iterator begin, int k, iterator end, Comparator c)`

As a result of calling `nth_element`, the item in the k th position is the k th smallest element, where counting as usual in C++ begins at 0.

Thus, in

```
nth_element( v.begin( ), 0, v.end( ) );
nth_element( v.begin( ), 0, v.end( ), greater<int>() );
nth_element( v.begin( ), v.begin( ) + ( v.end( ) - v.begin( ) / 2 ), v.end( ) );
```

the first call places the smallest element in the position given by `v.begin()`, the second call places the largest element in that position, and the third call places the median in the middle position.

43.4.1.3 Searching

Several generic searching algorithms are available for containers. The most basic is:

- `iterator find(iterator begin, iterator end, const Object & x)`: returns an iterator representing the first occurrence of x in the half-open range specified by `begin` and `end`, or `end` if x is not found.

`find` is simply a sequential search. If the range is sorted, `binary_search` can be used to find an object in logarithmic time. A comparator can be provided or the default ordering can be used. The signatures for `binary_search` are:

- `iterator binary_search(iterator begin, iterator end, const Object & x)`
- `iterator binary_search(iterator begin, iterator end, const Object & x, Comparator cmp)`

`equal_range`, `lower_bound`, and `upper_bound` search sorted ranges and behave with the same semantics as the identically named member functions in `set`.

44.1 Introduction

In the last four decades the role of computers has dramatically changed: once mainly used as *number processors* to perform fast numerical computations, they have gradually evolved into *information processors*, used to store, analyze, search, transfer, and update large collections of structured information. In order for computer programs to perform these tasks effectively, the data they manipulate must be well organized, and the methods for accessing and maintaining those data must be reliable and efficient. In other words, computer programs need advanced *data structures* and *algorithms*. Implementing advanced data structures and algorithms, however, is not an easy task and presents some risks:

Complexity Advanced data structures and algorithms are often difficult to understand thoroughly and to implement.

Unreliability Because of their complexity, the implementation of advanced data structures and algorithms is prone to subtle errors in boundary cases, which may require a considerable effort to identify and correct.

Long development time As a consequence, implementing and testing advanced data structures and algorithms is usually a time consuming process.

As a result, programmers tend to ignore advanced data structures and algorithms and to resort to simple ones, which are easier to implement and test but that are usually not as efficient. It is thus clear how the development of complex software applications, in particular their rapid prototyping, can greatly benefit from the availability of libraries of reliable and efficient data structures and algorithms.

Various libraries are available for the C++ programming language. They include the *Standard Template Library* (STL, see Chapter 43) [1], now part of the C++ standard, the extensive *Library of Efficient Data Structures and Algorithms* (LEDA, see Chapter 42) [2], and the *Computational Geometry Algorithms Library* (CGAL) [3].

The situation for the Java programming language is the following: a small library of data structures, usually referred to as *Java Collections* (JC), is included in the `java.util` package of the Java 2 Platform.[‡] An alternative to the Java Collections are the *Java Generic Libraries* (JGL) by Recursion Software, Inc.,[§] which are patterned after STL. Both the Java Collections and JGL provide implementations of basic data structures such as sequences, sets, maps, and dictionaries. JGL also provides a considerable number of generic programming algorithms for transforming, permuting, and filtering data.

None of the above libraries for Java, however, seems to provide a coherent framework, capable of accommodating both elementary and advanced data structures and algorithms, as required in the development of complex software applications. This

circumstance motivated the development of the *Data Structures Library in Java* (JDSL) [4], a collection of Java interfaces and classes implementing fundamental data structures and algorithms, such as:

- Sequences and trees;
- Priority queues, binary search trees, and hash tables;
- Graphs;
- Sorting and traversal algorithms;
- Topological numbering, shortest path, and minimum spanning tree.

JDSL is suitable for use by researchers, professional programmers, educators, and students. It comes with extensive documentation, including detailed Javadoc,^{*} an overview, a tutorial with seven lessons, and several associated research papers. It is available free of charge for noncommercial use at <http://www.jdsl.org/>.

The development of JDSL began in September 1996 at the Center for Geometric Computing at Brown University and culminated with the release of version 1.0 in 1998. A major part of the project in the first year was the experimentation with different models for data structures and algorithms, and the construction of prototypes. A significant reimplementation, documentation, and testing [5] effort was carried out in 1999 leading to version 2.0, which was officially released in 2000. Starting with version 2.1, released in 2003 under a new license, the source code has been included in the distribution. During its life cycle JDSL 2.0 was downloaded by more than 5700 users, while JDSL 2.1 has been downloaded by more than 3500 users as of this writing. During these seven years a total of 25 people[†] have been involved, at various levels, in the design and development of the library. JDSL has been used in data structures and algorithms courses worldwide as well as in two data structures and algorithms textbooks[‡] written by the first two authors [6,7].

In the development of JDSL we tried to learn from other approaches and to progress on them in terms of ease of use and modern design. The library was designed with the following goals in mind:

Functionality: The library should provide a significant collection of existing data structures and algorithms.

Reliability: Data structures and algorithms should be correctly implemented, with particular attention to boundary cases and degeneracies. All input data should be validated and, where necessary, rejected by means of exceptions.

Efficiency: The implementations of the data structures and algorithms should match their theoretical asymptotic time and space complexity; constant factors, however, should also be considered when evaluating efficiency.

Flexibility: Multiple implementations of data structures and algorithms should be provided, so that the user can experiment and choose the most appropriate implementation, in terms of time or space complexity, for the application at hand. It should also be possible for the user to easily extend the library with additional data structures and algorithms, potentially based on the existing ones.

Observe that there exist some trade-offs between these design goals, for example, between efficiency and reliability, or between efficiency and flexibility.

In JDSL each data structure is specified by an interface and each algorithm uses data structures only via the interface methods. Actual classes need only be specified when objects are instantiated. Programming through interfaces, rather than through actual classes, creates more general code. It allows different implementations of the same interface to be used interchangeably, without having to modify the algorithm code.

A comparison of the key features of the Java Collections, JGL, and JDSL is shown in Table 44.1. The main advantages of JDSL are the definition of a large set of data structure APIs (including binary tree, general tree, priority queue and graph) in terms of Java interfaces, the availability of reliable and efficient implementations of those APIs, and the presence of some fundamental graph algorithms. Note, in particular, that the Java Collections do not include trees, priority queues and graphs, and provide only sorting algorithms.

A good library of data structures and algorithms should be able to integrate smoothly with other existing libraries. In particular, we have pursued compatibility with the Java Collections. JDSL supplements the Java Collections and is not meant to replace them. No conflicts arise when using data structures from JDSL and from the Java Collections in the same program. To facilitate the use of JDSL data structures in existing programs, adapter classes are provided to translate a Java Collections data structure into a JDSL one and vice versa, whenever such a translation is applicable.

Serializability	✓	✓	

44.2 Design Concepts in JDSL

In this section we examine some data organization concepts and algorithmic patterns that are particularly important in the design of JDSL.

44.2.1 Containers and Accessors

In JDSL each data structure is viewed as a *container*, that is, an organized collection of objects, called the *elements* of the container. An element can be stored in many containers at the same time and multiple times in the same container. JDSL containers can store heterogeneous elements, that is, instances of different classes.*

JDSL provides two general and implementation-independent ways to access (but not modify) the elements stored in a container: individually, by means of accessors, and globally, by means of iterators (see Section 44.2.2). An *accessor* [8] abstracts the notion of membership of an element into a container, hiding the details of the implementation. It provides constant-time access to an element stored in a container, independently from its implementation. Every time an element is inserted in a container, an accessor associated with it is returned. Most operations on JDSL containers take one or more accessors as their operands.

We distinguish between two kinds of containers and, accordingly, of accessors (see Figure 44.1 for a diagram of the accessor interface hierarchy):

Positional containers: Typical examples are sequences, trees, and graphs. In a positional container, some topological relation is established among the “placeholders” that store the elements, such as the predecessor-successor relation in a sequence, the parent-child relation in a tree, and the incidence relation in a graph. It is the user who decides, when inserting an element in the container, what the relationship is between the new “placeholder” and the existing ones (in a sequence, for instance, the user may decide to insert an element before a given “placeholder”). A positional container does not change its topology, unless the user requests a change specifically. The implementation of these containers usually involves linked structures or arrays.

Positions: The concept of position is an abstraction of the various types of “placeholders” in the implementation of a positional container (typically the nodes of a linked structure or the cells of an array). Each position stores an element. Position implementations may store the following additional information:

* This is possible since in Java every class extends (directly or indirectly) `java.lang.Object`.

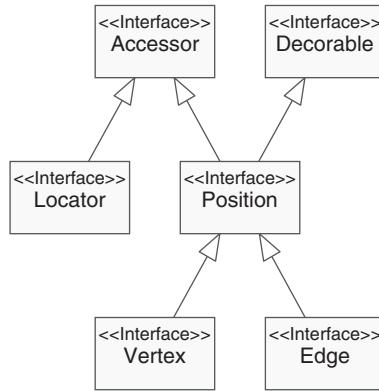

FIGURE 44.1 The accessors interface hierarchy.

- The adjacent positions (e.g., the previous and next positions in a sequence, the right and left child and the parent in a binary tree, the list of incident edges in a graph);
- Consistency information (e.g., what container the position is in, the number of children in a tree).

A position can be directly queried for its element through method `element()`, which hides the details of where the element is actually stored, be it an instance variable or an array cell. Through the positional container, instead, it is possible to replace the element of a position or to swap the elements between two positions. Note that, as an element moves about in its container, or even from container to container, its position changes. Positions are similar to the concept of items used in LEDA [2].

Key-based containers: Typical examples are dictionaries and priority queues. Every element stored in a key-based container has a *key* associated with it. Keys are used as an indexing mechanism for their associated elements. Typically, a key-based container is internally implemented using a positional container; for example, a possible implementation of a priority queue uses a binary tree (a heap). The details of the internal representation, however, are completely hidden to the user. Thus, the user has no control over the organization of the positions that store the key/element pairs. It is the key-based container itself that modifies its internal representation based on the keys of the key/element pairs inserted or removed.

Locators: The key/element pairs stored in a key-based container may change their positions in the underlying positional container, due to some internal restructuring, say, after the insertion of a new key/element pair. For example, in the binary tree implementation of a priority queue, the key/element pairs move around the tree to preserve the top-down ordering of the keys, and thus their positions change. Hence, a different, more abstract type of accessor, called locator, is provided to access a key/element pair stored in a key-based container. Locators hide the complications of dynamically maintaining the implementation-dependent binding between the key/element pairs and their positions in the underlying positional container.

A locator can be directly queried for its key and element, and through the key-based container it is possible to replace the key and the element of a locator. An example of using locators is given in Section 44.4.

44.2.2 Iterators

While accessors allow users to access single elements or key/element pairs in a container, *iterators* provide a simple mechanism for iteratively listing through a collection of objects. JDSL provides various iterators over the elements, the keys (where present), and the positions or the locators of a container (see Figure 44.2 for a diagram of the iterator interface hierarchy). They are similar to the iterators provided by the Java Collections.

All JDSL containers provide methods that return iterators over the entire container (e.g., all the positions of a tree or all the locators of a dictionary). In addition, some methods return iterators over portions of the container (e.g., the children of a position of a tree or the locators with a given key in a dictionary). JDSL iterators can be traversed only forward; however, they can be reset to start a new traversal.

For simplicity reasons iterators in JDSL have *snapshot* semantics: they refer to the state of the container at the time the iterator was created, regardless of the possible subsequent modifications of the container. For example, if an iterator is created over all the positions of a tree and then a subtree is cut off, the iterator will still include the positions of the removed subtree.

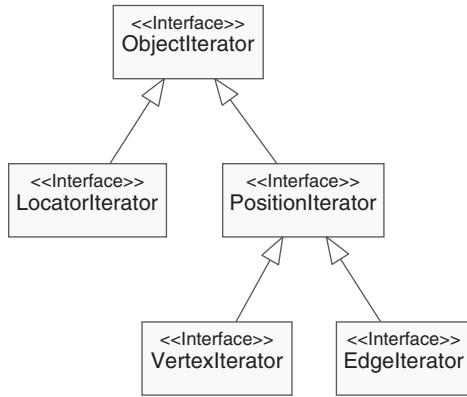

FIGURE 44.2 The iterators interface hierarchy.

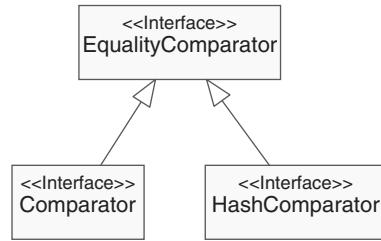

FIGURE 44.3 The comparators interface hierarchy.

44.2.3 Decorations

Another feature of JDSL is the possibility to “decorate” individual positions of a positional container with attributes, that is, with arbitrary objects. This mechanism is more convenient and flexible than either subclassing the position class to add new instance variables or creating global hash tables to store the attributes. Decorations are useful for storing temporary or permanent results of the execution of an algorithm. For example, in a depth-first search (DFS) traversal of a graph, we can use decorations to (temporarily) mark the vertices being visited and to (permanently) store the computed DFS number of each vertex. An example of using decorations is given in Section 44.4.

44.2.4 Comparators

When using a key-based container, the user should be able to specify the comparison relation to be used with the keys. In general, this relation depends on the type of the keys and on the specific application for which the key-based container is used: keys of the same type may be compared differently in different applications. One way to fulfill this requirement is to specify the comparison relation through a *comparator* object, which is passed to the key-based container constructor and is then used by the key-based container every time two keys need to be compared.

Three comparator interfaces are defined in JDSL (see Figure 44.3 for a diagram of the comparators interface hierarchy). The concept of comparator is present also in the `java.util` package of the Java 2 Platform, where a `Comparator` interface is defined.

44.2.5 Algorithms

JDSL views algorithms as objects that receive the input data as arguments of their `execute(.)` method, and provide access to the output during or after the execution via additional methods. Most algorithms in JDSL are implemented following the *template method pattern* [9]. The invariant part of the algorithm is implemented once in an abstract class, deferring the implementation of the steps that can vary to subclasses. These varying steps are defined either as abstract methods (whose implementation must be provided by a subclass) or as “hook” methods (whose default implementation may be overridden in a subclass). In other words, algorithms perform “generic” computations that can be specialized for specific tasks by subclasses.

An example of applying the template method pattern is given in Section 44.4, where we use the JDSL implementation of Dijkstra's single-source shortest path algorithm [10]. The algorithm refers to the edge weights by means of an abstract method that can be specialized depending on how the weights are actually stored or computed in the application at hand.

44.3 The Architecture of JDSL

In this section we describe the interfaces of the data structures present in JDSL, the classes that implement those interfaces, and the algorithms that operate on them. Most containers are described by two interfaces, one (whose name is prefixed with `Inspectable`) that comprise all the methods to query the container, and the other, extending the first, that comprise all the methods to modify the container. Inspectable interfaces can be used as variable or argument types in order to obtain an immutable view of a container (for instance, to prevent an algorithm from modifying the container it operates on).

As described in Section 44.2.1, we can partition the set of containers present in JDSL into two subsets: the positional containers and the key-based containers. Accordingly, the interfaces for the various containers are organized into two hierarchies (see Figures 44.4 and 44.5), with a common root given by interfaces `InspectableContainer` and `Container`. At the same time, container interfaces, their implementations, and algorithms that operate on them are grouped into various Java packages.

In the rest of this section, we denote with n the current number of elements stored in the container being considered.

44.3.1 Packages

JDSL currently consists of eight Java packages, each containing a set of interfaces and/or classes. Interfaces and exceptions for the data structures are defined in packages with the `api` suffix, while the reference implementations of these interfaces are defined in packages with the `ref` suffix. Interfaces, classes, and exceptions for the algorithms are instead grouped on a functional basis. As we will see later, the interfaces are arranged in hierarchies that may extend across different packages. The current packages are the following:

- `jdsl.core.api` Interfaces and exceptions that compose the API for the core containers (sequences, trees, priority queues, and dictionaries), for their accessors and comparators, and for the iterators on their elements, positions and locators.
- `jdsl.core.ref` Implementations of the interfaces in `jdsl.core.api`. Most implementations have names of the form `ImplementationStyleInterfaceName`. For instance, `ArrayListSequence` and `NodeSequence` implement the `jdsl.core.api.Sequence` interface with a growable array and with a linked structure, respectively. Classes with names of the form `AbstractInterfaceName` implement some methods of the interface for the convenience of developers building alternative implementations.
- `jdsl.core.algo.sorts` Sorting algorithms that operate on the elements stored in a `jdsl.core.api.Sequence` object. They are parameterized with respect to the comparison rule used to sort the elements, provided as a `jdsl.core.api.Comparator` object.
- `jdsl.core.algo.traversals` Traversal algorithms that operate on `jdsl.core.apiInspectableTree` objects. A traversal algorithm performs operations while visiting the nodes of the tree, and can be extended by applying the template method pattern.
- `jdsl.core.util` This package contains a `Converter` class to convert some JDSL containers to the equivalent data structures of the Java Collections and vice versa.
- `jdsl.graph.api` Interfaces and exceptions that compose the API for the graph container and for the iterators on its vertices and edges.
- `jdsl.graph.ref` Implementations of the interfaces in `jdsl.graph.api`; in particular, class `IncidenceListGraph` is an implementation of interface `jdsl.graph.api.Graph`.
- `jdsl.graph.algo` Basic graph algorithms, including depth-first search, topological numbering, shortest path, and minimum spanning tree, all of which can be extended by applying the template method pattern.

44.3.2 Positional Containers

All positional containers implement interfaces `InspectablePositionalContainer` and `PositionalContainer`, which extend `InspectableContainer` and `Container`, respectively (see Figure 44.4). Every positional container implements a set of essential operations, including being able to determine its own size (`size()`), to determine whether it contains a specific position (`contains(Accessor)`), to replace the element associated with a position (`replaceElement(Accessor, Object)`), to swap the elements associated with two positions (`swapElements(Position, Position)`), and to get iterators over the positions (`positions()`) or the elements (`elements()`) of the container.

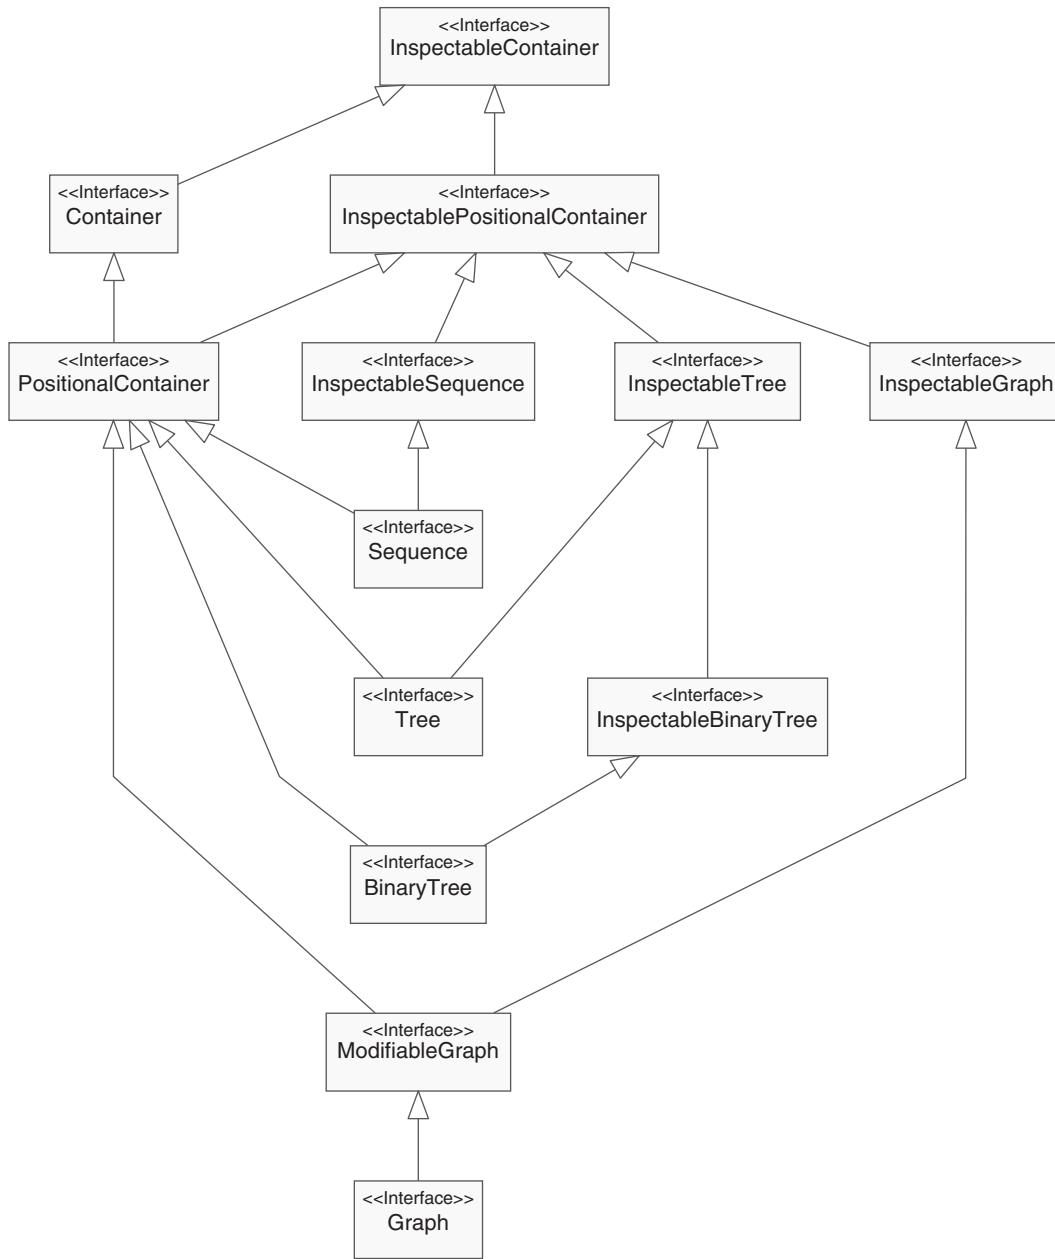

FIGURE 44.4 The positional containers interface hierarchy.

44.3.2.1 Sequences

A sequence is a basic data structure used for storing elements in a linear, ranked fashion (see Chapter 2). Sequences can be implemented in many ways, for example, as a linked list of nodes or on top of an array. In JDSL, sequences are described by interfaces `InspectableSequence` and `Sequence`, which extend `InspectablePositionalContainer` and `PositionalContainer`, respectively. In addition to the basic methods common to all positional containers, the sequence interfaces provide methods to access and modify positions at the sequence ends (methods such as `first()`, `insertLast()` and `removeFirst()`) or specific positions along the sequence (methods such as `after(Position)`, `atRank(int)`, `insertBefore(Position)` and `removeAtRank(int)`).

`NodeSequence` is an implementation of `Sequence` based on a doubly linked list of nodes. The nodes are the positions of the sequence. It takes $O(1)$ time to insert, remove, or access both ends of the sequence or a position before or after a given one, while it takes $O(n)$ time to insert, remove, or access positions at a given rank in the sequence. Thus, `NodeSequence` instances can be suitably used as stacks, queues, or deques.

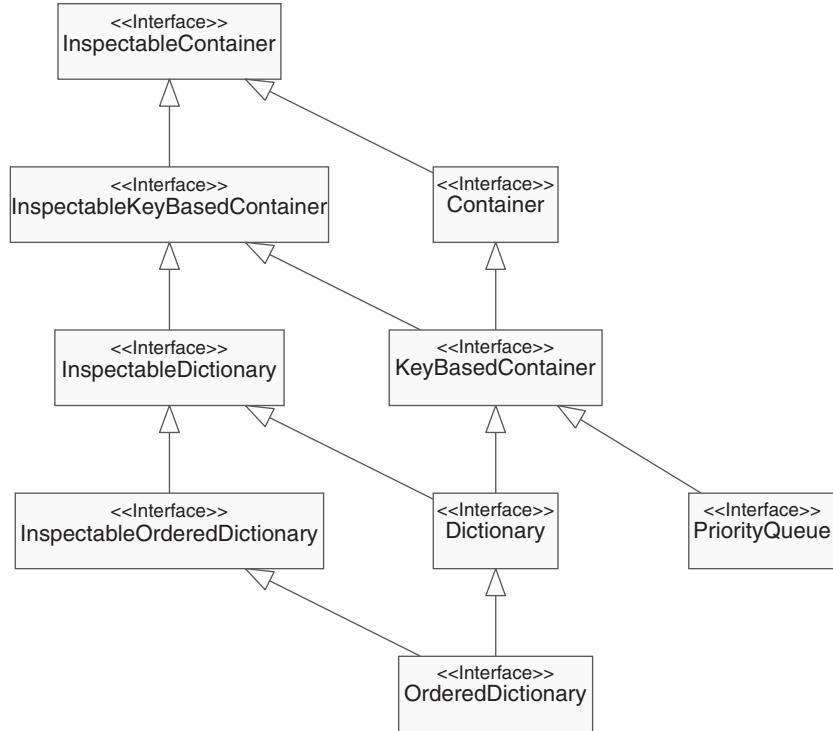

FIGURE 44.5 The key-based containers interface hierarchy.

`ArraySequence` is an implementation of `Sequence` based on a growable array of positions. Instances can be created with an initial capacity, and can be told whether or not to reduce this capacity when their size drops below a certain value, depending on whether the user prefers space or time efficiency. It takes $O(1)$ time to access any position in the sequence, $O(1)$ amortized time over a series of operations to insert or remove elements at the end of the sequence, and $O(n)$ time to insert or remove elements at the beginning or middle of the sequence. Hence, `ArraySequence` instances can be suitably used for quick access to the elements after their initial insertion, when filled only at the end, or as stacks.

44.3.2.2 Trees

Trees allow more sophisticated relationships between elements than is possible with a sequence: they allow relationships between a child and its parent, or between siblings of a parent (see Chapter 3). `InspectableTree` and `Tree` are the interfaces describing a general tree; they extend `InspectablePositionalContainer` and `PositionalContainer`, respectively. `InspectableBinaryTree`, which extends `InspectableTree`, and `BinaryTree`, which extends `PositionalContainer`, are the interfaces describing a binary tree. In addition to the basic methods common to all positional containers, the tree interfaces provide methods to determine where in the tree a position lies (methods such as `isRoot(Position)` and `isExternal(Position)`), to return the parent (`parent(Position)`), siblings (`siblings(Position)`) or children (methods such as `children(Position)`, `childAtRank(Position, int)` and `leftChild(Position)`) of a position, and to cut (`cut(Position)`) or link (`link(Position, Tree)`) a subtree.

`NodeTree` is an implementation of `Tree` based on a linked structure of nodes. The nodes are the positions of the tree. It is the implementation to use when a generic tree is needed or for building more specialized (nonbinary) trees. `NodeTree` instances always contain at least one node.

`NodeBinaryTree` is an implementation of `BinaryTree` based on a linked structure of nodes. The nodes are the positions of the tree. Similarly to `NodeTree`, `NodeBinaryTree` instances always contain at least one node; in addition, each node can have either zero or two children. If a more complex tree is not necessary, using `NodeBinaryTree` instances will be faster and easier than using `NodeTree` ones.

44.3.2.3 Graphs

A graph is a fundamental data structure describing a binary relationship on a set of elements (see Chapter 4) and it is used in a variety of application areas. Each vertex of the graph may be linked to other vertices through edges. Edges can be either one-way,

directed edges, or two-way, *undirected* edges. In JDSL, both vertices and edges are positions of the graph. JDSL handles all graph special cases such as self-loops, multiple edges between two vertices, and disconnected graphs.

The main graph interfaces are `InspectableGraph`, which extends `InspectablePositionalContainer`, `ModifiableGraph`, which extends `PositionalContainer`, and `Graph`, which extends both `InspectableGraph` and `ModifiableGraph`. These interfaces provide methods to determine whether two vertices are adjacent (`areAdjacent(Vertex, Vertex)`) or whether a vertex and an edge are incident (`areIncident(Vertex, Edge)`), to determine the degree of a vertex (`degree(Vertex)`), to determine the origin (`origin(Edge)`) or destination (`destination(Edge)`) of an edge, to insert (`insertVertex(Object)`) or remove (`removeVertex(Vertex)`) a vertex, to set the direction of an edge (`setDirectionFrom(Edge, Vertex)` and `setDirectionTo(Edge, Vertex)`), to insert (`insertEdge(Vertex, Vertex, Object)`), remove (`removeEdge(Edge)`), split (`splitEdge(Edge, Object)`), or unsplit (`unsplitEdge(Vertex, Object)`) an edge.

`IncidenceListGraph` is an implementation of `Graph`. As its name suggests, it is based on an incidence list representation of a graph.

44.3.3 Key-Based Containers

All key-based containers implement interfaces `InspectableKeyBasedContainer` and `KeyBasedContainer`, which extend `InspectableContainer` and `Container`, respectively (see Figure 44.5). Every key-based container implements a set of essential operations, including being able to determine its own size (`size()`), to determine whether it contains a specific locator (`contains(Accessor)`), to replace the key (`replaceKey(Locator, Object)`) or the element (`replaceElement(Accessor, Object)`) associated with a locator, to insert (`insert(Object, Object)`) or remove (`remove(Locator)`) a key/element pair, and to get iterators over the locators (`locators()`), the keys (`keys()`) or the elements (`elements()`) of the container.

44.3.3.1 Priority Queues

A priority queue is a data structure used for storing a collection of elements prioritized by keys, where the smallest key value indicates the highest priority (see Part II). It supports arbitrary insertions and deletions of elements and keeps track of the highest-priority key. A priority queue is useful, for instance, in applications where the user wishes to store a queue of tasks of varying priority, and always process the most important task.

Interface `PriorityQueue` extends `KeyBasedContainer`. In addition to the basic methods common to all the key-based containers, it provides methods to access (`min()`) or remove (`removeMin()`) the key/element pair with highest priority, that is, with minimum key. Note that the priority of an element can be changed using method `replaceKey(Locator, Object)`, inherited from `KeyBasedContainer`.

`ArrayHeap` is an efficient implementation of `PriorityQueue` based on a heap. Inserting, removing, or changing the key of a key/element pair takes $O(\log n)$ time, while examining the key/element pair with the minimum key takes $O(1)$ time. The implementation is parameterized with respect to the comparison rule used to order the keys; to this purpose, a `Comparator` object is passed as an argument to the `ArrayHeap` constructors.

44.3.3.2 Dictionaries

A dictionary is a data structure used to store key/element pairs and then quickly search for them using their keys (see Part III). An ordered dictionary is a particular dictionary where a total order on the set of keys is defined. All JDSL dictionaries are *multi-maps*, that is, they can store multiple key/element pairs with the same key.

The main dictionary interfaces are `InspectableDictionary` and `Dictionary`, which extend `InspectableKeyBasedContainer` and `KeyBasedContainer`, respectively. In addition to the basic methods common to all the key-based containers, these interfaces provide methods to find key/element pairs by their keys (`find(Object)` and `findAll(Object)`) and to remove all key/element pairs with a specific key (`removeAll(Object)`). Other dictionary interfaces are `InspectableOrderedDictionary` and `OrderedDictionary`, which extend `InspectableDictionary` and `Dictionary`, respectively. They provide additional methods to access the first (`first()`) or last (`last()`) key/element pair in the ordered dictionary, and to access the key/element pair before (`before(Locator)`) or after (`after(Locator)`) a given key/element pair.

`HashtableDictionary` is an implementation of `Dictionary`. As its name suggests, it is based on a hash table. Insertions and removals of key/element pairs usually take $O(1)$ time, although individual insertions and removals may require $O(n)$ time. The implementation is parameterized with respect to the hashing function used to store the key/element pairs; to this purpose, a `HashComparator` object is passed as an argument to the `HashtableDictionary` constructors. `HashtableDictionary` is a good choice when overall speed is necessary.

`RedBlackTree` is an implementation of `OrderedDictionary`. It is a particular type of binary search tree, where insertion, removal, and access to key/element pairs require each $O(\log n)$ time. The implementation is parameterized with respect to the comparison rule used to order the keys; to this purpose, a `Comparator` object is passed as an argument to the `RedBlackTree` constructors.

44.3.4 Algorithms

In addition to the data structures described above, JDSL includes various algorithms that operate on them.

44.3.4.1 Sequence Sorting

JDSL provides a suite of sorting algorithms for different applications. They all implement the `SortObject` interface, whose only method is `sort(Sequence, Comparator)`. Sorting algorithms with the prefix `List` are most efficient when used on instances of `NodeSequence` while those with the prefix `Array` are most efficient when used on instances of `ArraySequence`.

`ArrayQuicksort` is an implementation of the quicksort algorithm. This algorithm runs in $O(n \log n)$ expected time and performs very well in practice. Its performance, however, degrades greatly if the sequence is already very close to being sorted. Also, it is not *stable*, that is, it does not guarantee that elements with the same value will remain in the same order they were in before sorting. In all cases whether neither of these caveats apply, it is the best choice.

`ListMergeSort` and `ArrayMergeSort` are two implementations of the mergesort algorithm. This algorithm is not as fast as quicksort in practice, even though its theoretical time complexity is $O(n \log n)$. There are no cases where its performance will degrade due to peculiarities in the input data, and it is a stable sort.

`HeapSort` is an implementation of the heapsort algorithm, and uses an instance of `ArrayHeap` (see Section 44.3.3) as a sorting device. Its performance, like that of mergesort, will not degrade due to peculiarities in the input data, but it is not a stable sort. Its theoretical time complexity is $O(n \log n)$.

44.3.4.2 Iterator-Based Tree Traversals

JDSL provides two types of tree traversals. The first type is based on iterators: the tree is passed as an argument to the iterator constructor and is then iterated over using methods `hasNext()` and `nextPosition()`. Iterators give a quick traversal of the tree in a specific order, and are the proper traversals to use when this is all that is required. We recall that iterators in JDSL have snapshots semantics (see Section 44.2.2).

A preorder iterator visits the nodes of the tree in preorder, that is, it returns a node before returning any of its children. Preorder iterators work for both binary and general trees; they are implemented in class `PreOrderIterator`.

A postorder iterator visits the nodes of the tree in postorder, that is, it returns a node after returning all of its children. Postorder iterators work for both binary and general trees; they are implemented in class `PostOrderIterator`.

An inorder iterator visits the nodes of the tree in inorder, that is, it returns a node in between its left and right children. Inorder iterators work only for binary trees; they are implemented in class `InOrderIterator`.

44.3.4.3 Euler Tour Tree Traversal

The second type of tree traversals in JDSL is named Euler tour: it is implemented—in class `EulerTour`—as an algorithm object, which can be extended by applying the template method pattern.

The Euler tour visits each node of the tree several times, namely, a first time before traversing any of the subtrees of the node, then between the traversals of any two consecutive subtrees, and a last time after traversing all the subtrees. Each time a node is visited, one of the methods `visitFirstTime(Position)`, `visitBetweenChildren(Position)` and `visitLastTime(Position)`, if the node is internal, or method `visitExternal(Position)`, if the node is a leaf, is automatically called. A particular computation on the visited tree may be performed by suitably overriding those methods in a subclass of `EulerTour`.

The Euler tour is more powerful than the iterators described above as it can be used to implement more general kinds of algorithms. Note that, unlike the iterators, the Euler tour does not have snapshot semantics; this means that any modification of the tree during the execution of the Euler tour will cause undefined behavior.

44.3.4.4 Graph Traversals

The depth-first search (DFS) traversal of a graph is available in JDSL. Depth-first search proceeds by visiting an unvisited vertex adjacent to the current one; if no such vertex exists, then the algorithm backtracks to the previous visited vertex.

Similarly to the Euler tour, depth-first search is implemented in JDSL as an algorithm object, which can be extended by applying the template method pattern. The basic implementation of depth-first search—`DFS`—is designed to work on undirected graphs.

The user can specify actions to occur when a vertex is first or last visited or when different sorts of edges (such as “tree” edges of the DFS tree or “back” edges to previously visited vertices) are traversed by subclassing `DFS` and suitably overriding some methods.

`DFS` has two subclasses: `FindCycleDFS`, an algorithm for determining cycles in an undirected graph, and `DirectedDFS`, a depth-first search specialized for directed graphs. In turn, `DirectedDFS` has one subclass: `DirectedFindCycleDFS`, an algorithm for determining cycles in a directed graph. These subclasses are examples of how to apply the template method pattern to `DFS` in order to implement a more specific algorithm.

44.3.4.5 Topological Numbering

A topological numbering is a numbering of the vertices of a directed acyclic graph such that, if there is an edge from vertex u to vertex v , then the number associated with v is higher than the number associated with u .

Two algorithms that compute a topological numbering are included in JDSL: `TopologicalSort`, which decorates each vertex with a unique number, and `UnitWeightedTopologicalNumbering`, which decorates each vertex with a nonnecessarily unique number based on how far the vertex is from the source of the graph. Both topological numbering algorithms extend abstract class `AbstractTopologicalSort`.

44.3.4.6 Dijkstra’s Algorithm

Dijkstra’s algorithm computes the shortest path from a specific vertex to every other vertex of a weighted connected graph. The JDSL implementation of Dijkstra’s algorithm—`IntegerDijkstraTemplate`—follows the template method pattern and can be easily extended to change its functionality. Extending it makes it possible, for instance, to set the function for calculating the weight of an edge, to change the way the results are stored, or to stop the execution of the algorithm after computing the shortest path to a specific vertex (as done in subclass `IntegerDijkstraPathfinder`). An example of using Dijkstra’s algorithm is given in Section 44.4.

44.3.4.7 The Prim-Jarník Algorithm

The Prim-Jarník algorithm computes a *minimum spanning tree* of a weighted connected graph, that is, a tree that contains all the vertices of the graph and has the minimum total weight over all such trees. The JDSL implementation of the Prim-Jarník algorithm—`IntegerPrimTemplate`—follows the template method pattern and can be easily extended to change its functionality. Extending it makes it possible, for instance, to set the function for calculating the weight of an edge, to change the way the results are stored, or to stop the execution of the algorithm after computing the minimum spanning tree for a limited set of vertices.

44.4 A Sample Application

In this section we explore the implementation of a sample application using JDSL. In particular, we show the use of some of the concepts described above, such as the graph and priority queue data structures, locators, decorations, and the template method pattern.

44.4.1 Minimum-Time Flight Itineraries

We consider the problem of calculating a minimum-time flight itinerary between two airports. The flight network can be modeled using a weighted directed graph: each vertex of the graph represents an airport, each directed edge represents a flight from the origin airport to the destination airport, and the weight of each directed edge is the duration of the flight. The problem we are considering can be solved by computing a shortest path between two vertices of the directed graph or determining that a path does not exist. To this purpose, we can suitably modify the classical algorithm by Dijkstra [10], which takes as input a graph G with nonnegative edge weights and a distinguished source vertex s , and computes a shortest path from s to any reachable vertex of G . Dijkstra’s algorithm maintains a priority queue Q of vertices: at any time, the key of a vertex u in the priority queue is the length of the shortest path from s to u thus far. The priority queue is initialized by inserting vertex s with key 0 and all the other vertices with key $+\infty$ (some very large number). The algorithm repeatedly executes the following two steps:

1. Remove a minimum-key vertex u from the priority queue and mark it as *finished*, since a shortest path from s to u has been found.
2. For each edge e connecting u to an unfinished vertex v , if the path formed by extending a shortest path from s to u with edge e is shorter than the shortest known path from s to v , update the key of v (this operation is known as the *relaxation* of edge e).

```

```

FIGURE 44.6 Class `IntegerDijkstraTemplate`.

44.4.2 Class `IntegerDijkstraTemplate`

As seen in Section 44.3.4, JDSL provides an implementation of Dijkstra's algorithm that follows the template method pattern. The abstract class implementing Dijkstra's algorithm is `jdsl.graph.algo.IntegerDijkstraTemplate` (see [Figures 44.6](#); for brevity, the Javadoc comments present in the library code have been removed). The simplest way to run the algorithm is by calling `execute(InspectableGraph, Vertex)`, which first initializes the various auxiliary data structures with `init(g, source)`

```

protected Edgelterator incidentEdges (Vertex v) {
    return g .incidentEdges(v,EdgeDirection.OUT | EdgeDirection.UNDIR);
}

protected Vertex destination (Vertex origin, Edge e) {
    return g .opposite(origin,e);
}

protected VertexIterator vertices () {
    return g .vertices();
}

protected PriorityQueue newPQ () {
    return new ArrayHeap(new IntegerComparator());
}

// output instance methods

public final boolean isReachable (Vertex v) {
    return v.has(EDGE TO PARENT) && v.get(EDGE TO PARENT) != Edge.NONE;
}

public final int distance (Vertex v) throws InvalidQueryException {
    try {
        return ((Integer)v.get(DISTANCE)).intValue();
    }
    catch (InvalidAttributeException iae) {
        throw new InvalidQueryException(v+" has not been reached yet");
    }
}

public Edge getEdgeToParent (Vertex v) throws InvalidQueryException {
    try {
        return (Edge)v.get(EDGE TO PARENT);
    }
    catch (InvalidAttributeException iae) {
        String s = (v == source ) ? " is the source vertex" : " has not been reached yet";
        throw new InvalidQueryException(v+s);
    }
}

// instance methods composing the core of the algorithm

public void init (InspectableGraph g, Vertex source) {
    g = g;
    source = source;
    pq = newPQ();
    VertexIterator vi = vertices();
    while (vi.hasNext()) {
        Vertex u = vi.nextVertex();
        Integer uKey = (u == source ) ? ZERO : INFINITY;
        Locator uLoc = pq .insert(uKey,u);
        setLocator(u,uLoc);
    }
}

```

FIGURE 44.6 (Continued) Class `IntegerDijkstraTemplate`.

and then repeatedly calls `doOneIteration()`. Note that the number of times `doOneIteration()` is called is controlled by `should Continue()`. Another possibility, instead of calling `execute(InspectableGraph, Vertex)`, is to call `init(InspectableGraph, Vertex)` directly and then single-step the algorithm by explicitly calling `doOneIteration()`.

For an efficient implementation of the algorithm, it is important to access a vertex stored in the priority queue in constant time, whenever its key has to be modified. This is possible through the locator accessors provided by class `jds1.core.ref.ArrayHeap` (see Section 44.3.3). In `init(InspectableGraph, Vertex)`, each vertex `u` of the graph is inserted in the priority queue and a locator `uLoc` for the key/element pair is returned. By calling `setLocator(u, uLoc)`, each

```

protected final void runUntil () {
    while (!pq.isEmpty() && shouldContinue())
        doOneIteration();
}

public final void doOneIteration () throws InvalidEdgeException {
    Integer minKey = (Integer) pq.min().key();
    Vertex u = (Vertex) pq.removeMin(); // remove a vertex with minimum distance from the source
    if (minKey == INFINITY)
        vertexNotReachable(u);
    else { // the general case
        int uDist = minKey.intValue();
        shortestPathFound(u,uDist);
        int maxEdgeWeight = INFINITY.intValue() - uDist - 1;
        EdgeIterator ei = incidentEdges(u);
        while (ei.hasNext()) { // examine all the edges incident with u
            Edge uv = ei.nextEdge();
            int uvWeight = weight(uv);
            if (uvWeight < 0 || uvWeight > maxEdgeWeight)
                throw new InvalidEdgeException
                    ("The weight of "+uv+" is either negative or causing overflow");
            Vertex v = destination(u,uv);
            Locator vLoc = getLocator(v);
            if (pq.contains(vLoc)) { // v is not finished yet
                int vDist = ((Integer)vLoc.key()).intValue();
                int vDistViaUV = uDist + uvWeight;
                if (vDistViaUV < vDist) { // relax
                    pq.replaceKey(vLoc, new Integer(vDistViaUV));
                    setEdgeToParent(v,uv);
                }
                edgeRelaxed(u,uDist,uv,uvWeight,v,vDist);
            }
        }
    }
}

public final void execute (InspectableGraph g, Vertex source) {
    init(g,source);
    runUntil();
}

public void cleanup () {
    VertexIterator vi = vertices();
    while (vi.hasNext()) {
        vi.nextVertex().destroy(Locator);
        try {
            vi.vertex().destroy(EDGE_TO_PARENT);
            vi.vertex().destroy(DISTANCE);
        }
        catch (InvalidAttributeException iae) { }
    }
}

} // class IntegerDijkstraTemplate

```

FIGURE 44.6 (Continued) Class `IntegerDijkstraTemplate`.

vertex u is decorated with its locator $uLoc$; variable `LOCATOR` is used as the attribute name. Later, in `doOneIteration()`, the locator of vertex v is retrieved by calling `getLocator(v)` in order to access and possibly modify the key of v ; we recall that the key of v is the shortest known distance from the source vertex `source_to v`. In addition to its locator in the priority queue, every unfinished vertex v is also decorated with its last relaxed incident edge uv by calling `setEdgeToParent(v,uv)`; variable `EDGE_TO_PARENT` is used as the attribute name, in this case. When a vertex is finished, this decoration stores the edge to the parent in the shortest path tree, and can be retrieved with `getEdgeToParent(Vertex)`.

Methods `runUntil()` and `doOneIteration()` are declared final and thus cannot be overridden. Following the template method pattern, they call some methods, namely, `shouldContinue()`, `vertexNotReachable(Vertex)`, `shortestPathFound(Vertex, int)`, and `edgeRelaxed(Vertex, int, Edge, int, Vertex, int)`, that may be

overridden in a subclass for special applications. For each vertex u of the graph, either `vertexNotReachable(u)` or `shortestPathFound(u, uDist)` is called exactly once, when u is removed from the priority queue and marked as finished. In particular, `shortestPathFound(u, uDist)` decorates u with `uDist`, the shortest distance from `source_`; variable `DISTANCE` is used as the attribute name. Method `edgeRelaxed(u, uDist, uv, uvWeight, v, vDist)` is called every time an edge uv from a finished vertex u to an unfinished vertex v is examined. The only method whose implementation must be provided by a subclass is abstract method `weight(Edge)`, which returns the weight of an edge. Other important methods are `isFinished(Vertex)`, which returns whether a given vertex is marked as finished, and `distance(Vertex)`, which returns the shortest distance from `source_` to a given finished vertex.

44.4.3 Class IntegerDijkstraPathfinder

JDSL also provides a specialization of Dijkstra's algorithm to the problem of finding a shortest path between two vertices of a graph. This algorithm is implemented in abstract class `jdsl.graph.algo.IntegerDijkstraPathfinder` (see Figure 44.7;

```

package jdsl.graph.algo;

import jdsl.core.api.*;
import jdsl.core.ref.NodeSequence;
import jdsl.graph.api.*;
import jdsl.graph.ref.EdgeIteratorAdapter;

public abstract class IntegerDijkstraPathfinder extends IntegerDijkstraTemplate {

    // instance variables

    private Vertex dest;

    // overridden instance methods from IntegerDijkstraTemplate

    protected boolean shouldContinue () {
        return !isFinished(dest);
    }

    // output instance methods

    public boolean pathExists () {
        return isFinished(dest);
    }

    public EdgeIterator reportPath () throws InvalidQueryException {
        if (!pathExists())
            throw new InvalidQueryException("No path exists between "+source+" and "+dest);
        else {
            Sequence retval = new NodeSequence();
            Vertex currVertex = dest;
            while (currVertex != source) {
                Edge currEdge = getEdgeToParent(currVertex);
                retval.insertFirst(currEdge);
                currVertex = g.opposite(currVertex, currEdge);
            }
            return new EdgeIteratorAdapter(retval.elements());
        }
    }

    // instance methods

    public final void execute (InspectableGraph g, Vertex source, Vertex dest) {
        dest = dest;
        init(g, source);
        if (source != dest)
            runUntil();
    }
} // class IntegerDijkstraPathfinder

```

FIGURE 44.7 Class `IntegerDijkstraPathfinder`.

for brevity, the Javadoc comments present in the library code have been removed), which extends `IntegerDijkstraTemplate`. The algorithm is run by calling `execute(InspectableGraph, Vertex, Vertex)`. The execution of Dijkstra's algorithm is stopped as soon as the destination vertex is finished. To this purpose, `shouldContinue()` is overridden to return true only if the destination vertex has not been finished yet. Additional methods are provided in `IntegerDijkstraPathfinder` to test, after the execution of the algorithm, whether a path from the source vertex to the destination vertex exists (`pathExists()`), and, in this case, to return it (`reportPath()`).

44.4.4 Class FlightDijkstra

Our application for computing a minimum-time flight itinerary between two airports can be implemented as a specialization of `IntegerDijkstraPathfinder`. The distance of each vertex represents, in this case, the time elapsed from the beginning of the travel to the arrival at the airport represented by that vertex. In Figure 44.8 we show the code of class `FlightDijkstra`; this class is part of the tutorial^{*} distributed with JDSL. All it takes to implement our application is to override method `incidentEdges()`, so that only the outgoing edges of a finished vertex are examined, and to define method `weight(Edge)`. As noted before, the weighted graph representing the flight network is a directed graph. Each edge stores, as an element, an instance of auxiliary class `FlightSpecs` providing the departure time and the duration of the corresponding flight. Note that the weights of the edges are not determined before the execution of the algorithm, but rather depend on the computed shortest distance between the source vertex and the origin of each edge. Namely, they are obtained by adding the duration of the flight corresponding to the edge and the connecting time at the origin airport for that flight.[†] Method `TimeTable.diff(int, int)` simply computes the difference between its two arguments modulo 24 hours. The algorithm is run by calling `execute(InspectableGraph, Vertex, Vertex, int)`, where the fourth argument is the earliest time the passenger can begin traveling.

```

import jdsl.graph.api.*;
import jdsl.graph.algo.IntegerDijkstraPathfinder;
import support.*;

public class FlightDijkstra extends IntegerDijkstraPathfinder {

    // instance variables

    private int startTime_;

    // overridden instance methods from IntegerDijkstraPathfinder

    protected int weight (Edge e) {
        FlightSpecs eFS = (FlightSpecs)e.element(); // the flightspecs for the flight along edge e
        int connectingTime = TimeTable.diff(eFS.departureTime(), startTime_+distance(g_.origin(e)));
        return connectingTime+eFS.flightDuration();
    }

    protected Edgelterator incidentEdges (Vertex v) {
        return g_.incidentEdges(v,EdgeDirection.OUT);
    }

    // instance methods

    public void execute (InspectableGraph g, Vertex source, Vertex dest, int startTime) {
        startTime_ = startTime;
        super.execute(g,source,dest);
    }
}

```

FIGURE 44.8 Class `FlightDijkstra`.

^{*} <http://www.jdsl.org/tutorial/tutorial.html>

[†] In this sample application we ignore the minimum connecting time requirement, which however could be accommodated with minor code modifications.

As we can see from this example, the availability in JDSL of a set of carefully designed and extensible data structures and algorithms makes it possible to implement moderately complex applications with a small amount of code, thus dramatically reducing the development time.

Acknowledgments

We would like to thank all the members of the JDSL Team for their fundamental role in the design, implementation, and testing of JDSL. It has been a great experience and a real pleasure working together.

This work was supported in part by the National Science Foundation under grants CCR-0098068 and DUE-0231202.

45.1 Introduction

Important advances in programming languages have occurred since the early days of assembly languages and op codes, and modern programming languages have significantly simplified the task of writing computer programs. Unfortunately, tools for *understanding* programs have not achieved the accompanying levels of improvement. Software developers still face difficulties in understanding, analyzing, debugging, and improving code.

As an example of the difficulties still evident, consider a developer who has just implemented a new algorithm and is now ready to examine the program's behavior. After issuing a command to begin program execution, the developer examines output data and/or interactive behavior, attempting to ascertain if the program functioned correctly, and if not, the reasons for the program's failure. This task can be laborious and usually requires the use of a debugger or perhaps even the addition of explicit checking code, usually through output statements. Furthermore, the process can be quite challenging and the average developer may not be that skilled in fault diagnosis and correction. It would be extremely advantageous to have a tool that allows programmers to "look inside" programs as they execute, examining the changes to data and data structures that occur over time. Such a tool also could provide helpful context by identifying the current execution line, the active program unit, and the set of activations that have occurred to reach this configuration.

Tools, such as the one described above, are one form of *software visualization* [1]. Price, Baecker, and Small describe software visualization as, "the use of the crafts of typography, graphic design, animation, and cinematography with modern human-computer interaction and computer graphics technology to facilitate both the human understanding and effective use of computer software [2]." Fundamentally, software visualization seeks to take advantage of the visual perception and pattern matching skills of people to assist software development and software understanding. Human beings have very sophisticated visual perception systems that we constantly use to help us think [3]. Software visualization is a subfield in the larger area of *information visualization* [4,5] that studies how visualizations serve as external cognition aids.

Software visualization research and systems fall into two primary categories, *program visualization* and *algorithm visualization*.

Program visualization systems present data about and attributes of some existing software system. Typically, program visualizations are used in a software engineering context, that is, to help design, implement, optimize, test, or debug software. Thus, program visualization systems often illustrate source code, program data, execution statistics, program analysis information, or program objects such as data structures. The imagery in program visualization systems also is usually displayed with little or no input from the user/viewer. That is, a program (source code or executable) is analyzed by the system, which then automatically produces the graphics when the user requests them.

Algorithm visualization, conversely, strives to capture the abstractions and semantics of an algorithm or program primarily for pedagogical purposes. One often thinks of algorithm visualization as being more "high-level" as compared to program visualization being more "low level." The term *algorithm animation* is used interchangeably for this area simply because the displays are so dynamic and algorithm operations appear to animate over time. More specifically, Brown states, "Algorithm animation displays are, essentially, dynamic displays showing a program's fundamental *operations*—not merely its data or code

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

[6].” Algorithm visualizations typically are hand-crafted, user-conceptualized views of what is “important” about a program. These types of views usually require some person, often the system developer or the program’s creator, design and implement the graphics that accompany the program. The highly abstract, artificial nature of algorithm animations makes their automatic generation exceptionally difficult.

This chapter focuses on one specific subarea of software visualization, the visualization of data structures. By displaying pictures of data structures, one seeks to help people better understand the characteristics and the use of those structures.

How the data in computer programs are manipulated and organized by groups is a key aspect of successful programming. Understanding how elements of the data relate to other elements is a vital component in being able to comprehend and create sophisticated algorithms and programs. The word “structure” in “data structure” simply reinforces this point.

A person learning a new piece of software and seeking to modify it for some added functionality will likely ask a number of different questions. How are data elements organized? Is some kind of sequential structure used or is a more complicated organization present? Which items reference which other items? Understanding the answers to questions such as these helps a person to understand the utility and value of data structures. Providing pictures to express the relationships of data elements clearly then is one of the most useful ways to answer those questions.

45.2 Value of Data Structure Rendering

The graphical display of data structures can benefit a number of different activities, and one key role is as an aid for computer science education. It is not uncommon for students to have difficulty learning to understand and use non-trivial data structures such as arrays, lists, stacks, queues (Chapter 2), and trees (Chapter 3). One common problem occurs in the mapping back-and-forth between the pseudo code or programming language implementation of a structure and its conceptual model. In current educational methods, to foster understanding, the conceptual model (abstraction) is often presented in some graphical representation or picture—an interesting challenge is to find a book about data structures that does not make liberal use of pictures.

Systems for visualizing data structures typically provide or operate in an environment containing both the structures’ programming language implementation and their graphical display, which facilitates students making connections between the two. This allows an instructor to prepare a collection of “interesting” data structures for students to interact with and learn from. By examining the accompanying displays, students can make the connection from a structure’s abstract properties to its concrete implementation.

Another activity in which data structure visualization systems can provide significant help is program debugging. When a data structure display tool is used in conjunction with a traditional textual debugger, it allows the active data structures to be displayed and examined in some graphical format as program execution occurs and units of code are examined. When the program’s data change, the accompanying visualizations change too, reflecting the new program state.

The graphical display of data structures adds many advantages to strict textual debugging. Because a human’s visual perception system is a highly-tuned information processing machine, the sheer amount of information that can be transmitted to the user is much greater using graphics. With a textual debugger, people usually need to issue queries variable-by-variable to discover values. One glance at a computer display showing simultaneous representations of multiple structures may convey as much information as several minutes of the “query-reply” loop in a conventional debugger.

In addition to discovering data values, programmers use debuggers to access the relationships and connections between different pieces of data. This is a particular area in which graphical display is much more beneficial than textual interpreters. For example, to check the structure of a linked list in a language such as C++ or Java, a programmer must print out a list item’s values and references to other list items. By carefully examining the resulting values, the programmer can determine if the list is in the desired configuration. A data structure visualization tool that could display a linked list as a series of rectangular nodes with arrows acting as the references or pointers connecting the different nodes would tremendously simplify the programmer’s task of determining relationships among the data.

Data structure visualization tools also can aid the acquisition of contextual information about the state of a debugging session. For instance, a display could show a simple persistent view of the call stack and current execution line number in addition to the data pictures. In most debuggers, a user must often make repeated explicit queries to determine this information.

For these reasons and many more, data structure visualization systems remain a relatively untapped source of value to programmers. It is quite surprising that, given these benefits, more attention and research have not been devoted to the area, and data structure visualization systems have yet to achieve widespread use and adoption.

45.3 Issues in Data Structure Visualization Systems

45.3.1 Purpose and Environment

The software environment in which a data structure visualization system resides will influence many of the system’s capabilities. Data structure display systems usually target a specific programming language or set of languages for visualization. In particular,

many systems display only strongly-typed languages, simply because one is able to infer more information concerning the structure and composition of data objects in a strongly typed language. It also is easier to “customize” a specific graphical look for the different data structure types in a strongly typed language. A weakly typed language such as an assembly language generally forces a more generic looking display of data.

Clearly, the inherent characteristics of a particular programming language will also influence the language’s resulting data visualizations. We would expect the node-pointer list data depiction to be an integral part of a LISP visualization system, while imperative languages such as C or Pascal would necessitate repeated use of a flexible structured, tiled image with easy to recognize and identify sub-fields. The display of graphical objects representing class instances and some form of arcs or arrows for messages (method invocations) would be important for illustrating an object-oriented language such as C++ or Java.

The intended audience of a data structure visualization system also affects the system’s resulting displays. For example, a system designed for use by introductory programmers would probably stress consistent, simplified data structure views. Conversely, a system targeted to advanced programmers should support sophisticated, customized displays of complex, large data objects. Such a system should also allow a viewer to quickly suppress unwanted display objects and focus on items of special interest.

One common use of data structure visualization systems is in conjunction with other tools in a programming environment or an integrated development environment (IDE). For example, “attaching” a data structure visualization system to a program execution monitor allows the display of graphical data snap-shots at various points in the program’s execution. By consistently displaying imagery, a form of program data animation results, showing how a program’s data change over time.

Most often, a data structure visualization system functions in conjunction with a program debugger. In this arrangement, the display system provides a graphical window onto the program, permitting a persistent view of the data as opposed to the query-based approach of a textual debugger. While a programmer navigates through her program and its data by using a debugger, a data structure visualization system can map the particular data objects of interest onto a graphical format. As discussed in the previous section, the graphical format provides many benefits to typical debugging activities.

45.3.2 Data Structure Views

A primary distinguishing characteristic of a data structure visualization system is the types of data views it supports. Most systems provide a set of default views for the common data types such as integers, floats, and strings. Some systems also provide default views for more complex composite structures such as arrays, lists, and trees. Visualization systems frequently differ in their ability to handle a display request for a data object of a type other than those in the default view set. Reactions to such a query may range from taking no display action to utilizing a generic view applicable to all possible data types. Some systems also provide users with the ability to tailor a special graphical view for a particular, possibly uncommon data type. The process of defining these views is often tedious, however, discouraging such forms of improvisation.

Specific, relatively common data views that are often handled in varying ways include pointers/references, fields within composite structures, and arrays. Pointers/references, usually represented in a line-arrow manner, present a particularly tricky display problem because they involve issues similar to those evident in graph layout, a known difficult problem [7] (see also [Chapter 47](#)). Ideally, a view with pointers should minimize pointer overlap, edge crossings, and collisions with other display objects. Both polyline and spline display formats for pointers are common.

Representing fields within a composite data structure is a difficult problem because of spacing and layout concerns. Subfields can be complex structures themselves, complicating efforts to make the data structure view clear and comprehensible.

Arrays present a challenging visualization problem because of the variety of displays that are possible. For instance, a simple one-dimensional array can be presented in a horizontal or vertical format. The ideal view for multi-dimensional arrays can also be a difficult rendering task, particularly for arrays of dimension three or higher.

The ability to display multiple views of a specific data instance is also a valuable capability of a data structure visualization system because certain display contexts may be more informative in particular situations. Allowing varying levels of view abstraction on data is another important feature. For example, consider an array of structures in the C programming language. At one level, we may wish to view the array formation globally, with each structure represented by a small rectangle. At a closer level, we may wish to view a particular array structure element in full detail, with little attention paid to the other array elements.

Some data structure display systems provide visualizations for components of program execution such as program flow of control and the call stack. While these components are not program data structures, their graphical visualizations can be helpful additions to a data structure display system, especially when used in conjunction with a debugger.

45.3.3 Interacting with a System

Data structure visualization systems provide many different ways for users to interact with the system. For instance, consider the manner that users employ to actually display a particular piece of data. Systems that work in conjunction with a debugger may

provide a special *display* command in the debugger. Other systems may utilize a specialized user interface with a particular direct manipulation protocol for invoking data display, such as choosing a menu item and supplying a variable name or graphically selecting a variable in a source code view.

Visualization systems vary in the manner of interactions they provide to users as well. For instance, once data is selected for display, the corresponding image(s) must be rendered on the viewing area. One option for this rendering is to allow the viewer to position the images, usually with the mouse. This method has the advantage of giving the user explicit control, but often, such repeated positioning can become tedious. Another rendering option gives the system total placement control. This method has the advantage of requiring less viewer input, but it requires sophisticated layout algorithms to avoid poor layout decisions. Perhaps the most attractive rendering option is a combination of these two: automatic system display with subsequent user repositioning capabilities.

Limits in display window viewing area force data structure visualization systems to confront sizing issues also. One simple solution to the problem of limited viewing space is to provide an infinite, scrollable viewing plane. Another solution, one more closely integrated with the system, is to utilize varying display abstractions dependent upon the amount of space available to view a data object. For example, given no space limitations, an object could be rendered in its default view. With very limited space, the object could be rendered in a space-saving format such as a small rectangle.

Once data has been displayed in the viewing window, the viewer should be able to interact with and control the imagery. Allowing a user to interactively move and delete images is certainly desirable. Even more beneficial, however, is the capability to suppress aspects of the data that are not of interest. For instance, only a small section of an array may be “interesting,” so a visualization system could deemphasize other portions as a user dictates. Similarly, only certain sections of linked lists and trees may require attention, and only certain fields with a particular structure type may be of interest. Allowing a viewer to quickly dispose of uninteresting attributes and focus on the matter at hand is a very valuable feature.

If a data structure visualization system works in conjunction with a debugger, display interaction may take on a further role, that of interactive debugging itself. Graphical editing of data imagery by the viewer can be interpreted as corresponding changes to the underlying data. For example, a system may allow a viewer to enter a new data value for a variable by graphically selecting its accompanying image and overwriting the value displayed there. An even more sophisticated action is to allow a viewer to “grab” a pointer variable, usually represented by an arrow on the display, and alter its value by dragging and repositioning the arrow image in order to make the pointer reference some other object.

45.4 Existing Research and Systems

The idea of creating a system that would visualize data structures in computer programs is an old one, dating back even to the 1960’s [8]. During this long history, a number of systems for data structure visualization have been developed. Most, however, have only been research prototypes and have never been used by anyone outside the system’s creator(s). This relative lack of adoption is surprising in light of the potential benefits of data structure display identified above. A quick survey of widely-used current IDEs notes that none provide anything beyond the most limited abilities to persistently display data values, or more importantly, visualize data structures.

For a good overview of the aesthetic considerations and the general challenges in drawing data structures, see the article by Ding and Mateti [9]. The authors provide a rigorous survey of the different styles of drawings used in data structure diagrams. They enumerate a set of characteristics that influence people’s perceptions of data structure illustrations, including visual complexity, regularity, symmetry, consistency, modularity, size, separation, shape, and traditional ways of drawing. Further, they develop a set of guidelines for drawing aesthetically appealing diagrams. The guidelines are based on rules, factors, and objectives, and include the ability to quantitatively assess the aesthetics of different diagrams. Ding and Mateti note that the automatic drawing of data structure representations is difficult because a diagram should be determined not only by a structure’s declaration, but also by its intended usage.

Stasko and Patterson echo that thought by identifying the notion of *intention content* in program visualizations [10]. They note that a programmer’s intent in creating and using a data structure can significantly influence how the structure should best be visualized. For instance, a simple array of integers may be shown as a row of rectangles with the values inside; a row of rectangles whose height is scaled to the value of each element; a round pie chart with a wedge whose percentage size of the circle corresponds to the value of that array element; or a stack with the array elements sitting on top of each other. To generate the latter two representations, some knowledge of the purpose and goal of the surrounding program code is necessary.

In the remainder of this section, we present brief summaries of a few of the most noteworthy data structure visualization systems that have been developed. Each of these grew from research projects, and the final one, DDD, has been used significantly by outside users. In reviewing each system, we highlight its unique aspects, and we evaluate it with respect to the issues raised in the previous section.

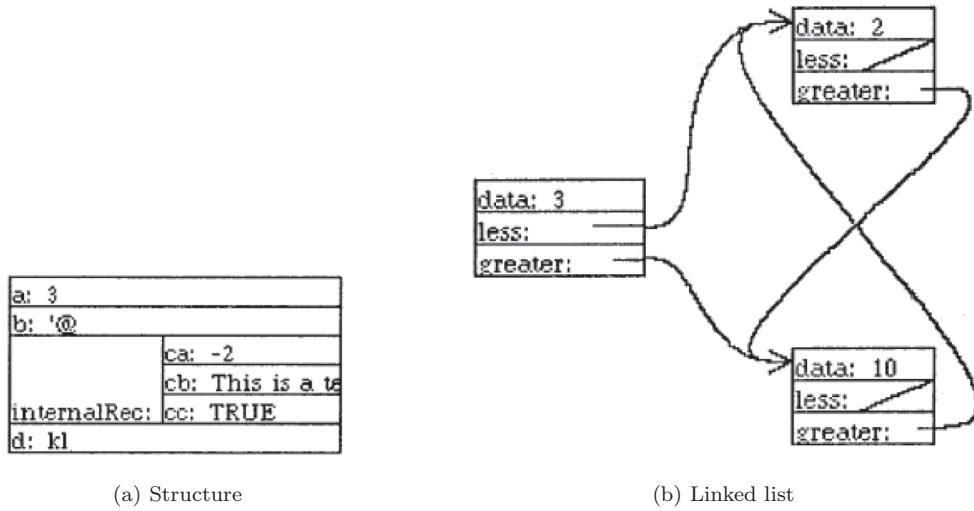

FIGURE 45.1 Example data structure views shown in the Incense system. Pictures provided by and reprinted with permission of Brad Myers.

45.4.1 Incense

The Incense system [11] developed by Myers was one of the earliest attempts to build a relatively full-featured data structure display system. Myers stated that Incense allowed a “programmer to interactively investigate data structures in actual programs.”

The system operated on a Xerox Alto personal computer and displayed data structures for the Mesa strongly typed programming language. In the system, data structures could be displayed at debug time by supplying a variable’s name; Incense examined the symbol table to determine the variable’s type. Once a variable was chosen, the user specified via the mouse a rectangular viewing area inside the active window to display the data. Incense automatically chose the appropriate view abstraction given the space requirements. Data with insufficient screen space were displayed as grey boxes.

The system included a large number of sophisticated default views for the language’s data types and structures, and it utilized a spline-based method for displaying pointers. Examples of views of different types of data structures are shown in Figure 45.1. Additionally, users could define their own data views using a predefined graphics library in Mesa. The difficulty of that process is unclear.

In order to implement Incense, Myers created the concept of an *artist*, a collection of procedures and data that handled display, erasure, and modification of the data being displayed. An artist had to be associated with a piece of data in the system in order to display it. To display pointers as arrows, Incense utilized *layouts*, special types of artists designed to locate and manage the various pointer and referent components of data.

The system was designed to allow users to also edit variables’ values at run-time in the graphical presentation, but it does not appear that this feature was ever implemented. Unfortunately, the host hardware’s space and processing limitations made Incense’s performance relatively poor which likely restricted it to being a research prototype. The system did, however, illustrate a multitude of valuable capabilities that a data structure visualization system could offer.

45.4.2 VIPS

The VIPS [12] visual debugger by Shimomura and Isoda focused on providing a flexible set of views of lists in programs. The system ran on top of the DBX debugger, with VIPS and DBX communicating through pipes. For instance, when a user would issue a request to display a list, the VIPS system would send necessary messages to DBX to extract information needed for the display. In addition to views of list data structures, VIPS provided views (windows) of program text, I/O, variable displays, as well as control windows for debugger interactions.

VIPS provided two main views of program lists, the whole list view and the partial list view. In the whole view, shown on the left side of Figure 45.2, list nodes were represented as small black rectangles thus allowing more than 100 nodes to be shown at once. The basic layout style used by the system was a classic binary tree node-link layout with the root at the left and the tree growing horizontally to the right. The whole list view assisted users in understanding structure. The partial list view, shown on the right-hand side of Figure 45.2, presented each node in a more magnified manner, allowing the user to see the values of individual fields within the node. By dragging a rectangle around a set of nodes in the whole list view, a user could issue a command to

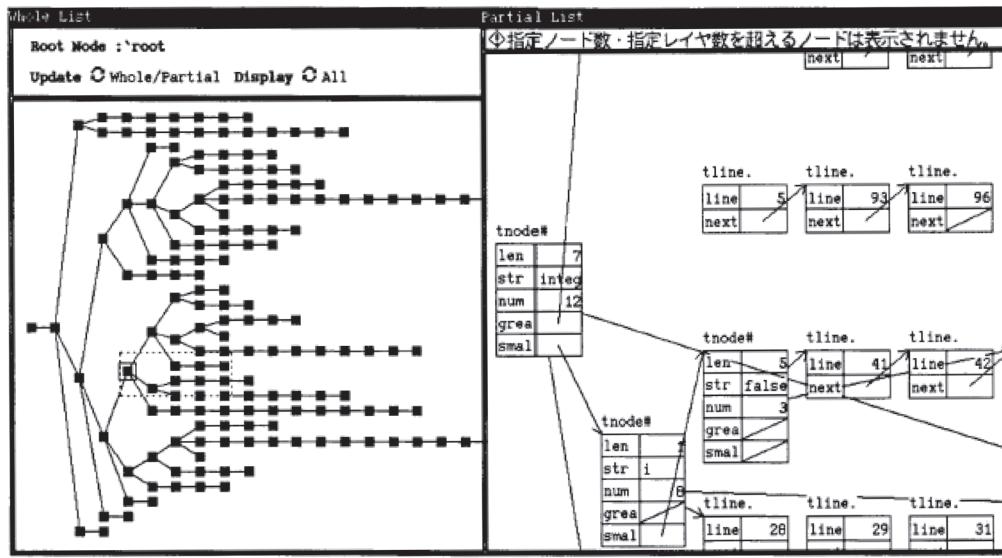

FIGURE 45.2 Data structure views in the VIPS system. (Picture reprinted with permission from T. Shimomura and S. Isoda. *IEEE Software*, 8, 3, 1991, 44–51 page 47, copyright 1991 IEEE.)

generate a new partial list view. VIPS also allowed users to select particular pointer fields in list structures and only have the nodes connected by those pointers to be displayed.

To assist debugging, VIPS also provided a *highlight* feature in which list structures with values that had recently changed were highlighted in order to draw the viewer's attention.

An earlier version of the system [13] provided multiple run-time views of executing Ada programs. Default data views in the system included scalars, linked lists, one-dimensional arrays and records. VIPS also allowed users to design their own data displays or “figures” by writing programs in the Figure Description Language FDL, a subset of Ada. FDL programs contained parameters that could be associated with a variable or variables, promoting view control via data values. Data displays were rendered automatically by the system. When space was tight, smaller representations were utilized.

The VIPS debugger provided one of the most extensive graphically-aided debugging systems onto a particular language. By adding views of the call stack, data flow, and program structure to program data visualizations, the system explored the boundary of visual debugging efforts at that time.

45.4.3 GELO

The GELO system [14] was designed to ease the production and display of complex pictures of programs and data structures. In the system, strongly typed data structures were displayed as picture objects of types data, tile, layout, arc, and empty. GELO differed from many other data structure display systems in that diagrams were not described in a world coordinate space, but by giving a set of topological constraints for their views.

The system was organized as three components: GELO managed the specification and display of classical program and data structures; APPLE allowed a user to design and customize the way that a particular data structure would appear by providing mechanisms for defining the mapping between the data structure and the GELO structures (more than one mapping was allowed); PEAR used these mappings to allow the user to edit the structures' display, thereby modifying the underlying data structures.

GELO allowed users to specify both the data instances to be displayed and the drawing attributes of the display through fairly complex dialog box selections. It provided default displays for common structures such as lists and trees, as well as various heuristics for graph layout. A sample list view is shown in Figure 45.3 and a tree view is shown in Figure 45.4. GELO included view panning and zooming, abstractions on small objects, and scrollable windows.

Reiss noted that the system's topological layout scheme was sometimes overly restrictive; users may have wanted to have a picture “look just so” but GELO did not provide this capability. The sheer amount of dialog and menu choices for designing a display also appeared to be daunting, but the sophistication of automatic layout GELO provided was quite impressive.

45.4.4 DDD

The DDD System [15,16], developed by Zeller, provides some of the most sophisticated graphical layout capabilities ever found in a data structure display system. DDD is technically a front-end to command-line debuggers such as GDB and DBX, and it provides

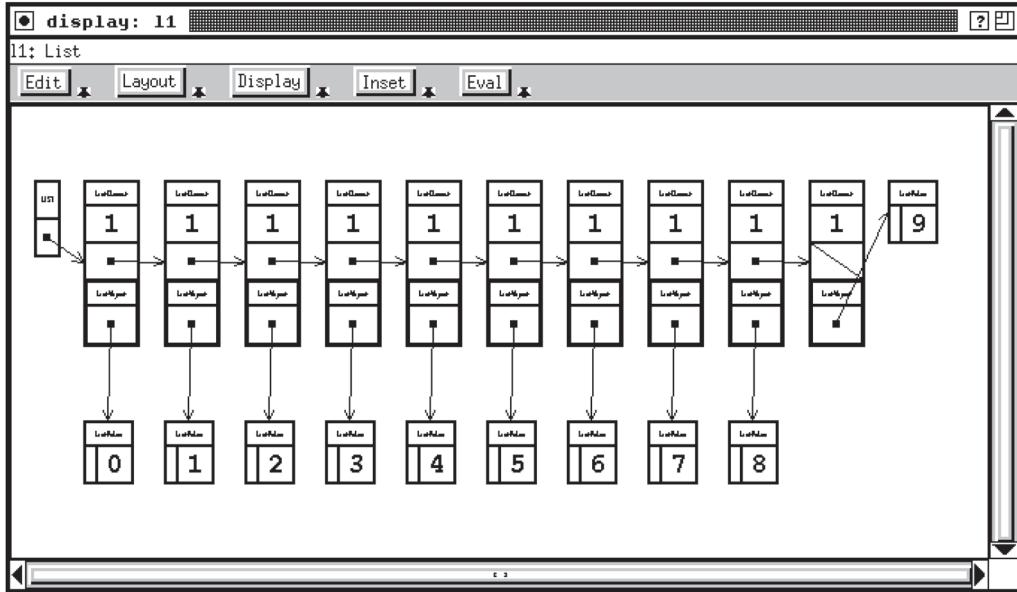

FIGURE 45.3 GELO view of a list. Picture provided courtesy of Steve Reiss.

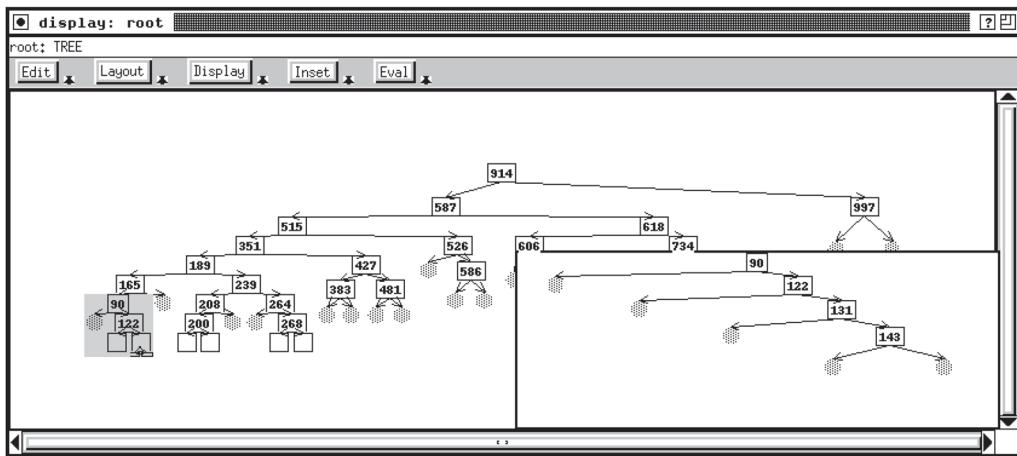

FIGURE 45.4 GELO view of a tree. Picture provided courtesy of Steve Reiss.

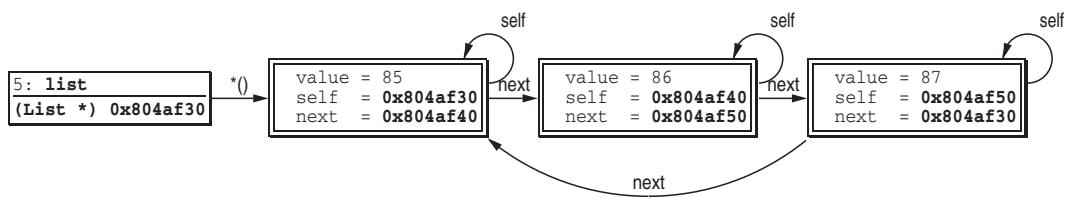

FIGURE 45.5 An example DDD representation of a linked list structure. Picture provided courtesy of Andreas Zeller.

all the capabilities of those debuggers. Additionally, program variables can be visualized in *displays*, rectangular windows that can be placed on a user's canvas.

DDD's sophistication comes in its techniques for visualizing pointer dereferencing. It draws a directed edge from one display to another to indicate the reference. DDD contains simple placement rules with edges pointing right and downward, or if desired, sophisticated graph layout algorithms can be invoked. Figure 45.5 shows an example data structure view from DDD.

In the default display mode, only one edge can point to any display. Thus, it is possible to have a visualization in which a display (variable or specific piece of memory) appears multiple times. DDD also provides alias detection, however, so that all program data residing at the same location are consolidated to the same display object. Thus, lists with cycles will be shown as the circular representation that one would expect.

DDD is particularly noteworthy in that the system is available as free software and it has been widely downloaded and utilized. It is perhaps the data structure visualization that has been most used by people other than the system creators.

45.4.5 Other Systems

In addition to the systems mentioned above, a number of other data structure display tools have been developed over the years. Some of the more noteworthy ones include

- GDBX [17]—A graphical extension to the UNIX debugger DBX.
- PROVIDE [18]—An ambitious process visualization and debugging environment for programs written in a subset/variant of the C programming language.
- Amethyst [19]—A system intended to simplify data structure visualization for novice programmers.
- DS-Viewer [20]—A system that focused on the display of structures in a weakly typed language such as an assembler language.
- Lens [21]—A layer on top of the DBX debugger that provided, via programmer annotations, both data structure display capabilities as well as simple algorithm animation operations.
- SWAN [22]—A system that allowed instructors and students to easily annotate programs to produce data structure views.

45.5 Summary and Open Problems

Although the systems summarized in this paper have shown the promise that data structure visualization holds, data structure display systems still are not widely used in teaching and still are not commonly included in IDEs for programmers to use. Until data structure display systems achieve more general acceptance, the area will continue to exhibit unfulfilled potential. Anyone who has ever programmed will surely agree that a visualization of the complex interactions of data can only help comprehension and debugging of computer programs. Now that software and hardware improvements for graphical displays have made these types of visualizations routine, hopefully, this unfulfilled potential will be reached. Below we describe some specific problems that remain to be solved in order to help foster the growth of data structure visualization.

- **User-defined displays** – Invariably, advanced programmers or programmers in a specific application area will want to build customized views of particular data types and structures. Existing systems have only either provided generic default displays or have required people to do tedious graphical design in order to build custom views. A powerful data structure display system should allow users to *quickly* and *easily* demonstrate a new graphical form for a data structure. Thus, a data structure display system likely must include some form of sophisticated graphical editor or toolkit to facilitate view design.
- **Mapping data to their display** – In addition to designing new views, designers must be able to specify how data is to be interpreted to generate the views. Creating an easy-to-understand and easy-to-use mapping scheme is quite difficult, particularly if multiple pieces of data can “drive” a particular view or one piece of data can be presented in different view abstractions.
- **Complex, large data** – With the possible exception of DDD, prior data structure display systems have been better suited for programming-in-the-small with relatively straightforward, moderate-sized data structures. Sophisticated display imagery becomes significantly more difficult as the complexity and sheer size of the data increases, thereby complicating screen layout issues. Further abstraction and mapping strategies are required to properly address these issues also.

46.1 Introduction

Constructing geometric representations of graphs in a readable and efficient way is crucial for understanding the inherent properties of the structures in many applications. The desire to generate a layout of such representations by algorithms and not by hand meeting certain aesthetics has motivated the research area *Graph Drawing*. Examples of these aesthetics include minimizing the number of edge crossings, minimizing the number of edge bends, minimizing the display area of the graph, visualizing a common direction (flow) in the graph, maximizing the angular resolution at the vertices, and maximizing the display of symmetries. Certainly, two aesthetic criteria cannot be simultaneously optimized in general and it depends on the data which criterion should be preferably optimized. Graph Drawing Software relies on a variety of mathematical results in graph theory, topology, geometry, as well as computer science techniques mainly in the areas algorithms and data structures, software engineering and user interfaces.

A typical graph drawing problem is to create for a graph $G = (V, E)$ a geometric representation where the nodes in V are drawn as geometric objects such as points or two dimensional shapes and edges $(u, v) \in E$ are drawn as simple Jordan curves connecting the geometric objects associated with u and v . Apart from the, in the context of this book obvious, visualization of Data Structures, other application areas are, for example, software engineering (Unified Modelling Language (UML)), data flow diagrams, subroutine-call graphs) databases (entity-relationship diagrams), decision support systems for project management (business process management, work flow).

A fundamental issue in Automatic Graph Drawing is to display trees, since trees are a common type of data structures. Thus a good drawing of a tree is often a powerful intuitive guide for analyzing data structures and debugging their implementations. It is a trivial observation that a tree $T = (V, E)$ always admits a planar drawing, that is a drawing in the plane such that no two edges cross. Thus all algorithms that have been developed construct a planar drawing of a tree. Furthermore it is noticed that for trees the condition $|E| = |V| - 1$ holds and therefore the time complexity of the layout algorithms is always given in dependency to the number of nodes $|V|$ of a tree.

In 1979, Wetherell and Shannon [1] presented a linear time algorithm for drawing binary trees satisfying the following aesthetic requirements: the drawing is *strictly upward*, that is, the y-coordinate of a node corresponds to its level, so that the hierarchical structure of the tree is displayed; the left child of a node is placed to the left of the right child, that is, the order of the children is displayed; finally, each parent node is centered over its children. Moreover, edges are drawn *straight line*. Nevertheless, this algorithm showed some deficiencies. In 1981, Reingold and Tilford [2] improved the Wetherell-Shannon algorithm by adding the following feature: each pair of isomorphic subtrees is drawn identically up to translation, that is, the drawing does not depend

^{*} This chapter has been reprinted from first edition of this Handbook, without any content updates.

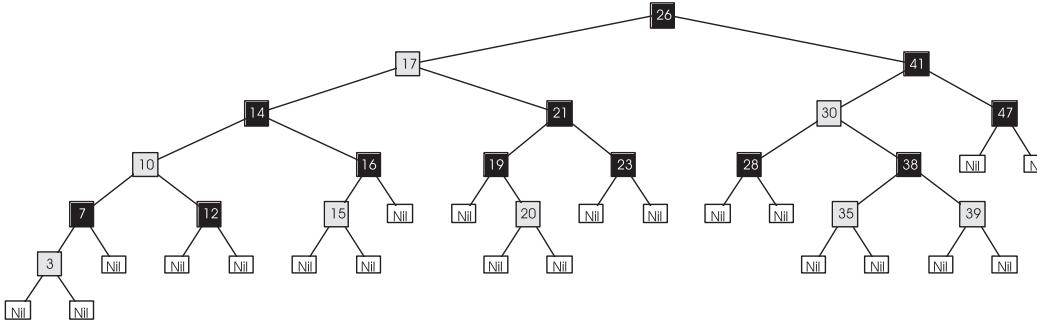

FIGURE 46.1 A typical layout of a binary tree. The tree is a red-black tree as given in Reference 3.

on the position of a subtree within the complete tree. They also made the algorithm symmetrical: if all orders of children in a tree are reversed, the computed drawing is the reflected original one. The width of the drawing is not always minimized subject to these conditions, but it is close to the minimum in general. The algorithm of Reingold and Tilford that runs in linear time, is given in Section 46.3. [Figure 46.1](#) gives an example of a typical layout produced by Reingold and Tilfords Algorithm.

Extending this algorithm to rooted ordered trees of unbounded degree in a straightforward way produces layouts where some subtrees of the tree may get clustered on a small space, even if they could be dispersed much better. This problem was solved in 1990 by the quadratic time algorithm of Walker [4], which spaces out subtrees whenever possible. Very recently Buchheim et al. [5] showed how to improve the algorithm of Walker to linear running time. The algorithm by Buchheim et al. is given in Section 46.4, including a pseudo code that allows the reader a straightforward application of the algorithm. This algorithm for n -ary trees gives similar results on binary trees as the algorithm of Reingold and Tilford.

In Section 46.5 algorithms for straight line circular drawings (see [6–9]) are introduced. This type of layout proved to be useful for free trees that do not have a designated node as a root. Section 46.6 presents *hv*-drawings, an approach for drawing binary and n -ary trees on a grid. For binary trees, edges in an *hv*-drawing are drawn as rightward horizontal or downward vertical segments. This type of drawing is straight line *upward orthogonal*. It is, however, not strictly upward. Such drawings are for example, investigated in References 10–17.

Variations of the *hv*-layout algorithms have been used to obtain results on minimal area requirements of tree layouts. Shiloach and Crescenzi et al. [10,16] showed that any rooted tree admits an upward straight-line drawing with area $O(|V| \log |V|)$. Crescenzi et al. [10] moreover proved that there exists a class of rooted trees that require $\Omega(|V| \log |V|)$ area if drawn strictly upward straight-line. In [10,18] algorithms are given that produce $O(|V|)$ -area strictly upward straight line drawings for some classes of balanced trees such as complete binary trees, Fibonacci trees, and AVL trees. These results have been expanded in Reference 19 to a class of balanced trees that include k -balanced trees, red-black trees, BB $[\alpha]$ -trees, and (a, b) -trees. Garg et al. [20] gave an $O(|V| \log |V|)$ area algorithm for ordered trees that produces upward layouts with polyline edges. Moreover they presented an upward orthogonal (not necessarily straight line) algorithm with an asymptotically optimal area of $O(|V| \log \log |V|)$.

Shin et al. [21] showed that bounded degree trees admit upward straight line layouts with an $O(|V| \log \log |V|)$ area. The result can be modified to derive an algorithm that gives an upward polyline grid drawing with an $O(|V| \log \log |V|)$ area, at most one bend per edge, and $O(|V| / \log |V|)$ bends in total. Moreover in Reference 21 an $O(|V| \log \log |V|)$ area algorithm has been presented for non upward straight line grid layouts with arbitrary aspect ratio. Recently, Garg and Rusu [22] improved this result giving for binary trees an $O(|V|)$ area algorithm for non upward straight line orthogonal layouts with a pre specified aspect ratio in the range of $[1, |V|^\alpha]$, with $\alpha \in [0, 1]$ that can be constructed in $O(|V|)$.

46.2 Preliminaries

A (*rooted*) *tree* T is a directed acyclic graph with a single source, called the *root* of the tree, such that there is a unique directed path from the root to any other node. The *level* $l(v)$ of a node v is the length of this path. The largest level of any node in T is the height $h(T)$ of T . For each edge (v, w) , v is the *parent* of w and w is a *child* of v . Children of the same node are called *siblings*. Each node w on the path from the root to a node v is called an *ancestor* of v , while v is called a *descendant* of w . A node that has no children is a *leaf*. If v_1 and v_2 are two nodes such that v_1 is not an ancestor of v_2 and vice versa, the *greatest distinct ancestors* of v_1 and v_2 are defined as the unique ancestors w_1 and w_2 of v_1 and v_2 , respectively, such that w_1 and w_2 are siblings. Each node v of a rooted tree T induces a unique subtree $T(v)$ of T with root v .

Binary trees are trees with a maximum number of two children per node. In contrast to binary trees, trees that have an arbitrary number of children are called *n-ary trees*. A tree is said to be ordered if for every node the order of its children is fixed. The first

(last) child according to this order is called the *leftmost (rightmost)* child. The *left (right) sibling* of a node v is its predecessor (successor) in the list of children of the parent of v . The *leftmost (rightmost) descendant* of v on a level l is the leftmost (rightmost) node on the level l belonging to the subtree $T(v)$ induced by v . Finally, if w_1 is the left sibling of w_2 , v_1 is the rightmost descendant of w_1 on some level l , and v_2 is the leftmost descendant of w_2 on the same level l , the node v_1 is called the *left neighbor* of v_2 and v_2 is the *right neighbor* of v_1 .

To draw a tree into the plane means to assign x- and y-coordinates to its nodes and to represent each edge (v, w) by a straight line connecting the points corresponding to v and w . Objects that represent the nodes are centered above the point corresponding to the node. The computation of the coordinates must respect the sizes of the objects. For simplicity however, we assume throughout this paper that all nodes have the same dimensions and that the minimal distance required between neighbors is the same for each pair of neighbors. Both restrictions can be relaxed easily, since we will always compare a single pair of neighbors.

Reingold and Tilford have defined the following aesthetic properties for drawings of trees:

- A1. The layout displays the hierarchical structure of the tree, that is, the y-coordinate of a node is given by its level.
- A2. A parent is centered above its children.
- A3. The drawing of a subtree does not depend on its position in the tree, that is, isomorphic subtrees are drawn identically up to translation.

By their appearance, these drawings are called *level drawings*. If the tree that has to be drawn is ordered, we additionally require the following:

- A4. The order of the children of a node is displayed in the drawing, thus a left child is placed to the left with a smaller x-coordinate and a right child is placed to the right with a bigger x-coordinate.
- A5. A tree and its mirror image are drawn identically up to reflection.

Here, the *reflection* of an ordered tree is the tree with reversed order of children for each parent node. It is desirable to find a layout satisfying (A1–A5) with a small width. However, it has been shown by Supovit and Reingold [23] that achieving the minimum grid width is NP-hard. Moreover, there is no polynomial time algorithm for achieving a width that is smaller than $\frac{25}{24}$ time the minimum width, unless $P = NP$. If on the other hand continuous coordinates instead of integral coordinates are allowed, minimum width drawing can be found in linear time by applying linear programming techniques (see [23]).

46.3 Level Layout for Binary Trees

For ordered binary trees, the first linear time algorithm satisfying (A1–A5) was presented by Reingold and Tilford [2]. The algorithm follows the divide and conquer principle implemented in form of a postorder traversal of a tree $T = (V, E)$ and places the nodes on grid units. For each $v \in V$ with left and right child w_{left}, w_{right} the algorithm computes layouts for the trees $T(w_{left})$ and $T(w_{right})$ up to horizontal translation. When v is visited, the drawing of the right subtree $T(w_{right})$ is shifted to the right such that on every level l of the subtrees the rightmost node v_{left} of $T(w_{left})$ and its neighbor, the leftmost node v_{right} of $T(w_{right})$ are separated at least by two or three grid points. The separation value between v_{left} and v_{right} is chosen such that v can be centered above the roots of $T(w_{left})$ and $T(w_{right})$ at an integer grid coordinate.

Shifting $T(w_{right})$ is partitioned into two subtask: first, determining the amount of shift and second, performing the shift of the subtree. To determine the amount of shift, define the *left contour* of a tree T to be the vertices with minimum x-coordinate at each level in the tree. The *right contour* is defined analogously. For an illustration, see Figure 46.2, where nodes belonging to the contours are shaded. To place $T(w_{right})$ as close to $T(w_{left})$ as possible, the right contour of $T(w_{left})$ and the left contour of $T(w_{right})$ are traversed calculating for every level l the amount of shift to separate the two subtrees on that specific level l . The maximum over all shift then gives the displacement for the trees such that they do not overlap. Since each node belongs to the traversed part of the left contour of the right subtree at most for one subtree combination, the total number of such comparisons is linear for the complete tree.

In order to achieve linear running time it must be ensured that the contours are traversed without traversing (too many) nodes not belonging to the contours. This is achieved by introducing a *thread* for each leaf of the subtree that has a successor in the same contour. The thread is a pointer to this successor. See Figure 46.2 for an illustration where the threads are represented by dotted arrows. For every node of the contour, we now have a pointer to its successor in the left (right) contour given either by its leftmost (rightmost) child or by the thread. Finally, to update the threads, a new thread has to be added whenever two subtrees of different height are combined.

Once the shift has been determined for $T(w_{right})$ we omit shifting the subtree by updating the coordinates of its nodes, since this would result in quadratic running time. Instead, the position of each node is only determined preliminary and the shift for $T(w_{right})$ is stored at w_{right} as the *modifier* $mod(w_{right})$ (see [1]). Only $mod(w_{right})$ and the preliminary x-coordinate $prelim(v)$ of

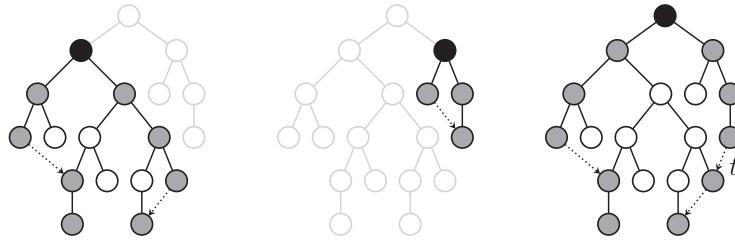

FIGURE 46.2 Combining two subtrees and adding a new thread t .

the parent v are adjusted by the shift of $T(w_{right})$. The modifier of w_{right} is interpreted as a value to be added to all preliminary x -coordinates in the subtree rooted at w_{right} , except for w_{right} itself. Thus, the coordinates of a node v in T in the final layout is its preliminary position plus the aggregated modifier $modsum(v)$ given by the sum of all modifiers on the path from the parent of v to the root. Once all preliminary positions and modifiers have been determined the final coordinates can be easily computed by a top-down sweep.

Theorem 46.1

[Reingold and Tilford [2]] The layout algorithm for binary trees meets the aesthetic requirements (A1–A5) and can be implemented such that the running time is $O(|V|)$.

Proof. By construction of the algorithm it is obvious that the algorithm meets (A1–A5). So it is left to show that the running time is linear in the number of nodes. Every node of T is traversed once during the postorder and the preorder traversal. So it is left to show that the time needed to traverse the contour of the two subtrees $T(w_{left})$ and $T(w_{right})$ for every node v with children w_{left} and w_{right} is linear in the number of nodes of T over all such traversals.

It is obviously necessary to travel down the contours of $T(w_{left})$ and $T(w_{right})$ only as far as the tree with lesser height. Thus the time spent processing a vertex v in the postorder traversal is proportional to the minimum of the height of $h(T(w_{left}))$ and $h(T(w_{right}))$. The running time of the postorder traversal is then given by:

$$\sum_{v \in T} (1 + \min\{h(T(w_{left})), h(T(w_{right}))\}) = |V| + \sum_{v \in T} \min\{h(T(w_{left})), h(T(w_{right}))\}$$

The sum $\sum_{v \in T} \min\{h(T(w_{left})), h(T(w_{right}))\}$ can be estimated as follows. Consider a node w that is part of a contour of a subtree $T(w_{left})$. When comparing the right contour of $T(w_{left})$ and the left contour of $T(w_{right})$ two cases are possible. Either w is not traversed and therefore will be part of the contour of $T(v)$ or it is traversed when comparing $T(w_{left})$ and $T(w_{right})$. In the latter case, w is part of the right contour of $T(w_{left})$ and after merging $T(w_{left})$ and $T(w_{right})$ the node w is not part of the right contour of $T(v)$. Thus every node of T is traversed at most twice and the total number of comparisons is bounded by $|V|$. ■

We do not give the full algorithm for drawing binary trees here. Instead, the layout algorithm for n -ary trees is given in full length in the next section. The methods presented there are an expansion of Reingold and Tilfords algorithm to the more general case and still proceed for binary trees as described in this section.

46.4 Level Layout for n -ary Trees

A straightforward manner to draw trees of unbounded degree is to adjust the Reingold-Tilford algorithm by traversing the children of each node v from left to right, successively computing the preliminary coordinates and the modifiers.

This however violates property (A5): the subtrees are placed as close to each other as possible and small subtrees between larger ones are piled to the left; see Figure 46.3a. A simple trick to avoid this effect is to add an analogous second traversal from right to left; see Figure 46.3b, and to take average positions after that. This algorithm satisfies (A1–A5), but smaller subtrees are usually clustered then; see Figure 46.3c.

To obtain a layout where smaller subtrees are spaced out evenly between larger subtrees as for example shown in Figure 46.3d, we process the subtrees for each node $v \in V$ from left to right, see Figure 46.4. In a first step, every subtree is then placed as close as possible to the right of its left subtrees. This is done similarly to the algorithm for binary trees as described in Section 46.3 by traversing the left contour of the right subtree $T(w_{right})$ and the right contour of the subforest induced by the left siblings of w_{right} .

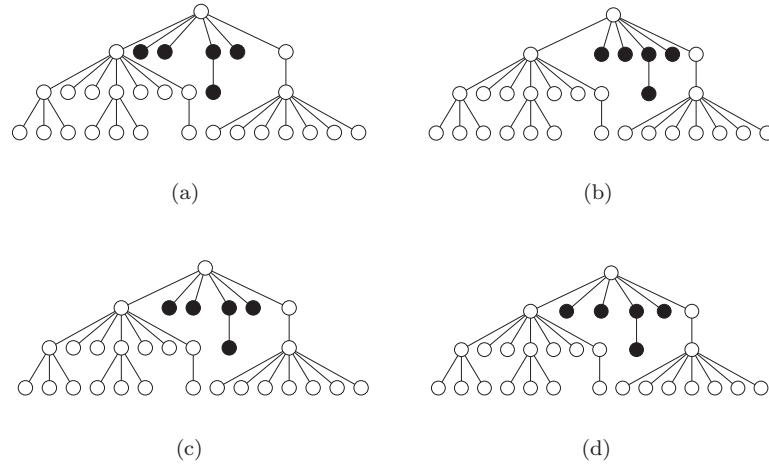

FIGURE 46.3 Extending the Reingold-Tilford algorithm to trees of unbounded degree.

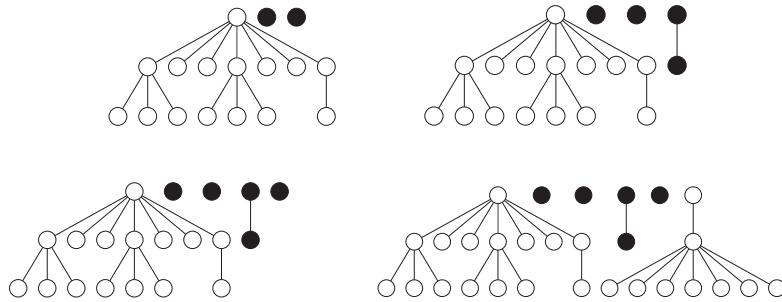

FIGURE 46.4 Spacing out the smaller subtrees.

Whenever two conflicting neighbors v_{left} and v_{right} are detected, forcing v_{right} to be shifted to the right by an amount of σ , we apply an appropriate shift to all smaller subtrees between the subtrees containing v_{left} and v_{right} .

More precisely, let w_{left} and w_{right} be the greatest distinct ancestors of v_{left} and v_{right} . Notice that both w_{left} and w_{right} are children of the node v that is currently processed. Let k be the number of children w_1, w_2, \dots, w_k of the current root between w_{left} and w_{right} plus 1. The subtrees between w_{left} and w_{right} are spaced out by shifting the subtree $T(w_i)$ to the right of w_{left} by an amount of $i \cdot \sigma/k$, for $i = 1, 2, \dots, k$. We notice that spacing out the smaller subtrees may result in subtrees that are shifted more than once. Below, the effect on the running time for computing the shifts is determined and it is shown how to obtain a linear time implementation.

It is easy to see that this approach satisfies (A1–A5) and in addition spaces out the smaller subtrees between larger subtrees evenly. In contrast to the algorithm for binary trees (see Section 46.3) nodes are not placed on integer coordinates. Instead real values are used.

Figure 46.5 gives a layout example of a 5-ary tree. The layout algorithm considers different nodes sizes.

Figure 46.6 shows a layout of a PQ -tree produced by the algorithm for binary trees. A straightforward modification of the algorithm allows the application of different nodes sizes to the Q -nodes and the usage of strictly vertical edges for the children of the O -nodes.

The algorithm **TREELAYOUT** given below works as a frame that initializes modifiers, threads, and ancestors (see Section 46.4.3), before evoking the methods **PREPOSITION** and **ADJUST**. The method **PREPOSITION** computes the shifts and preliminary positions of the nodes.

Based on the results of the function PREPOSITION the function ADJUST given in Algorithm 46.2 computes the final coordinates by summing up the modifiers recursively.

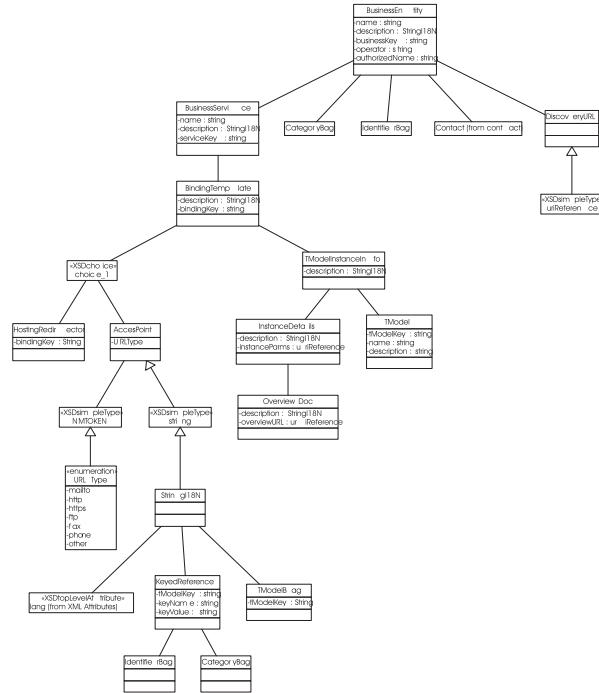

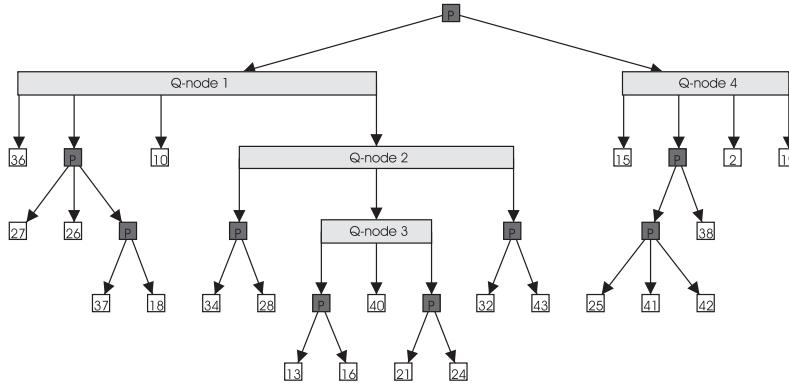

FIGURE 46.5 A level layout of an n -ary tree with different node sizes.

FIGURE 46.6 A level layout of a PQ-tree.

Algorithm 46.1: TreeLayout (T)

forall children  $w$  of  $v$  do
    ADJUST( $w, m + mod(v)$ );
od

```

46.4.1 PrePosition

Algorithm 46.3 presents the method $\text{PREPOSITION}(v)$ that computes a preliminary x-coordinate for a node v . PREPOSITION is applied recursively to the children of v . After each call of PREPOSITION on a child w a function APPORTION is executed on w . The procedure APPORTION is the core of the algorithm and shifts a subtree such that it does not conflict with its left subforest. After spacing out the smaller subtrees by calling EXECUTESHIFTS , the node v is placed to the midpoint of its outermost children. The value $distance$ prescribes the minimal distance between two nodes. If objects of different size are considered for the representation of the nodes, or if different minimal distances, that is, between subtrees, are specified, the value $distance$ has to be modified appropriately.

Algorithm 46.3: $\text{PREPOSITION}(v)$

```

if  $v$  is a leaf then
     $\text{prelim}(v) = 0;$ 
if  $v$  has a left sibling  $w$  then
     $\text{prelim}(v) = \text{prelim}(w) + distance;$ 
end
else
    let  $\text{defaultAncestor}$  be the leftmost child of  $v$ ;
    forall children  $w$  of  $v$  from left to right do
         $\text{PREPOSITION}(w);$ 
         $\text{APPORTION}(w, \text{defaultAncestor});$ 
    od
     $\text{EXECUTESHIFTS}(v);$ 
     $midpoint = \frac{1}{2}(\text{prelim}(\text{leftmost child of } v) + \text{prelim}(\text{rightmost child of } v));$ 
    if  $v$  has a left sibling  $w$  then
         $\text{prelim}(v) = \text{prelim}(w) + distance;$ 
         $\text{mod}(v) = \text{prelim}(v) - midpoint;$ 
    else
         $\text{prelim}(v) = midpoint;$ 
    end
end

```

46.4.2 Combining a Subtree and its Left Subforest

Before presenting APPORTION in detail, we need to consider efficient strategies for the different tasks that are performed by this function.

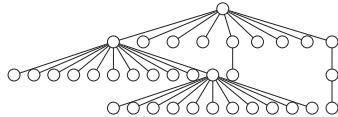

Similar to the threads used for binary trees (see Section 46.3), APPORTION uses threads to follow the contours of the right subtree and the left subforest. The fact that the left subforest is no tree in general does not create any additional difficulty.

One major task of APPORTION is that it has to space out the smaller subtrees between the larger ones. More precisely, if APPORTION shifts a subtree to the right to avoid a conflict with its left subforest, APPORTION has to make sure that the shifts of the smaller subtrees of the left subforest are determined.

A straightforward implementation computes the shifts for the intermediate smaller subtrees after the right subtree has been moved. However, as has been shown in Reference 5, this strategy has an aggregated runtime of $\Omega(|V|^{3/2})$. To prove this consider a tree T^k such that the root has k children v_1, v_2, \dots, v_k (see Figure 46.7 for $k = 3$). The children are numbered from left to right. Except for v_1 let the i -th child v_i be the root of a subtree $T^k(v_i)$ that consists of a chain of i nodes. Between each pair v_i, v_{i+1} , $i = 1, 2, \dots, k-1$, of these children, add k children as leaves. Moreover, the subtree $T^k(v_1)$ is modified as follows. Its root v_1 has $2k+5$ children, and up to level $k-1$, every rightmost child of the $2k+5$ children again has $2k+5$ children. The number of nodes of T^k is

$$1 + \sum_{i=1}^k i + (k-1)k + (k-1)(2k+5) \in \Theta(k^2).$$

When traversing the nodes v_1, v_2, \dots, v_k in order to determine their shifts, the subtree chain $T^k(v_i)$ conflicts with the first subtree $T^k(v_1)$ on level i . Hence, all $(i-1)(k+1) - 1$ smaller subtrees between $T^k(v_1)$ and $T^k(v_i)$ are shifted. Thus, the total number of

FIGURE 46.7 T^3 .

shifting steps is

$$\sum_{i=2}^k ((i-1)(k+1) - 1) = (k+1)k(k-1)/2 - k + 1 \in \Theta(k^3).$$

Since the number of nodes in T_k is $|V| \in \Theta(k^2)$, this shows that a straightforward implementation needs $\Omega(|V|^{3/2})$ time in total.

Let $T(v_i)$, $i \in \{2, 3, \dots, k\}$ be the subtree that has to be shifted. Let v_{left} and v_{right} be two neighboring nodes on some level l such that

- v_{left} is in the left subforest $\cup_{h=1}^{i-1} T(v_h)$ and v_{right} is in $T(v_i)$ respectively, and
- v_{left} and v_{right} determine the shift of $T(v_i)$.

In order to develop an efficient method for spacing out the smaller subtrees two tasks have to be solved.

- The tree $T(v_j)$, $j \in \{1, 2, \dots, i-1\}$, with $v_{left} \in T(v_j)$ has to be maintained in order to determine the smaller subtrees to the left of $T(v_i)$ that have to be spaced out.
- Shifting the smaller subtrees between $T(v_j)$ and $T(v_i)$ has to be done efficiently.

The next Section 46.4.3 shows how to obtain the tree $T(v_j)$ efficiently. Section 46.4.4 gives a detailed description on how to compute the shift of $T(v_i)$. and Section 46.4.5 presents a method that spaces out smaller subtrees.

46.4.3 Ancestor

We first describe how to obtain the subtree $T(v_j)$ that contains the node v_{left} . The problem is equivalent to finding the greatest distinct ancestors w_{left} and w_{right} of the nodes v_{left} and v_{right} , where in this case w_{left} is equal to the root v_j of the subtree that we need to determine and $w_{right} = v_i$. It is possible to apply an algorithm by Schieber and Vishkin [24] that determines for each pair of nodes its greatest distinct ancestors in constant time, after an $O(|V|)$ preprocessing step. Since their algorithm is somewhat tricky, and one of the greatest distinct ancestors, namely v_i , is known anyway, we apply a much simpler algorithm. Furthermore, as v_{right} is always the right neighbor of v_{left} , the left one of the greatest distinct ancestors only depends on v_{left} . Thus we may shortly call it *the ancestor* of v_{left} in the following.

To store the ancestor of a node u a pointer $ancestor(u)$ is introduced and initialize it to u itself. The pointer $ancestor(u)$ for any node u is not updated throughout the algorithm. Instead, a *defaultAncestor* is used and ancestors are only determined for the nodes u on the right contour of the left subforest $\cup_{h=1}^{i-1} T(v_h)$ during the shift of the subtree $T(v_i)$. This strategy ensures that we obtain linear running time.

We make sure that for every $i = 2, 3, \dots, k$ the following property for all nodes u on the right contour of $\cup_{h=1}^{i-1} T(v_h)$ holds:

(*) If $ancestor(u)$ is up to date, that is, u is a child of v , then $ancestor(u) = w_{left}$; otherwise, *defaultAncestor* is the correct *ancestor* of u .

For $i = 2$ we have that $\cup_{h=1}^{i-1} T(v_h) = T(v_1)$. The *defaultAncestor* for all nodes on the right contour is obviously v_1 and therefore *defaultAncestor* is set equal to v_1 . It is easy to recognize if a node u on the right contour has a pointer $ancestor(u)$ that is up to date: either $ancestor(u) = v_1$, or the level $l(ancestor(u))$ is greater than $l(v_1)$. This obviously fulfills property (*), see Figure 46.8a for an illustration.

After adding a subtree $T(v_{i-1})$ to $\cup_{h=1}^{i-2} T(v_h)$ for each $i = 3, 4, \dots, k$ two cases need to be considered. If the height $h(T(v_{i-1}))$ is lesser or equal to the height of the subforest $\cup_{h=1}^{i-2} T(v_h)$, the pointer $ancestor(u)$ is set to v_{i-1} for all nodes u on the right contour of $T(v_{i-1})$. This obviously fulfills property (*); see Figure 46.8b for an illustration. Moreover, the number of update operations is equal to the number of comparisons between the nodes on the left contour of $T(v_{i-1})$ and their neighbors in $\cup_{h=1}^{i-2} T(v_h)$. Hence the total number of all these update operations is in $O(|V|)$.

If the height $h(T(v_{i-1}))$ is greater than the height of $\cup_{h=1}^{i-2} T(v_h)$, we omit updating all nodes on the right contour of $T(v_{i-1})$ in order to obtain linear running time. Instead, it suffices to set *defaultAncestor* to v_{i-1} , since either $ancestor(u) = v_{i-1}$, or $l(ancestor(u)) > l(v_1)$ holds for any node in the right contour, and all smaller subtrees in the $\cup_{h=1}^{i-1} T(v_h)$ do not contribute to the right contour anymore. Thus property (*) is fulfilled; see Figure 46.8c for an illustration.

In algorithm 46.4 the function ANCESTOR is given. It returns w_{left} of u as described above.

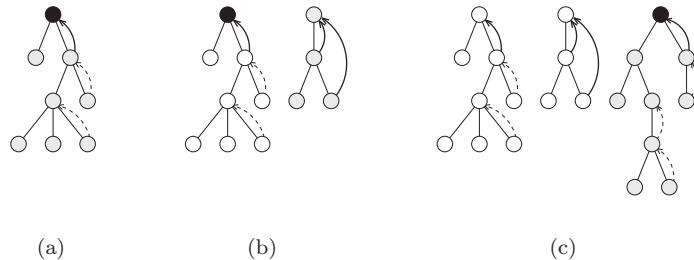

FIGURE 46.8 Adjusting ancestor pointers when adding new subtrees: the pointer $\text{ancestor}(u)$ is represented by a solid arrow if it is up to date and by a dashed arrow if it is expired. In the latter case, the defaultAncestor is used and drawn black. When adding a small subtree, all ancestor pointers $\text{ancestor}(u)$ of its right contour are updated. When adding a large subtree, only defaultAncestor is updated.

Algorithm 46.4: $\text{ANCESTOR}(u, w_{\text{right}}, \text{defaultAncestor})$

```

if ancestor(u) is a sibling of wright then
    return ancestor(wright);
else
    return defaultAncestor;
end

```

46.4.4 Apportion

To give the function `APPORTION` in Algorithm 46.5 a more readable annotation, we use subscripts f and o to describe the different contours of the left subforest and the right subtree. The subscript f is used for neighboring nodes on the contours that are *facing* each other and thus is used for the nodes on the right contour of the left subforest $\cup_{h=1}^{i-1} T(v_h)$ and the left contour of the right subtree $T(v_i)$, $i = 2, 3, \dots, k$. We use o for the left contour of $\cup_{h=1}^{i-1} T(v_h)$ and for the right contour of $T(v_i)$, describing the nodes that are on the *outside* of the combined subforest $\cup_{h=1}^i T(v_h)$.

The nodes traversing the contours are v^f_{right} , v^f_{left} , v^o_{left} , and v^o_{right} , where the subscript *left* describes nodes of the left subforest and *right* nodes of the right subtree. For summing up the modifiers along the contour (see also Sect. 46.3), respective variables s^f_{right} , s^f_{left} , s^o_{left} , and s^o_{right} are used.

Whenever two nodes of the facing contours conflict, we compute the left one of the greatest distinct ancestors using the function ANCESTOR and call MOVESUBTREE to shift the subtree and prepare the shifts of smaller subtrees.

Finally, a new thread is added (if necessary) as explained in Section 46.3. Observe that we have to adjust $\text{ancestor}(v^o_{\text{right}})$ or defaultAncestor to keep property (*). The functions `NEXTLEFT` and `NEXTRIGHT` return the next node on the left and right contour, respectively (see Algorithms 46.6 and 46.7).

46.4.5 Shifting the Smaller Subtrees

For spacing out the smaller subtrees evenly, the number of the smaller subtrees between the larger ones has to be maintained. Since simply counting the number of smaller children between two larger subtrees $T(v_j)$ and $T(v_i)$, $1 \leq j < i \leq k$ would result in $\Omega(n^{3/2})$ time in total, it is determined as follows. The children of v are numbered consecutively. Once the pair of nodes v_{left} , v_{right} that defines the maximum shift on $T(v_i)$ has been determined, the greatest distinct ancestors $w_{left} = v_j$ and $w_{right} = v_i$ are easily determined by the approach described in Section 46.4.3. The number $i - j - 1$ gives the number of in between subtrees in constant time.

In order to obtain a linear runtime, we make sure that each smaller subtree between a pair of larger ones is shifted at most once.

Thus whenever a subtree of $T(v_i)$ is considered to be placed next to the left subforest $\cup_{h=1}^{i-1} T(v_h)$, we do not modify the shift of the smaller subtrees. Such an approach would result in quadratic runtime by the fact that smaller subtrees are shifted every time they are in between a pair of greater subtrees. Instead, a system is installed, that allows to adopt the shift of the smaller subtrees by traversing the nodes v_1, v_2, \dots, v_k once after the last child v_k of v has been shifted.

For every node v_g , $g = 1, 2, \dots, k$, real numbers $shift(v_g)$ and $change(v_g)$ are introduced and initialized by zero. Let $T(v_j)$, $1 \leq j < i \leq k$, be the subtree that defines the σ on the subtree $T(v_i)$. Let $\theta = i - j$ be the number of subtrees between v_i and v_j , plus 1. Then, for $t = 1, 2, \dots, i - j - 1$, the t -th subtree $T(v_{j+t})$ has to be moved by $t \cdot \sigma / \theta$. In other words: the tree $T(v_{j+t})$ is shifted by $\sigma - (i - (j + t)) \cdot \sigma / \theta$, for example,

Algorithm 46.5: APPORTION($v, defaultAncestor$)

```

if  $v$  has a left sibling  $w$  then
     $v_{right}^f = v_{right}^o = v;$ 
     $v_{left}^f = w;$ 
     $v_{left}^o$  be the leftmost sibling of  $v_{right}^f$ ;
     $s_{right}^f = mod(v_{right}^f);$ 
     $s_{right}^o = mod(v_{right}^o);$ 
     $s_{left}^f = mod(v_{left}^f);$ 
     $s_{left}^o = mod(v_{left}^o);$ 
    while NEXTRIGHT( $v_{left}^f$ )  $\neq 0$  and NEXTLEFT( $v_{right}^f$ )  $\neq 0$  do
         $v_{left}^f = \text{NEXTRIGHT}(v_{left}^f);$ 
         $v_{right}^f = \text{NEXTLEFT}(v_{right}^f);$ 
         $v_{left}^o = \text{NEXTLEFT}(v_{left}^o);$ 
         $v_{right}^o = \text{NEXTRIGHT}(v_{right}^o);$ 
         $ancestor(v_{right}^o) = v;$ 
         $\sigma = (prelim(v_{left}^f) + s_{left}^f) - (prelim(v_{right}^f) + s_{right}^f) + distance;$ 
        if  $\sigma > 0$  then
            MOVESUBTREE(ANCESTOR( $v_{left}^f$ ,  $v, defaultAncestor$ ),  $v, \sigma$ );
             $s_{right}^f = s_{right}^f + \sigma;$ 
             $s_{right}^o = s_{right}^o + \sigma;$ 
        end
         $s_{left}^f = s_{left}^f + mod(v_{left}^f);$ 
         $s_{right}^f = s_{right}^f + mod(v_{right}^f);$ 
         $s_{left}^o = s_{left}^o + mod(v_{left}^o);$ 
         $s_{right}^o = s_{right}^o + mod(v_{right}^o);$ 
    end
end
if NEXTRIGHT( $v_{left}^f$ )  $\neq 0$  and NEXTRIGHT( $v_{right}^o$ )  $= 0$  then
     $thread(v_{right}^o) = \text{NEXTRIGHT}(v_{left}^f);$ 
     $mod(v_{right}^o) = mod(v_{right}^o) + s_{left}^f - s_{right}^o;$ 
end
if NEXTLEFT( $v_{right}^f$ )  $\neq 0$  and NEXTLEFT( $v_{left}^o$ )  $= 0$  then
     $thread(v_{left}^o) = \text{NEXTLEFT}(v_{right}^f);$ 
     $mod(v_{left}^o) = mod(v_{left}^o) + s_{right}^f - s_{left}^o;$ 
     $defaultAncestor = v;$ 
end

```

Algorithm 46.6: NEXTLEFT(v)

```

if  $v$  has a child then
    return the leftmost child of  $v$ ;
else
    return  $thread(v)$ ;
end

```

Algorithm 46.7: NEXTRIGHT(v)

```

if  $v$  has a child then
    return the rightmost child of  $v$ ;
else
    return  $\text{thread}(v)$ ;
end

```

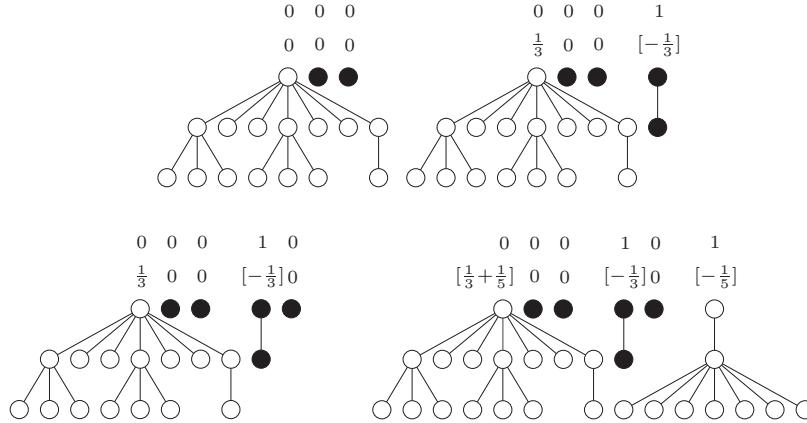

FIGURE 46.9 Aggregating the shifts: the top number at every node u indicates the value of $shift(u)$, and the bottom number indicates the value of $change(u)$.

- for $t = i - j - 1$ the subtree $T(v_{i-1})$ is shifted by $\sigma - \sigma/\theta$,
- for $t = i - j - 2$ the subtree $T(v_{i-2})$ is shifted by $\sigma - 2\cdot\sigma/\theta$,
- and for $t = 1$ the subtree $T(v_{j+1})$ is shifted by $\sigma - (i - j - 1)\cdot\sigma/\theta$.

The shift of the subtrees $T(v_{j+t})$, $t = 1, 2, \dots, i - j - 1$, depends on the shift of $T(v_i)$ and if traversed from right to left, is decreased linearly by σ/θ .

Since the decrease σ/θ is linear for every pair of greater subtrees, we use a trick and aggregate the amount of shift for the intermediate smaller subtrees by storing σ in an array $shift()$ of size k and by storing the σ/θ in an array $change()$ of size k . The values for shifting the subtrees $T(v_{j+t})$, $t = 1, 2, \dots, i - j - 1$, are then stored at v_i and v_j :

1. The value $shift(v_i)$ is increased by σ
2. The value $change(v_i)$ is decreased by σ/θ
3. The value $change(v_j)$ is increased by σ/θ

Figure 46.9 shows an example on setting the values of $shift()$ and $change()$.

By construction of the arrays $shift()$ and $change()$ we then obtain the shift of $T(v_g)$, $g = 1, 2, \dots, k$, (including the “original” shift of the subtree $T(v_i)$) as follows. The children v_g , $g = k, k-1, \dots, 1$, are traversed from right to left. Two real values σ and $change$ are maintained to store the shifts and the decreases of shift per subtree, respectively. These values are initialized with zero. When visiting child v_g , $g \in \{k, k-1, \dots, 1\}$ the subtree $T(v_g)$ is shifted to the right by σ (i.e., we increase $prelim(v_g)$ and $mod(v_g)$ by σ). Furthermore, $change$ is increased by $change(v_g)$, and σ is increased by $shift(v_g)$ and by $change(v_g)$ and we continue with v_{g-1} .

It is easy to see that this algorithm shifts each subtree by the correct amount, see Figure 46.10 for an example.

The function $\text{MOVESUBTREE}(w_{left}, w_{right}, \sigma)$ given in algorithm 46.8 performs an update of the arrays $shift()$ and $change()$. We recall that w_{left} and w_{right} are the greatest distinct ancestors of v_{left} and v_{right} and correspond to children v_i and v_j , $1 \leq i < j \leq k$, respectively. MOVESUBTREE shifts the subtree $T(w_{right})$ by increasing $prelim(w_{right})$ and $mod(w_{right})$ by the amount of σ . The shifts of the intermediate smaller subtrees between $T(w_{left})$ and $T(w_{right})$ are prepared by adjusting $change(w_{right})$, $shift(w_{right})$, and $change(w_{left})$.

The function $\text{EXECUTESHIFTS}(v)$ traverses its children from right to left and determines the total shift of the children based on the arrays $shift()$ and $change()$.

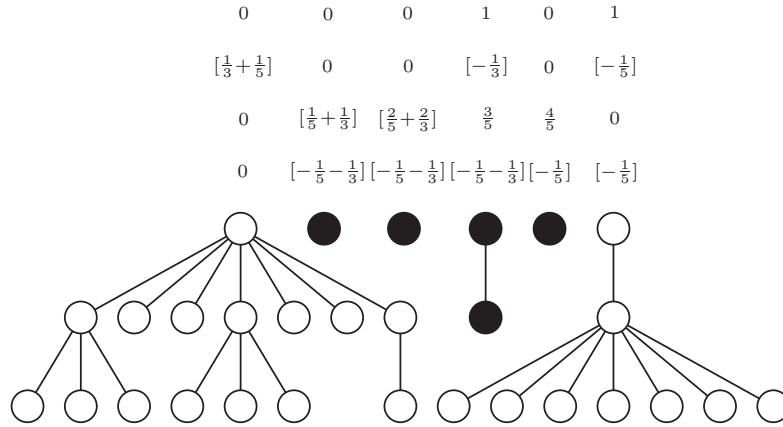

FIGURE 46.10 Executing the shifts: the third and the fourth line of numbers at a node u indicate the values of σ and $change$ before shifting u , respectively.

Algorithm 46.8: MOVESUBTREE($w_{left}, w_{right}, \sigma$)

```

 $\theta = number(w_{right}) - number(w_{left});$ 
 $change(w_{right}) = change(w_{right}) - \sigma / \theta;$ 
 $shift(w_{right}) = shift(w_{right}) + \sigma;$ 
 $change(w_{left}) = change(w_{left}) + \sigma / \theta;$ 
 $prelim(w_{right}) = prelim(w_{right}) + \sigma;$ 
 $mod(w_{right}) = mod(w_{right}) + \sigma;$ 

```

Algorithm 46.9: EXECUTESHIFTS

```

 $\sigma = 0;$ 
 $change = 0;$ 
forall children  $w$  of  $v$  from right to left do
     $prelim(w) = prelim(w) + \sigma;$ 
     $mod(w) = mod(w) + \sigma;$ 
     $change = change + change(w);$ 
     $\sigma = \sigma + shift(w) + change;$

```

Theorem 46.2

[Buchheim et al [5]] The layout algorithm for n -ary trees meets the aesthetic requirements (A1)–(A5), spaces out smaller subtrees evenly, and can be implemented to run in $O(|V|)$.

Proof. By construction of the algorithm it is obvious that the algorithm meets (A1–A5) and spaces out the smaller subtrees evenly. So it is left to show that the running time is linear in the number of nodes.

Every node of T is traversed once during the traversals PREPOSITION and ADJUST. Similar reasoning as in the proof of theorem 46.1 for binary trees shows that the time needed to traverse the left contour of the subtree $T(v_i)$ and the right contour of subforest $\cup_{h=1}^{i-1} T(v_h)$, $i = 2, 3, \dots, k$ for every node v with children v_i , $i = 1, 2, \dots, k$ is linear in the number of nodes of T over all such traversals. Moreover, we have that by construction the number of extra operations for spacing out the smaller subtrees is linear in $|V|$ plus the number of nodes traversed in the contours. This proofs the theorem. ■

46.5 Radial Layout

A *radial layout* of a tree is a variation of a level drawing, where the levels are concentric circles $c_1, c_2, \dots, c_{h(T)}$ around the root placed at the origin c_0 . Figure 46.11 shows an example of a radial layout. The radius of a circle c_i , $i = 1, 2, \dots, h(T)$, is given by an

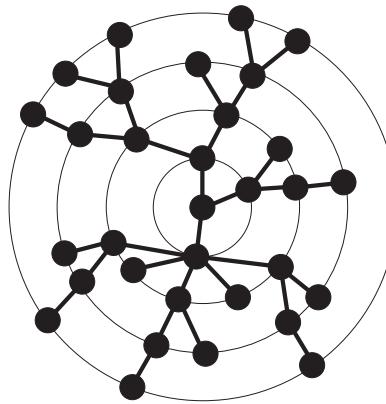

FIGURE 46.11 A radial layout of a binary tree.

increasing function $r(i)$. This type of layout is frequently used for representing a free tree. A free tree is a tree without a specific root. To layout a free tree, a node is chosen as a fictitious root that minimizes the height of the resulting subtrees. A straightforward manner to obtain a radial layout of a tree is to modify the algorithms for level drawings as presented in Sections 46.3 and 46.4.

To guarantee that the resulting drawing is planar, the subtree $T(v)$ of each node v is drawn within an *annulus wedge* $w(v)$. In order to permit edges with endpoints in $w(v)$ to extend outside $w(v)$ and thus to conflict with other edges, the nodes in the subtree $T(v)$ are placed within a convex subset $s(v)$ of $w(v)$. Given the level $l(v)$, the node v is placed on $c_{l(v)}$. Suppose that the tangent to $c_{l(v)}$ through v meets the points a and b on $c_{l(v)+1}$. Then $s(v)$ is chosen to be the unbounded region that is given by the line segment ab and the rays from the root of T and the node a and b . The children $v_j, j = 1, 2, \dots, k$ of v are then arranged on $c_{l(v)+1}$ within $s(v)$ according to the number of leaves in $T(v_j)$.

If the distance between consecutive circles $c_i, c_{i+1} i = 0, 1, \dots, h(T) - 1$, is equal, it can be easily shown that the area occupied by the layout is in

$$O(h(T)^2 \max_{v \in T} \{k \mid k \text{ number of children of } v\}).$$

Different algorithms for the radial layout of trees have been presented by [6–8] depending on the choice of the root, the radii of the circles and the angle of the annulus wedge. Symmetry oriented algorithms have also been developed, see for example, [9].

46.6 HV-Layout

An *hv*-layout of a binary tree is an upward (but not strictly upward) straight line orthogonal drawing with edges drawn as rightward horizontal or downward vertical segments. The “hv” stands for horizontal-vertical. For any vertex v in a binary tree T we either have:

1. A child of v is either
 - a. Aligned horizontally with v and to the right of v or
 - b. Vertically aligned below v .
2. The smallest rectangles that cover the area of the subtrees of the children of v in the layout do not intersect.

Figure 46.12 shows an example of a *hv*-layout

A *hv*-layout is generated by applying a divide and conquer approach. The divide step constructs the *hv*-layout of the left and the right subtrees, while the conquer step either performs a *horizontal* or a *vertical combination*. Figure 46.13 shows the two types of combination.

If the left subtree a node v is placed to the left in a horizontal combination and below in a vertical combination, the layout preserves the ordering of the children of v . The height and width of such a drawing is at most $|V| - 1$. A straightforward way to reduce the size of a *hv*-drawing to a height of at most $\log |V|$ is to use only horizontal combinations and to place the larger subtree (in terms of number of nodes) to the right of the smaller subtree. This *right heavy hv layout* is not order preserving and can be produced in $O(|V|)$ requiring only an area of $O(|V| \log |V|)$. The right heavy *hv* approach can be easily extended to draw n -ary trees as sketched in Figure 46.14.

AS already presented in the introduction, this type of layout has been extensively studied for example, in References 10–21 21 to obtain results on minimal area requirements of tree layouts.

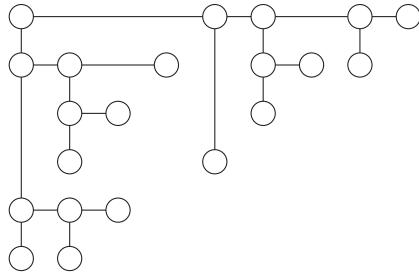

FIGURE 46.12 A hv-layout of a binary tree.

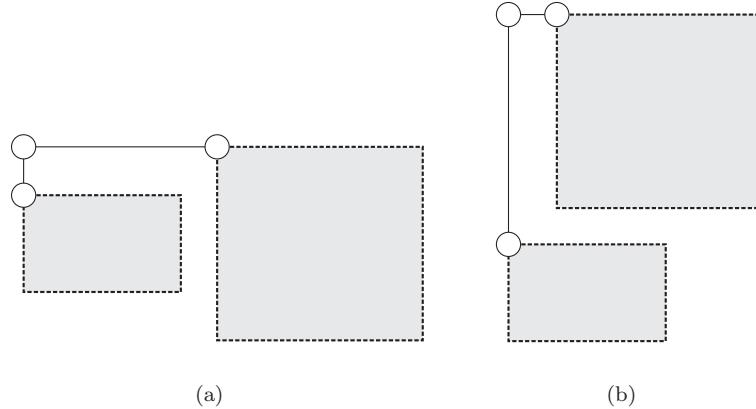

FIGURE 46.13 A horizontal combination (a) and a vertical combination (b).

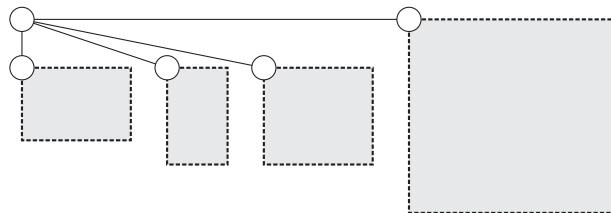

FIGURE 46.14 A hv-layout of a n -ary tree.

Recently Garg and Ruse [22] showed by flipping the subtrees rooted at a node v horizontally or vertically, it is possible to obtain tree layouts for binary trees with an $O(|V|)$ area and with a pre specified aspect ratio in the range of $[1, |V|^\alpha]$, with $\alpha \in [0, 1]$. These layouts are non upward straight line orthogonal layouts.

Acknowledgments

I gratefully acknowledge the contributions of Christoph Buchheim, who provided the figures and the implementation from our paper [5] and Merijam Percan for careful proof reading.

47.1 Introduction

Graph Drawing is the art of making pictures of relationships. For example, consider the social network defined in [Table 47.1](#). This table expresses the “has-written-a-joint-paper-with” relation for a small academic community.

It is easier to understand this social network if we draw it. A drawing is in [Figure 47.1a](#); a better drawing is in [Figure 47.1b](#). The challenge for Graph Drawing is to automatically create good drawings of graphs such as in [Figure 47.1b](#), starting with tables such as in [Table 47.1](#).

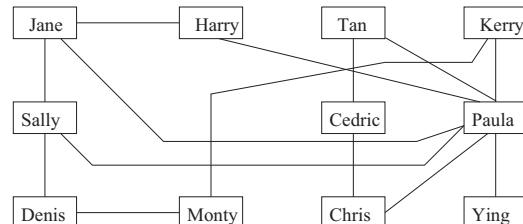

The *criteria* of a good drawing of a graph have been the subject of a great deal of attention (see, e.g., [\[1–3\]](#)). The four criteria below are among the most commonly used criteria.

- *Edge crossings* should be avoided. Human tests clearly indicate that edge crossings inhibit the readability of the graph [\[3\]](#). [Figure 47.1a](#) has 6 edge crossings, and [Figure 47.1b](#) has none; this is the main reason that [Figure 47.1b](#) is more readable than [Figure 47.1a](#). The algorithms presented in this chapter deal with *planar drawings*, that is, drawings with no edge crossings.
- The *resolution* of a graph drawing should be as large as possible. There are several ways to define the intuitive concept of resolution; the simplest is the *vertex resolution*, that is, the ratio of the minimum distance between a pair of vertices to the maximum distance between a pair of vertices. High resolution helps readability because it allows a larger font size to be used in the textual labels on vertices. In practice it can be easier to measure the *area* of the drawing, given that the minimum distance between a pair of vertices is one. If the vertices in [Figure 47.1](#) are on an integer grid, then the drawing is 4 units by 2 units, for both (a) and (b). Thus the vertex resolution is $1/2\sqrt{5} \approx 0.2236$, and the area is 8. One can refine the concept of resolution to define *edge resolution* and *angular resolution*.
- The *symmetry* of the drawing should be maximized. Symmetry conveys the structure of a graph, and Graph Theory textbooks commonly use drawings that are as symmetric as possible. Intuitively, [Figure 47.1b](#) displays more symmetry than [Figure 47.1a](#). A refined concept of symmetry display is presented in Section 47.4.
- *Edge bends* should be minimized. There is some empirical evidence to suggest that bends inhibit readability. In [Figure 47.1a](#), three edges contain bends and eleven are straight lines; in total, there are seven edge bends. [Figure 47.1b](#) is much better: all edges are straight lines.

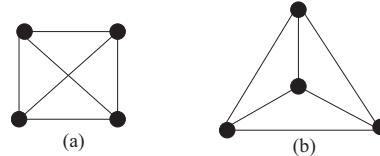

FIGURE 47.2 Two drawings of a graph.

Each of these criteria can be measured. Thus Graph Drawing problems are commonly stated as optimization problems: given a graph G , we need to find a drawing of G for which one or more of these measures are optimal. These optimization problems are usually NP-complete.

In most cases it is not possible to optimize one of the criteria above without compromise on another. For example, the graph in Figure 47.2a has 8 symmetries but one edge crossing. It is possible to draw this graph without edge crossings, but in this case we can only get 6 symmetries, as in Figure 47.2b.

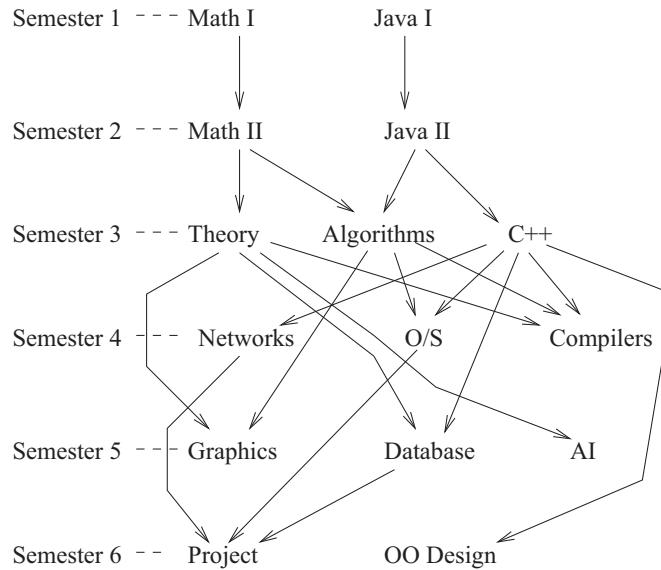

FIGURE 47.3 Prerequisite diagram.

The optimization problem may be constrained. For example, consider a graph representing prerequisite dependencies between the units in a course, as in Figure 47.3; in this case, the y coordinate of a unit depends on the semester in which the unit ought to be taken.

Graph Drawing has a long history in Mathematics, perhaps beginning with the theorem of Wagner that every planar graph can be drawn with straight line edges [4]. The importance of graph drawing algorithms was noted early in the history of Computer Science (note the paper of Knuth on drawing flowcharts, in 1960 [5], and the software developed by Read in the 1970s [6]). In the 1980s, the availability of graphics workstations spawned a broad interest in visualization in general and in graph visualization in particular. The field became mature in the mid 1990s with a conference series (e.g., see the annual proceedings of Symposium on Graph Drawing), some books [7–10], and widely available software (see Reference 11).

In this chapter we briefly describe just a few of the many graph available drawing algorithms. Section 47.3 presents some algorithms to draw planar graphs with straight line edges and convex faces. Section 47.4 describes two algorithms that can be used to construct planar symmetric drawings. Section 47.5 presents a method for constructing “visibility” representations of planar graphs, and shows how this method can be used to construct drawings with few bends and reasonable resolution.

47.2 Preliminaries

Basic concepts of mathematical Graph Theory are described in Reference 12. In this section we define mathematical notions that are used in many Graph Drawing algorithms.

A *drawing* D of a graph $G = (V, E)$ assigns a location $D(u) \in R^2$ for every vertex $u \in V$ and a curve $D(e)$ in R^2 for every edge $e \in E$ such that if $e = (u, v)$ then the curve $D(e)$ has endpoints $D(u)$ and $D(v)$. If $D(u)$ has integer coordinates for each vertex u , then D is a *grid* drawing. If the curve $D(e)$ is a straight line segment for each edge e , then D is a *straight line* drawing.

For convenience we often identify the vertex u with its location $D(u)$, and the edge e with its corresponding curve $D(e)$; for example, when we say “the edge e crosses the edge f ,” strictly speaking we should say “the curve $D(e)$ crosses the curve $D(f)$.” A graph drawing is *planar* if adjacent edges intersect only at their common endpoint, and no two nonadjacent edges intersect. A graph is *planar* if it has a planar drawing. Planarity is a central concern of Graph Theory, Graph Algorithms, and especially Graph Drawing; see Reference 12.

A planar drawing of a graph divides the plane into regions called *faces*. One face is unbounded; this is the outside face. Two faces are *adjacent* if they share a common edge. The graph G together its faces and the adjacency relationship between the faces is a *plane graph*. The graph whose vertices are the faces of a plane graph G and whose edges are the adjacency relationships between faces is the *planar dual*, or just *dual*, of G . A graph and its planar dual are in Figure 47.4.

The *neighborhood* $N(u)$ of a vertex u is the list of vertices that are adjacent to u . If G is a plane graph, then $N(u)$ is given in the clockwise circular ordering about u .

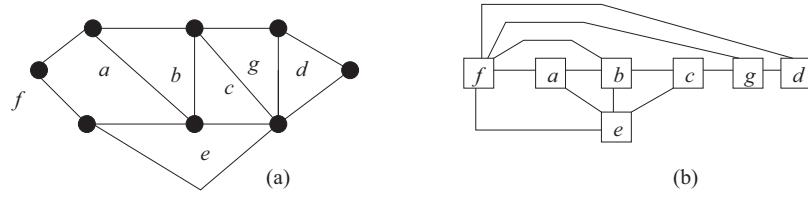

FIGURE 47.4 (a) A graph G and its faces. (b) The dual of G .

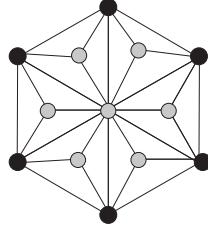

FIGURE 47.5 Example output from the algorithm of Tutte.

47.3 Convex Drawing

A straight-line drawing of a planar graph is *convex* if all every face is drawn as convex polygon. This section reviews three different algorithms for constructing such a drawing for planar graphs.

47.3.1 Barycenter Algorithm

Tutte showed that a convex drawing exist for triconnected planar graphs and gave an algorithm for constructing such representations [13,14].

The algorithm divides the vertex set V into two subsets; a set of *fixed* vertices and a set of *free* vertices. The fixed vertices are placed at the vertices of a strictly convex polygon. The positions of free vertices are decided by solving a system of $O(n)$ linear equations, where n is the number of vertices of the graph [14]. In fact, solving the equations is equivalent to placing each free vertex at the barycenter of its neighbors. That is, each position $p(v) = (x(v), y(v))$ of a vertex v is:

$$x(v) = \frac{1}{\deg(v)} \sum_{(v,w) \in E} x(w), \quad y(v) = \frac{1}{\deg(v)} \sum_{(v,w) \in E} y(w). \quad (47.1)$$

An example of a drawing computed by the barycenter algorithm is illustrated in Figure 47.5. Here the black vertices represent fixed vertices.

The main theorem can be described as follows.

Theorem 47.1: (Tutte [13,14])

Suppose that f is a face in a planar embedding of a triconnected planar graph G , and P is a strictly convex planar drawing of f . Then the barycenter algorithm with the vertices of f fixed and positioned according to P gives a convex planar drawing of G .

The matrix resulting from the equations can be solved in $O(n^{1.5})$ time at best, using a sophisticated sparse matrix elimination method [15]. However, in practice a Newton-Raphson iteration of the equation above converges rapidly.

47.3.2 Divide and Conquer Algorithm

Chiba, Yamanouchi and Nishizeki [16] present a linear time algorithm for constructing convex drawings of planar graphs, using divide and conquer. The algorithm constructs a convex drawing of a planar graph, if it is possible, with a given outside face. The drawing algorithm is based on a classical result by Thomassen [17].

The input to their algorithm is a biconnected plane graph with given outside face and a convex polygon. The output of their algorithm is a convex drawing of the biconnected plane graph with outside face drawn as the input convex polygon, if this is possible. The conditions under which such a drawing is possible come from the following theorem [17].

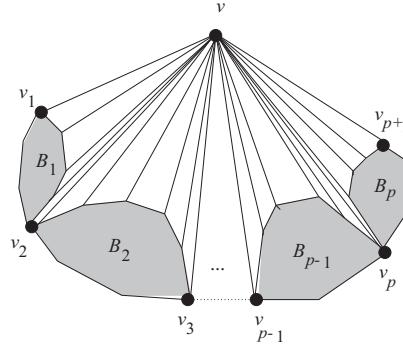

FIGURE 47.6 The algorithm of Chiba et al.

Theorem 47.2: (Thomassen [17])

Let G be a biconnected plane graph with outside facial cycle S , and let S^* be a drawing of S as a convex polygon. Let P_1, P_2, \dots, P_k be the paths in S , each corresponding to a side of S^* . (Thus S^* is a k -gon. It should be noted that not every vertex of the cycle S is necessarily an apex of the polygon S^* .) Then S^* can be extended to a convex drawing of G if and only if the following three conditions hold.

1. For each vertex v of $G - V(S)$ having degree at least three in G , there are three paths disjoint except at v , each joining v and a vertex of S ;
2. The graph $G - V(S)$ has no connected component C such that all the vertices on S adjacent to vertices in C lie on a single path P_i ; and no two vertices in each P_i are joined by an edge not in S ; and
3. Any cycle of G which has no edge in common with S has at least three vertices of degree at least 3 in G .

The basic idea of the algorithm of Chiba et al. [16] is to reduce the convex drawing of G to those of several subgraphs of G as follows:

Algorithm ConvexDraw(G, S, S^)*

1. Delete from G an arbitrary apex v of S^* together with edges incident to v .
2. Divide the resulting graph $G' = G - v$ into the biconnected components B_1, B_2, \dots, B_p .
3. Determine a convex polygon S_i^* for the outside facial cycle S_i of each B_i so that B_i with S_i^* satisfies the conditions in Theorem 47.2.
4. Recursively apply the algorithm to each B_i with S_i^* to determine the positions of vertices not in S_i .

The main idea of the algorithm is illustrated in Figure 47.6; for more details see Reference 16.

It is easy to show that the algorithm runs in linear time, and its correctness can be established using Theorem 47.2.

Theorem 47.3: (Chiba, Yamanouchi and Nishizeki [16])

Algorithm ConvexDraw constructs a convex planar drawing of a biconnected plane graph with given outside face in linear time, if such a drawing is possible.

47.3.3 Algorithm Using Canonical Ordering

Both the Tutte algorithm and the algorithm of Chiba et al. give poor resolution. Kant [18] gives a linear time algorithm for constructing a planar convex grid drawing of a triconnected planar graph on a $(2n - 4) \times (n - 2)$ grid, where n is the number of vertices. This guarantees that the vertex resolution of the drawing is $\Omega(1/n)$.

Kant's algorithm is based on a method of de Fraysseix, Pach and Pollack [19] for drawing planar *triangulated* graphs on a grid of size $(2n - 4) \times (n - 2)$.

The algorithm of de Fraysseix et al. [19] computes a special ordering of vertices called the *canonical ordering* based on fixed embedding. Then the vertices are added, one by one, in order to construct a straight-line drawing combined with shifting method. Note that the outside face of the drawing is always triangle, as shown in Figure 47.7.

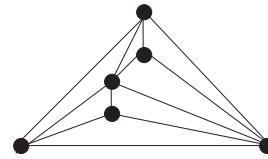

FIGURE 47.7 Planar straight-line grid drawing given by de Fraysseix, Pach and Pollack method.

Kant [18] uses a generalization of the canonical ordering called *leftmost canonical ordering*. The main difference from the algorithm of de Fraysseix et al. [19] is that it gives a convex drawing of *triconnected* planar graph. The following Theorem summarizes his main result.

Theorem 47.4: (Kant [18])

There is a linear time algorithm to construct a planar straight-line convex drawing of a triconnected planar graph with n vertices on a $(2n - 4) \times (n - 2)$ grid.

Details of Kant's algorithm are in Reference [18]. Chrobak and Kant improved the algorithm so that the size of the grid is $(n - 2) \times (n - 2)$ [20].

47.4 Symmetric Drawing

A graph drawing can have two kinds of symmetry: *axial* (or *reflectional*) symmetry and *rotational* symmetry. For example, see Figure 47.8. The drawing in Figure 47.8a displays four rotational symmetries and Figure 47.8b displays one axial symmetry. Figure 47.8c displays eight symmetries, four rotational symmetries as well as four axial symmetries.

Manning [21] showed that, in general, the problem of determining whether a given graph can be drawn symmetrically is NP-complete. De Fraysseix [22] presents heuristics for symmetric drawings of general graphs. Exact algorithms for finding symmetries in general graphs were presented by Buchheim and Junger [23], and Abelson, Hong and Taylor [24].

There are linear time algorithms available for restricted classes of graphs. Manning and Atallah present a liner time algorithm for detecting symmetries in trees [25] and outerplanar graphs [26]. Hong, Eades and Lee present a linear time algorithm for drawing series-parallel digraphs symmetrically [27]. A linear time algorithm for drawing planar graphs with maximum number of symmetries are given by Hong, McKay and Eades [28] for triconnected planar graphs, by Hong and Eades for biconnected planar graphs [29], and oneconnected planar graphs [30], and disconnected planar graphs [31]. Recently, a linear time algorithm for symmetric convex drawings of internally-triconnected planar graphs are given by Hong and Nagamochi [32]. For a recent survey on symmetric graph drawing, see Reference 33.

In this section, we briefly describe a linear time algorithm to draw triconnected planar graphs with maximum symmetry. Note that the algorithm of Tutte described in Section 47.3.1 can be used to construct symmetric drawings of triconnected planar graphs, but it does not work in linear time. Here we give the linear time algorithm of Hong, McKay and Eades [28]. It has two steps:

1. *Symmetry finding*: this step finds symmetries, or so-called *geometric automorphisms* [24,34], in graphs.
2. *Symmetric drawing*: this step constructs a drawing that displays these automorphisms.

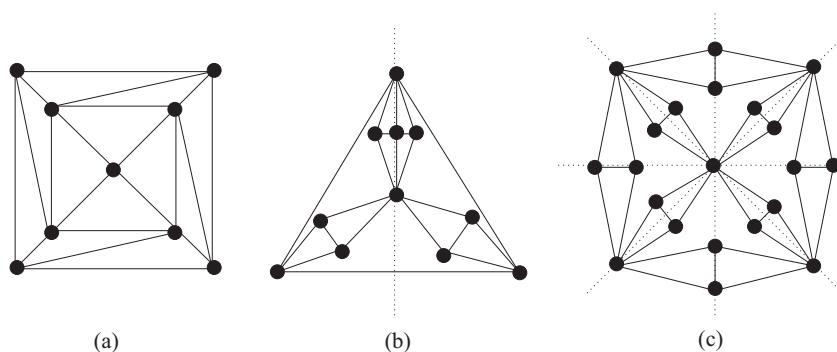

FIGURE 47.8 Three symmetric drawings of graphs.

More specifically, the symmetry finding step finds a plane embedding that displays the maximum number of symmetries. It is based on a classical theorem from group theory called the orbit-stabilizer theorem [35]. It also uses a linear time algorithm of an algorithm of Fontet [36] to compute orbits and generators for groups of geometric automorphisms. For details, see Reference 28. Here we present only the second step, that is, the drawing algorithm. This constructs a straight-line planar drawing of a given triconnected plane graph such that given symmetries are displayed.

The drawing algorithm has three routines, each corresponding to a type of group of symmetries in two dimensions:

1. The *cyclic* case: displaying k rotational symmetries;
2. One *axial* case: displaying one axial symmetry;
3. The *dihedral* case: displaying $2k$ symmetries (k rotational symmetries and k axial symmetries).

The dihedral case is important for displaying *maximum* number of symmetries, however it is the most difficult to achieve. Here, we concentrate on the first two cases; the cyclic case and the one axial case. In Section 47.4.1, we describe an algorithm for constructing a drawing displaying rotational symmetry and in Section 47.4.2 we describe an algorithm for constructing a drawing displaying axial symmetry. We briefly comments on the dihedral case in Section 47.4.3.

The input of the drawing algorithm is a triconnected plane graph; note that the outside face is given. Further, the algorithm needs to compute a triangulation as a preprocessing step. More specifically, given a plane embedding of triconnected planar graphs with a given outside face, we triangulate each internal face by inserting a new vertex in the face and joining it to each vertex of the face. This process is called star-triangulation and clearly it takes only linear time.

A major characteristic of symmetric drawings is the repetition of congruent drawings of isomorphic subgraphs. The algorithms use this property, that is, they compute a drawing for a subgraph and then use copies of it to draw the whole graph. More specifically, each symmetric drawing algorithm consists of three steps. First, it finds a subgraph. Then it draws the subgraph using the algorithm of Chiba et al. [16] as a subroutine. The last step is to replicate the drawing; that is, merge copies of the subgraphs to construct a drawing of the whole graph.

The application of Theorem 47.2 is to subgraphs of a triconnected plane graph defined by a cycle and its interior. In that case Thomassen's conditions can be simplified. Suppose that P is a path in a graph G ; a *chord* for P in G is an edge (u, v) of G not in P , but whose endpoints are in P .

Corollary 47.1

Let G be a triconnected plane graph and let S be a cycle of G . Let W be the graph consisting of S and its interior. Let S^* be a drawing of S as a convex k -gon (where S might have more than k vertices). Let P_1, P_2, \dots, P_k be the paths in S corresponding to the sides of S^* . Then S^* is extendable to a straight-line planar drawing of W if and only if no path P_i has a chord in W .

Proof. We can assume that the interior faces of W are triangles, since otherwise we can star triangulate them.

We need to show that Thomassen's three conditions are met. Condition 1 is a standard implication of the triconnectivity of G , and Condition 3 follows just from the observation that the internal vertices have degree at least 3.

To prove the first part of Condition 2, suppose on the contrary that C is a connected component of $W - S$ which is adjacent to P_i but not to any other of P_1, \dots, P_k . Let u and v be the first and last vertices on P_i which are adjacent to C . If $u = v$, or u and v are adjacent on P_i , then $\{u, v\}$ is a cut (separation pair) in G , which is impossible as G is triconnected. Otherwise, there is an interior face containing u and v and so u and v are adjacent contrary to our hypothesis (since the internal faces are triangles).

The second part of Condition 2 is just the condition that we are imposing. ■

47.4.1 Displaying Rotational Symmetry

Firstly, we consider the cyclic case, that is, displaying k rotational symmetries. Note that after the star-triangulation, we may assume that there is either an edge or a vertex fixed by the symmetry. The fixed edge case can only occur if $k = 2$ and this case can be transformed into the fixed vertex case by inserting a dummy vertex into the fixed edge with two dummy edges. Thus we assume that there is a fixed vertex c .

The symmetric drawing algorithm for the cyclic case consists of three steps.

Algorithm Cyclic

1. `Find_Wedge_Cyclic`.
2. `Draw_Wedge_Cyclic`.
3. `Merge_Wedges_Cyclic`.

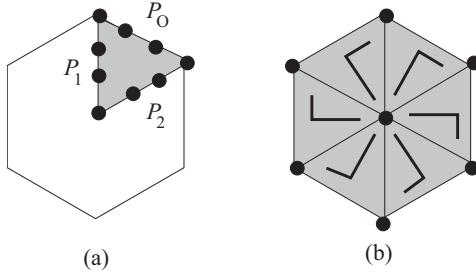

FIGURE 47.9 Example of (a) a wedge and (b) merging.

The first step is to find a subgraph W , called a wedge, as follows.

Algorithm Find_Wedge_Cyclic

1. Find the fixed vertex c .
2. Find a shortest path P_1 , from c to a vertex v_1 on the outside face. This can be done in linear time by breadth first search.
3. Find the path P_2 which is a mapping of P_1 under the rotation.
4. Find the induced subgraph of G enclosed by the cycle formed from P_1 , P_2 and a path P_0 along the outside face from v_1 to v_2 (including the cycle). This is the wedge W .

A wedge W is illustrated in Figure 47.9a. It is clear that Algorithm *Find_Wedge_Cyclic* runs in linear time.

The second step, *Draw_Wedge_Cyclic*, constructs a drawing D of the wedge W using Algorithm *ConvexDraw*, such that P_1 and P_2 are drawn as straight-lines. This is possible by the next lemma.

Lemma 47.1

Suppose that W is the wedge computed by Algorithm *Find_Wedge_Cyclic*, S is the outside face of W , and S^* is the drawing of the outside face S of W using three straight-lines as in Figure 47.9a. Then S^* is extendable to a planar straight-line drawing of W .

Proof. One of the three sides of S^* corresponds to part of the outside face of G , which cannot have a chord as G is triconnected. The other two sides cannot have chords either, as they are shortest paths in G . Thus W and S^* satisfy the conditions of Corollary 47.1. ■

The last step, *Merge_Wedges_Cyclic*, constructs a drawing of the whole graph G by replicating the drawing D of W , k times. Note that this merge step relies on the fact that P_1 and P_2 are drawn as straight-lines. This is illustrated in Figure 47.9b.

Clearly, each of these three steps takes linear time. Thus the main result of this section can be stated as follows.

Theorem 47.5

Algorithm *Cyclic* constructs a straight-line drawing of a triconnected plane graph which shows k rotational symmetry in linear time.

47.4.2 Displaying Axial Symmetry

A critical element of the algorithm for displaying one axial symmetry is the subgraph that is fixed by the axial symmetry. Consider a drawing of a star-triangulated planar graph with one axial symmetry. There are fixed vertices, edges and/or fixed faces on the axis. The subgraph formed by these vertices, edges and faces, is called a *fixed string of diamonds*.

The first step of the algorithm is to identify the fixed string of diamonds. Then the second step is to use Algorithm *Symmetric_ConvexDraw*, a modified version of Algorithm *ConvexDraw*. Thus Algorithm *One_Axial* can be described as follows.

Algorithm One_Axial

1. Find a fixed string of diamonds. Suppose that $\omega_1, \omega_2, \dots, \omega_k$ are the fixed edges and vertices in the fixed string of diamonds, in order from the outside face (ω_1 is on the outside face). For each ℓ , ω_ℓ may be a vertex or an edge. This is illustrated in Figure 47.10.
2. Choose an axially symmetric convex polygon S^* for the outside face of G .
3. *Symmetric_ConvexDraw*(1, S^* , G).

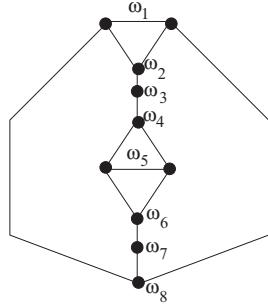

FIGURE 47.10 A string of diamonds.

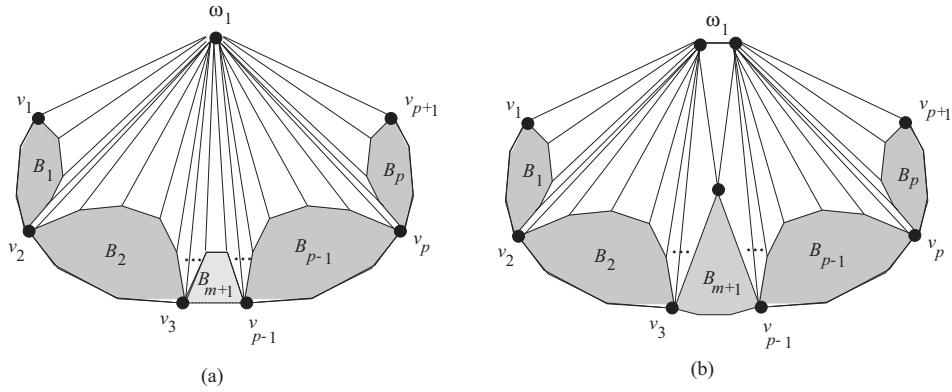

FIGURE 47.11 Symmetric version of ConvexDraw.

The main subroutine in Algorithm One_Axial is Algorithm Symmetric_ConvexDraw. This algorithm, described below, modifies Algorithm ConvexDraw so that the following three conditions are satisfied.

1. Choose v in Step 1 of Algorithm ConvexDraw to be ω_1 . In Algorithm ConvexDraw, v must be a vertex; here we extend Algorithm ConvexDraw to deal with an edge or a vertex. The two cases are illustrated in Figure 47.11.
2. Let $D(B_i)$ be the drawing of B_i and α be the axial symmetry. Then, $D(B_i)$ should be a reflection of $D(B_j)$, where $B_j = \alpha(B_i)$, $i = 1, 2, \dots, m$ and $m = \lfloor p/2 \rfloor$.
3. If p is odd, then $D(B_{m+1})$ should display one axial symmetry.

It is easy to see that satisfying these three conditions ensures the display a single axial symmetry.

Let $B_j = \alpha(B_i)$. The second condition can be achieved as follows. First define S_j^* to be the reflection of S_i^* , $i = 1, 2, \dots, m$. Then apply Algorithm ConvexDraw for B_i , $i = 1, 2, \dots, m$ and construct $D(B_j)$ using a reflection of $D(B_i)$. If p is odd then we recursively apply Algorithm Symmetric_ConvexDraw to B_{m+1} . Thus Algorithm Symmetric_ConvexDraw can be described as follows.

Algorithm Symmetric_ConvexDraw(ℓ, S^, G)*

1. Delete ω_ℓ from G together with edges incident to ω_ℓ . Divide the resulting graph $G' = G - \omega_\ell$ into the blocks B_1, B_2, \dots, B_p , ordered anticlockwise around the outside face. Let $m = \lfloor p/2 \rfloor$.
2. For each $i = 1$ to m , determine a convex polygon S_i^* of the outside facial cycle S_i of each B_i so that B_i with S_i^* satisfy the conditions in Theorem 47.2 and chose S_{p-i+1}^* to be a reflection of S_i^* .
3. For each $i = 1$ to m ,
 - a. Construct a drawing $D(B_i)$ of B_i using Algorithm ConvexDraw.
 - b. Construct $D(B_{p-i+1})$ as a reflection of $D(B_i)$.
4. If p is odd, then construct a drawing $D(B_{m+1})$ using Symmetric_ConvexDraw($\ell + 1, S_{m+1}^*, B_{m+1}$).
5. Merge the $D(B_i)$ to form a drawing of G .

Using the same argument as for the linearity of Algorithm ConvexDraw [16], one can show that Algorithm One_Axial takes linear time.

Theorem 47.6

Algorithm One_Axial constructs a straight-line drawing of a triconnected plane graph which shows one axial symmetry in linear time.

47.4.3 Displaying Dihedral Symmetry

In this section, we briefly review an algorithm for constructing a drawing displaying k axial symmetries and k rotational symmetries.

As with the cyclic case, we assume that there is a vertex fixed by all the symmetries. The algorithm adopts the same general strategy as for the cyclic case: divide the graph into “wedges,” draw each wedge, then merge the wedges together to make a symmetric drawing. However, the dihedral case is more difficult than the pure rotational case, because an axial symmetry in the dihedral case can have fixed edges and/or fixed faces. This requires a much more careful applications of the Algorithm ConvexDraw and Algorithm Symmetric_ConvexDraw; for details see Reference 28.

Nevertheless, using three steps above, a straight-line drawing of a triconnected plane graph which shows dihedral symmetry can be constructed in linear time.

In conclusion, the symmetry finding algorithm together with the three drawing algorithms ensures the following theorem which summarizes their main result.

Theorem 47.7: (Hong, McKay and Eades [28])

There is a linear time algorithm that constructs maximally symmetric planar drawings of triconnected planar graphs, with straight-line edges.

47.5 Visibility Drawing

In general, a *visibility representation* of a graph has a geometric shape for each vertex, and a “line of sight” for each edge. Different visibility representations involve different kinds of geometric shapes and different restrictions on the “line of sight.” A three dimensional visibility representation of the complete graph on five vertices is in Figure 47.12. Here the geometric objects are rectangular prisms, and each “line of sight” is parallel to a coordinate axis.

Visibility representations have been extensively investigated in both two and three dimensions.

For two dimensional graph drawing, the simplest and most common visibility representation uses horizontal line segments (called “bars”) for vertices and vertical line segments for “lines of sight.” More precisely, a *bar visibility representation* of a graph $G = (V, E)$ consists of a horizontal line segment ω_u for each vertex $u \in V$, and a vertical line segment λ_e for each edge $e \in E$, such that the following properties hold:

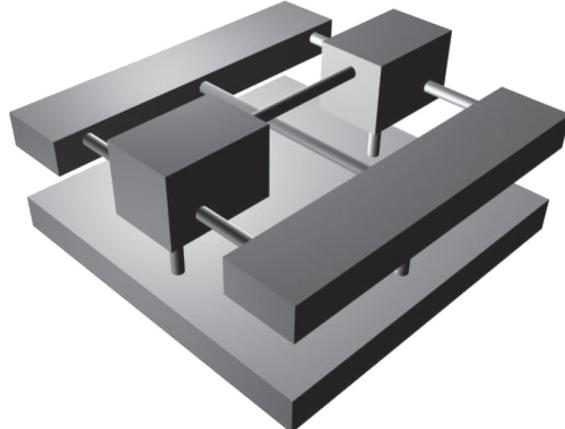

FIGURE 47.12 A visibility representation in three dimensions (courtesy of Nathalie Henry).

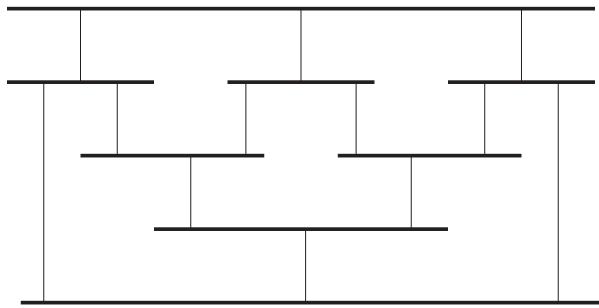

FIGURE 47.13 A bar visibility representation of the 3-cube.

- If u and u' are distinct vertices of G , then ω_u has empty intersection with $\omega_{u'}$.
 - If e and e' are distinct edges of G , then λ_e has empty intersection with $\lambda_{e'}$.
 - If e is not incident with u then λ_e has empty intersection with ω_u .
 - If e is incident with u then the intersection of λ_e and ω_u consists of an endpoint of λ_e on ω_u .

Figure 47.13 shows a bar visibility representation of the 3-cube.

It is clear that if G admits a bar visibility representation, then G is planar. Tamassia and Tollis [37] and Rosenstiehl and Tarjan [38] proved the converse: every planar graph has a bar visibility representation. Further, they showed that the resulting drawing has quadratic area, that is, the resolution is good. The algorithms from [37] and [38] construct such a representation in linear time.

In the Section 47.5.1 below we describe some concepts used to present the algorithm. Section 47.5.2 describes the basic algorithm for constructing bar visibility representations, and Sections 47.5.3 and 47.5.4 show how to apply these representations to obtain layered drawings and orthogonal drawings respectively.

The algorithm in Section 47.5.2 and some of the preceding results are stated in terms of biconnected planar graphs. Note that this restriction can be avoided by augmenting graphs of lower connectivity with dummy edges.

47.5.1 Planar St-graphs

Bar visibility representation algorithms use the theory of planar st-graphs. This is a powerful theory which is useful in a variety of graph drawing applications. In this section we describe enough of this theory to allow presentation of a bar visibility algorithm; for proofs of the results here, and more details about planar st-graphs, see Reference 7.

A directed plane graph is a *planar st-graph* if it has one source s and one sink t , and both s and t are on the outside face. We say that a vertex u on a face f of a planar st-graph is a *source for f* (respectively *sink for f*) if the edges incident with u on f are out-edges (respectively in-edges).

Lemma 47.2

Every face f of a planar st-graph has one source s_f for f and one sink t_f for f .

We need to extend the concept of the “planar dual,” defined in Section 47.2, to directed graphs. For a directed plane graph G , the *directed dual* G^* has a vertex v_f for each internal face f of G , as well as two vertices ℓ_{ext} and r_{ext} for the external face of G .

To define the edges of G^* , we must first define the *left* and *right* side face of each edge of G . Suppose that f is an internal face of G , and the cycle of edges traversing f in a clockwise direction is (e_1, e_2, \dots, e_k) . The clockwise traversal may pass through some edges in the same direction as the edge, and some edges in the opposite direction. If we pass through e_i in the same direction as e_i then we define $\text{right}(e_i) = v_f$; if we pass through e_i in the opposite direction to e_i then we define $\text{left}(e_i) = v_f$.

Now consider a clockwise traversal $(e'_1, e'_2, \dots, e'_k)$ of the external face of G . If we pass through e'_i in the same direction as e'_i then we define $\text{left}(e_i) = \ell_{\text{ext}}$; if we pass through e_j in the opposite direction to e_j then we define $\text{right}(e_j) = r_{\text{ext}}$.

One can easily show that the definitions of *left* and *right* are well founded, that is, that for each edge e there is precisely one face f of G such that $\text{left}(e) = v_f$ and precisely one face f' of G such that $\text{right}(e) = v_{f'}$.

For each edge e of G , G^* has an edge from $\text{left}(e)$ to $\text{right}(e)$.

An example is in Figure 47.14. Here $\ell_{ext} = 1 = left(e)$, and $r_{ext} = 5 = right(j) = right(g)$, $left(f) = left(i) = 2$, $right(f) = right(h) = 4$, and $left(h) = right(i) = 3$.

The following Lemma (see Reference 7 for a proof) is important for the bar visibility algorithm.

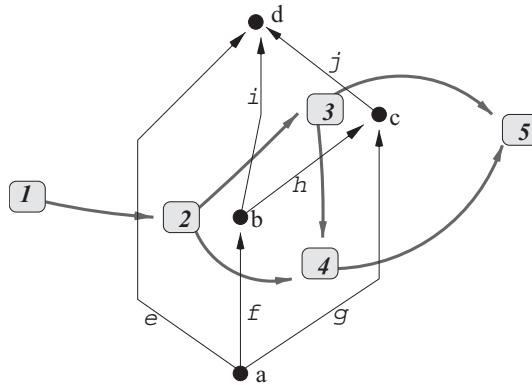

FIGURE 47.14 A directed planar graph and its directed dual.

Lemma 47.3

Suppose that f and f' are faces in a planar st-graph G . Then precisely one of the following statements is true.

- There is a directed path in G from the sink of f to the source of f' .
- There is a directed path in G from the sink of f' to the source of f .
- There is a directed path in G^* from v_f to $v_{f'}$.
- There is a directed path in G^* from $v_{f'}$ to v_f .

The next Lemma is, in a sense, dual to Lemma 47.2.

Lemma 47.4

Suppose that u is a vertex in a planar st-graph. The outgoing edges from u are consecutive in the circular ordering of $N(u)$, and the incoming edges are consecutive in the circular ordering of $N(u)$.

Lemma 47.4 leads to a definition of the *left* and *right* of a vertex. Suppose that (e_1, e_2, \dots, e_k) is the circular list of edges around a non-source non-sink vertex u , in clockwise order. From Lemma 47.4, for some i , edge e_i comes into u and edge e_{i+1} goes out from u . we say that e_i is the *leftmost in-edge* of u and e_{i+1} is the *leftmost out-edge* of u . If f is the face shared by e_i and e_{i+1} then we define $\text{left}(u) = f$. Similarly, there is a j such that edge e_j goes out from u and edge e_{j+1} comes into u ; we say that e_j is the *rightmost out-edge* of u and e_{j+1} is the *rightmost in-edge* of u . If f' is shared by e_j and e_{j+1} then we define $\text{right}(e_j) = f'$. If u is either the source or the sink, then $\text{left}(u) = \ell_{\text{ext}}$ and $\text{right}(u) = r_{\text{ext}}$.

In Figure 47.14, for example, $\text{left}(a) = \text{left}(d) = 1$, $\text{left}(b) = 2$, $\text{left}(c) = 3$, $\text{right}(b) = 4$, and $\text{right}(a) = \text{right}(c) = \text{right}(d) = 5$. Finally, we need the following Lemma, which is a kind of dual to Lemma 47.3.

Lemma 47.5

Suppose that u and u' are vertices in G . Then precisely one of the following statements is true.

- There is a directed path in G from u to u' .
- There is a directed path in G from u' to u .
- There is a directed path in G^* from $\text{right}(u)$ to $\text{left}(u')$.
- There is a directed path in G^* from $\text{right}(u')$ to $\text{left}(u)$.

47.5.2 The Bar Visibility Algorithm

The bar visibility algorithm takes a biconnected plane graph as input, and converts it to a planar st-graph. Then it computes the directed dual, and a “topological number” (defined below) for each vertex in both the original graph and the dual. Using these numbers, it assigns a y coordinate for each vertex and an x coordinate for each edge. The bar representing the vertex extends far enough to touch each incident edge, and the vertical line representing the edge extends far enough to touch each the bars representing its endpoints.

If $G = (V, E)$ is an acyclic directed graph with n vertices, a *topological numbering* Z of G assigns an integer $Z(u) \in \{0, 1, \dots, n - 1\}$ to every vertex $u \in V$ such that $Z(u) < Z(v)$ for all directed edges $(u, v) \in E$. Note that we do not require that the function Z be one-one, that is, it is possible that two vertices are assigned the same number.

The algorithm is described below.

Algorithm Bar_Visibility

Input: a biconnected plane graph $G = (V, E)$

Output: a bar visibility representation of G

1. Choose two vertices s and t of G on the same face.
2. Direct the edges of G so that s is the only source, t is the only sink, and the resulting digraph is acyclic.
3. Compute a topological numbering Y for G .
4. Compute the directed planar dual $G^* = (V^*, E^*)$ of G .
5. Compute a topological numbering X for G^* .
6. For each vertex u , let ω_u be the line segment $[(X(\text{left}(u)), Y(u)), (X(\text{right}(u)) - 1, Y(u))]$.
7. For each edge $e = (u, v)$, let λ_e be the line segment $[(X(\text{left}(e)), Y(u)), (X(\text{left}(e)), Y(v))]$.

Step 2 can be implemented by a simple variation on the depth-first-search method, based on a biconnectivity algorithm.

There are many kinds of topological numberings for acyclic digraphs: for example, one can define $Z(u)$ to be the number of edges in the longest path from the source s to u . Any of these methods can be used in steps 3 and 5.

Theorem 47.8: (Tamassia and Tollis [37]; Rosenstiehl and Tarjan [38])

A visibility representation of a biconnected planar graph with area $O(n) \times O(n)$ can be computed in linear time.

Proof. We need to show that the drawing defined by ω and λ in Algorithm Bar_Visibility satisfies the four properties P1, P2, P3 and P4 above.

First consider P1, and suppose that u and u' are two vertices of G . If $Y(u) \neq Y(u')$ then ω_u has empty intersection with $\omega_{u'}$ and so P1 holds. Now suppose that $Y(u) = Y(u')$. Since Y is a topological numbering of G , it follows that there is no directed path in between u and u' (in either direction). Thus, from Lemma 47.5, in G^* either there is a directed path from $\text{right}(u)$ to $\text{left}(u')$ or a directed path from $\text{right}(u')$ to $\text{left}(u)$. The first case implies that $X(\text{right}(u)) < X(\text{left}(u'))$, so that the whole of ω_u is to the left of $\omega_{u'}$; the second case implies that the whole of $\omega_{u'}$ is to the left of ω_u . This implies P1.

Now consider P2, and suppose that $e = (u, v)$ and $e' = (u', v')$ are edges of G , and denote $\text{left}(e)$ by f and $\text{left}(e')$ by f' . If $X(f) \neq X(f')$ then λ_e cannot intersect $\lambda_{e'}$, and P2 holds. Now suppose that $X(f) = X(f')$; thus in G^* there is no directed path between f and f' . It follows from Lemma 47.3 that in G either there is a directed path from the sink t_f of f to the source $s_{f'}$ of f' , or a directed path from the sink $t_{f'}$ of f' to the source s_f of f . In the first case we have $Y(t_f) < Y(s_{f'})$. Also, since e is on f and e' is on f' , we have $Y(v) \leq Y(t_f)$ and $Y(s_{f'}) \leq Y(u')$; thus $Y(v) < Y(u')$ and λ_e cannot intersect $\lambda_{e'}$. The second case is similar and so P2 holds.

A similar argument shows that P3 holds.

Property P4 follows from the simple observation that for any edge $e = (u, v)$, $X(\text{left}(u)) \leq X(\text{left}(e)) \leq X(\text{right}(u))$.

The drawing has dimensions $\max_{v_f \in V^*} X(v_f) \times \max_{u \in V} Y(u)$, which is $O(n) \times O(n)$.

It is easy to see that each step can be implemented in linear time. ■

47.5.3 Bar Visibility Representations and Layered Drawings

A graph in which the nodes are constrained to specified y coordinates, as in Figure 47.3, is called a layered graph. More precisely, a layered graph consists of a directed graph $G = (V, E)$ as well as a topological numbering L of G . We say that $L(u)$ is the *layer* of u . A drawing of G that satisfies the layering constraint, that is, the y coordinate of u is $L(u)$ for each $u \in V$, is called a *layered drawing*. Drawing algorithms for layered graphs have been extensively explored [7].

A layered graph is *planar* (sometimes called *h-planar*) if it can be drawn with no edge crossings, subject to the layering constraint. Note that underlying the prerequisite Figure 47.3 is a planar graph; however, as a layered graph, it is not planar. The theory of planarity for layered graphs has received some attention; see References 39–42.

If a planar layered graph has one source and one sink, then it is a planar st-graph. Clearly the source s has $L(s) = \min_{u \in V} L_u$ and the sink t has $L(t) = \max_{v \in V} L_v$. Since the layers define a topological numbering of the graph, application of Algorithm Bar_Visibility yields a visibility representation that satisfies the layering constraints. Further, this can be used to construct a graph drawing by using simple local transformations, illustrated in Figure 47.15.

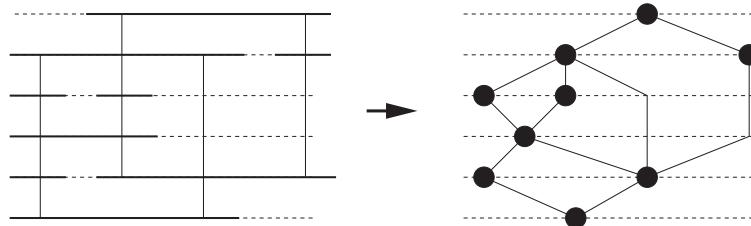

FIGURE 47.15 Transformation from a visibility representation of a layered graph to a layered drawing.

The following theorem is immediate.

Theorem 47.9

If G is a planar layered graph then we can construct a planar layered drawing of G in linear time, with the following properties:

- There are at most two bends in each edge.
- The area is $O(n) \times O(n)$.

Although Algorithm `Bar_Visibility` produces the visibility representation with good resolution, it may not produce minimum area drawings. Lin and Eades [42] give a linear time variation on Algorithm *Bar Visibility* that, for a fixed embedding, maximizes resolution. The algorithm works by using a topological numbering for the dual computed from a dependency relation between the edges.

47.5.4 Bar Visibility Representations for Orthogonal Drawings

An *orthogonal drawing* of a graph G has each vertex represented as a point and each edge represented by a polyline whose line segments are parallel to a coordinate axis. An orthogonal drawing of the 3-cube is in [Figure 47.16](#).

It is clear that a graph that has a planar orthogonal drawing, has maximum degree of G at most 4. Conversely, one can obtain a planar orthogonal drawing of a planar graph with maximum degree at most 4 from a visibility representation by using a simple set of local transformations, described in [Figure 47.17](#).

[Figure 47.16](#) can be obtained from [Figure 47.13](#) by applying transformation (c) in [Figure 47.17](#) to the source and sink, and applying transformation (d) to each other vertex.

Note that the transformations involve the introduction of a few bends in each edge. The worst case is for where a transformation introduces two bends near a vertex; this may occur at each end of an edge, and thus may introduce 4 bends into an edge.

Theorem 47.10

If G is a planar graph then we can construct a planar orthogonal drawing of G in linear time, with the following properties:

- There are at most four bends in each edge.
- The area is $O(n) \times O(n)$.

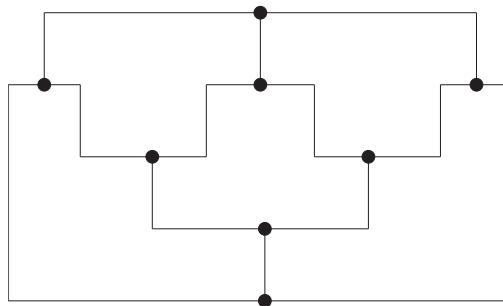

FIGURE 47.16 An orthogonal drawing of the 3-cube.

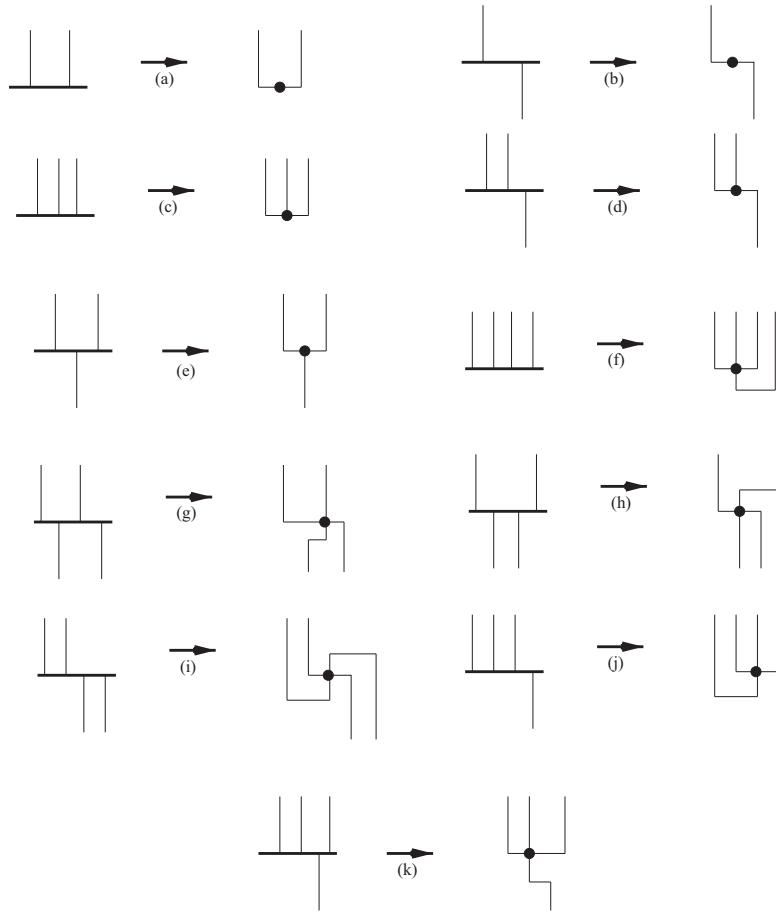

FIGURE 47.17 Local transformations to transform a visibility representation to an orthogonal drawing.

In fact, a variation of Algorithm `Visibility` together with a careful application of some transformations along the lines of those in Figure 47.17 can ensure that the resulting drawing has a total of at most $2n + 4$ bends, where n is the number of vertices; see Reference 7.

47.6 Conclusion

In this chapter we have described just a small sample of graph drawing algorithms. Notable omissions include:

- *Force directed methods*: A graph can be used to define a system of forces. For example, we can define a Hooke's law spring force between two adjacent vertices, and magnetic repulsion between nonadjacent vertices. A minimum energy configuration of the graph can lead to a good drawing. For methods using the force-directed paradigm, see References 7–10, 43.
- *Clustered graph drawing*: in practice, to handle large graphs, one needs to form clusters of the vertices to form “supervertices.” Drawing graphs in which some vertices represent graphs is a challenging problem. For algorithms drawing clustered graphs, see References 8,40.
- *Three dimensional graph drawing*: the widespread availability of cheap three dimensional graphics systems has lead to the investigation of graph drawing in three dimensions. For algorithms drawing graphs in three dimensions, see References 8,10, 44.
- *Crossing minimization methods*: in this chapter we have concentrated on planar graphs. In practice, we need to deal with non-planar graphs, by choosing a drawing with a small number of crossings. For algorithms drawing non-planar graphs with crossing minimization methods, see References 7–10, 45,46.
- *Generalization of convex drawing*: Note that graphs admit convex drawings if and only if they are internally-triconnected [16,17]. In practice, we need to relax and generalize convex drawings to “good” non-convex drawings for biconnected graphs. For algorithms drawing planar graphs with non-convex boundary constraints (such as star-shaped

boundary), called *inner convex drawings*, see Reference 47. For algorithms drawing biconnected planar graphs with star-shaped faces, called *star-shaped drawings*, see Reference 48; algorithms for star-shape drawings with minimum number of concave corners, see References 49,50. For algorithms drawing biconnected planar graphs with non-convex polytopes in three dimensions, called *upward star-shaped polytopes*, see Reference 51.

- *Beyond planar graphs:* Recently, the problem of drawing non-planar graphs with specific types of crossing constraints or forbidden crossing constraints, called *beyond planar graphs* and *beyond planarity*, have been studied [52–57]. This include *k-planar graphs*, that is, graphs that can be drawn in the plane with at most k crossings per edge. For algorithms testing beyond planarity and drawing beyond planar graphs, see Reference 56 for drawing 1-planar graphs, see Reference 53 for drawing almost planar graphs, see Reference 54 for testing maximal-1-planar graphs, see Reference 55 for testing outer-1-planar graphs, see Reference 52 for testing maximal-outer-fanplanar graphs, and see Reference 57 for testing full-outer-2-planar graphs.

The proliferation of commercial shared-memory multiprocessor machines has brought about significant changes in the art of concurrent programming. Given current trends towards low-cost chip multithreading (CMT), such machines are bound to become ever more widespread.

Shared-memory multiprocessors are systems that concurrently execute multiple threads of computation which communicate and synchronize through data structures in shared memory. The efficiency of these data structures is crucial to performance, yet designing effective data structures for multiprocessor machines is an art currently mastered by few. By most accounts, concurrent data structures are far more difficult to design than sequential ones because threads executing concurrently may interleave their steps in many ways, each with a different and potentially unexpected outcome. This requires designers to modify the way they think about computation, to understand new design methodologies, and to adopt a new collection of programming tools. Furthermore, new challenges arise in designing *scalable* concurrent data structures that continue to perform well as machines that execute more and more concurrent threads become available. This chapter provides an overview of the challenges involved in designing concurrent data structures, and a summary of relevant work for some important data structure classes. Our summary is by no means comprehensive; instead, we have chosen popular data structures that illustrate key design issues, and hope that we have provided sufficient background and intuition to allow the interested reader to approach the literature we do not survey.

48.1 Designing Concurrent Data Structures

Several features of shared-memory multiprocessors make concurrent data structures significantly more difficult to design and to verify as correct than their sequential counterparts.

The primary source of this additional difficulty is concurrency: Because threads are executed concurrently on different processors, and are subject to operating system scheduling decisions, page faults, interrupts, etc., we must think of the computation as completely asynchronous, so that the steps of different threads can be interleaved arbitrarily. This significantly complicates the task of designing correct concurrent data structures.

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

† We have used this author's affiliation from the first edition of this handbook, but note that this may have changed since then.

```

oldval = X;
X = oldval + 1;
return oldval;
    acquire(Lock);
    oldval = X;
    X = oldval + 1;
    release(Lock);
    return oldval;

```

FIGURE 48.1 Code fragments for sequential and lock-based fetch-and-inc operations.

Designing concurrent data structures for multiprocessor systems also provides numerous challenges with respect to performance and scalability. On today's machines, the layout of processors and memory, the layout of data in memory, the communication load on the various elements of the multiprocessor architecture all influence performance. Furthermore, the issues of correctness and performance are closely tied to each other: algorithmic enhancements that seek to improve performance often make it more difficult to design and verify a correct data structure implementation.

The following example illustrates various features of multiprocessors that affect concurrent data structure design. Suppose we wish to implement a *shared counter* data structure that supports a *fetch-and-inc* operation that adds one to the counter and returns the value of the counter immediately before the increment. A trivial sequential implementation of the *fetch-and-inc* operation contains code like that shown on the left in Figure 48.1.*

If we allow concurrent invocations of the *fetch-and-inc* operation by multiple threads, this implementation does not behave correctly. To see why, observe that most compilers will translate this source code into machine instructions that load *X* into a register, then add one to that register, then store that register back to *X*. Suppose that the counter is initially 0, and two *fetch-and-inc* operations execute on different processors concurrently. Then there is a risk that both operations read 0 from *X*, and therefore both store back 1 and return 0. This is clearly incorrect: one of the operations should return 1.

The incorrect behavior described above results from a “bad” interleaving of the steps of the two *fetch-and-inc* operations. A natural and common way to prevent such interleavings is to use a mutual exclusion lock (also known as a *mutex* or a *lock*). A lock is a construct that, at any point in time, is unowned or is owned by a single thread. If a thread t_1 wishes to acquire ownership of a lock that is already owned by another thread t_2 , then t_1 must wait until t_2 releases ownership of the lock.

We can obtain a correct sequential implementation of the *fetch-and-inc* operation by using a lock as shown on the right in Figure 48.1. With this arrangement, we prevent the bad interleavings by preventing *all* interleavings. While it is easy to achieve a correct shared counter this way, this simplicity comes at a price: Locking introduces a host of problems related to both performance and software engineering.

48.1.1 Performance

The *speedup* of an application when run on P processors is the ratio of its execution time on a single processor to its execution time on P processors. It is a measure of how effectively the application is utilizing the machine it is running on. Ideally, we want *linear speedup*: we would like to achieve a speedup of P when using P processors. Data structures whose speedup grows with P are called *scalable*. In designing scalable data structures we must take care: naive approaches to synchronization can severely undermine scalability.

Returning to the lock-based counter, observe that the lock introduces a *sequential bottleneck*: at any point in time, at most one *fetch-and-inc* operation is doing useful work, that is, incrementing the variable *X*. Such sequential bottlenecks can have a surprising effect on the speedup one can achieve. The effect of the sequentially executed parts of the code on performance is illustrated by a simple formula based on Amdahl's law [1]. Let b be the fraction of the program that is subject to a sequential bottleneck. If the program takes 1 time unit when executed on a single processor, then on a P -way multiprocessor the sequential part takes b time units, and the concurrent part takes $(1 - b)/P$ time units in the best case, so the speedup S is at most $1/(b + (1 - b)/P)$. This implies that if just 10% of our application is subject to a sequential bottleneck, the best possible speedup we can achieve on a 10-way machine is about 5.3: we are running the application at half of the machine's capacity. Reducing the number and length of sequentially executed code sections is thus crucial to performance. In the context of locking, this means reducing the number of locks acquired, and reducing *lock granularity*, a measure of the number of instructions executed while holding a lock.

A second problem with our simple counter implementation is that it suffers from *memory contention*: an overhead in traffic in the underlying hardware as a result of multiple threads concurrently attempting to access the same locations in memory. Contention can be appreciated only by understanding some aspects of common shared-memory multiprocessor architectures. If the lock protecting our counter is implemented in a single memory location, as many simple locks are, then in order to acquire

* Throughout our examples, we ignore the fact that, in reality, integers are represented by a fixed number of bits, and will therefore eventually “wrap around” to zero.

the lock, a thread must repeatedly attempt to modify that location. On a *cache-coherent* multiprocessor^{*} for example, exclusive ownership of the cache line containing the lock must be repeatedly transferred from one processor to another; this results in long waiting times for each attempt to modify the location, and is further exacerbated by the additional memory traffic associated with unsuccessful attempts to acquire the lock. In Section 48.1.7, we discuss lock implementations that are designed to avoid such problems for various types of shared memory architectures.

A third problem with our lock-based implementation is that, if the thread that currently holds the lock is delayed, then all other threads attempting to access the counter are also delayed. This phenomenon is called *blocking*, and is particularly problematic in *multiprogrammed* systems, in which there are multiple threads per processor and the operating system can preempt a thread while it holds the lock. For many data structures, this difficulty can be overcome by devising *nonblocking* algorithms in which the delay of a thread does not cause the delay of others. By definition, these algorithms cannot use locks.

Below we continue with our shared counter example, discussing blocking and nonblocking techniques separately; we introduce more issues related to performance as they arise.

48.1.2 Blocking Techniques

In many data structures, the undesirable effects of memory contention and sequential bottlenecks discussed above can be reduced by using a *fine-grained* locking scheme. In fine-grained locking, we use multiple locks of small granularity to protect different parts of the data structure. The goal is to allow concurrent operations to proceed in parallel when they do not access the same parts of the data structure. This approach can also help to avoid excessive contention for individual memory locations. For some data structures, this happens naturally; for example, in a hash table, operations concerning values that hash to different buckets naturally access different parts of the data structure.

For other structures, such as the lock-based shared counter, it is less clear how contention and sequential bottlenecks can be reduced because—abstractly—all operations modify the same part of the data structure. One approach to dealing with contention is to spread operations out in time, so that each operation accesses the counter in a separate time interval from the others. One widely used technique for doing so is called *backoff* [2]. However, even with reduced contention, our lock-based shared counter still lacks parallelism, and is therefore not scalable. Fortunately, more sophisticated techniques can improve scalability.

One approach, known as a *combining tree* [3–6], can help implement a scalable counter. This approach employs a binary tree with one leaf per thread. The root of the tree contains the actual counter value, and the other internal nodes of the tree are used to coordinate access to the root. The key idea is that threads climb the tree from the leaves towards the root, attempting to “combine” with other concurrent operations. Every time the operations of two threads are combined in an internal node, one of those threads—call it the loser—simply waits at that node until a return value is delivered to it. The other thread—the winner—proceeds towards the root carrying the sum of all the operations that have combined in the subtree rooted at that node; a winner thread that reaches the root of the tree adds its sum to the counter in a single addition, thereby effecting the increments of all of the combined operations. It then descends the tree distributing a return value to each waiting loser thread with which it previously combined. These return values are distributed so that the effect is as if all of the increment operations were executed one after the other at the moment the root counter was modified.

The technique losers employ while waiting for winners in the combining tree is crucial to its performance. A loser operation waits by repeatedly reading a memory location in a tree node; this is called *spinning*. An important consequence in a cache-coherent multiprocessor is that this location will reside in the local cache of the processor executing the loser operation until the winner operation reports the result. This means that the waiting loser does not generate any unnecessary memory traffic that may slow down the winner’s performance. This kind of waiting is called *local spinning*, and has been shown to be crucial for scalable performance [7].

In so-called *non-uniform memory access* (NUMA) architectures, processors can access their local portions of shared memory faster than they can access the shared memory portions of other processors. In such architectures, *data layout*—the way nodes of the combining tree are placed in memory—can have a significant impact on performance. Performance can be improved by locating the leaves of the tree near the processors running the threads that own them. (We assume here that threads are statically bound to processors.)

Data layout issues also affect the design of concurrent data structures for cache-coherent multiprocessors. Recall that one of the goals of the combining tree is to reduce contention for individual memory locations in order to improve performance. However, because cache-coherent multiprocessors manage memory in cache-line-sized chunks, if two threads are accessing different memory locations that happen to fall into the same cache line, performance suffers just as if they had been accessing the same memory location. This phenomenon is known as *false sharing*, and is a common source of perplexing performance problems.

^{*} A *cache-coherent* multiprocessor is one in which processors have local caches that are updated by hardware in order to keep them consistent with the latest values stored.

By reducing contention for individual memory locations, reducing memory traffic by using local spinning, and allowing operations to proceed in parallel, counters implemented using combining trees scale with the number of concurrent threads much better than the single lock version does [5]. If all threads manage to repeatedly combine, then a tree of width P will allow P threads to return P values after every $O(\log P)$ operations required to ascend and descend the tree, offering a speedup of $O(P/\log P)$ (but see Section 48.1.4).

Despite the advantages of the combining tree approach, it also has several disadvantages. It requires a known bound P on the number of threads that access the counter, and it requires $O(P)$ space. While it provides better throughput under *heavy loads*, that is, when accessed by many concurrent threads, its best-case performance under low loads is poor: It must still traverse $O(\log P)$ nodes in the tree, whereas a `fetch-and-inc` operation of the single-lock-based counter completes in constant time. Moreover, if a thread fails to combine because it arrived at a node immediately after a winner left it on its way up the tree, then it must wait until the winner returns before it can continue its own ascent up the tree. The coordination among ascending winners, losers, and ascending late threads, if handled incorrectly, may lead to *deadlocks*: threads may block each other in a cyclic fashion such that none ever makes progress. Avoiding deadlocks significantly complicates the task of designing correct and efficient implementations of blocking concurrent data structures.

In summary, blocking data structures can provide powerful and efficient implementations if a good balance can be struck between using enough blocking to maintain correctness, while minimizing blocking in order to allow concurrent operations to proceed in parallel.

48.1.3 Nonblocking Techniques

As discussed earlier, nonblocking implementations aim to overcome the various problems associated with the use of locks. To formalize this idea, various nonblocking progress conditions—such as *wait-freedom* [8,9], *lock-freedom* [8], and *obstruction-freedom* [10]—have been considered in the literature. A *wait-free* operation is guaranteed to complete after a finite number of its own steps, regardless of the timing behavior of other operations. A *lock-free* operation guarantees that after a finite number of its own steps, *some* operation completes. An *obstruction-free* operation is guaranteed to complete within a finite number of its own steps after it stops encountering interference from other operations.

Clearly, *wait-freedom* is a stronger condition than *lock-freedom*, and *lock-freedom* in turn is stronger than *obstruction-freedom*. However, all of these conditions are strong enough to preclude the use of blocking constructs such as locks.* While stronger progress conditions seem desirable, implementations that make weaker guarantees are generally simpler, more efficient in the common case, and easier to design and to verify as correct. In practice, we can compensate for the weaker progress conditions by employing backoff [2] or more sophisticated contention management techniques [11].

Let us return to our shared counter. It follows easily from results of Fischer et al. [12] (extended to shared memory by Herlihy [8] and Loui and Abu-Amara [13]) that such a shared counter cannot be implemented in a lock-free (or wait-free) manner using only `load` and `store` instructions to access memory. These results show that, in any proposed implementation, a bad interleaving of operations can cause incorrect behaviour. These bad interleavings are possible because the `load` and `store` are separate operations. This problem can be overcome by using a hardware operation that atomically combines a `load` and a `store`. Indeed, all modern multiprocessors provide such synchronization instructions, the most common of which are *compare-and-swap* (CAS) [14–16] and *load-linked/store-conditional* (LL/SC) [17–19]. The semantics of the CAS instruction is shown in Figure 48.2. For purposes of illustration, we assume an *atomically* keyword which requires the code block it labels to be executed *atomically*, that is, so that no thread can observe a state in which the code block has been partially executed. The CAS operation atomically loads from a memory location, compares the value read to an expected value, and stores a new value to the location if the comparison succeeds. Herlihy [8] showed that instructions such as CAS and LL/SC are *universal*: there exists a wait-free implementation for *any* concurrent data structure in a system that supports such instructions.

A simple lock-free counter can be implemented using CAS. The idea is to perform the `fetch-and-inc` by loading the counter’s value and to then use CAS to atomically change the counter value to a value greater by one than the value read. The CAS instruction fails to increment the counter only if it changes between the load and the CAS. In this case, the operation can retry, as the failing CAS had no effect. Because the CAS fails only as a result of another `fetch-and-inc` operation succeeding, the implementation is lock-free. However, it is not wait-free because a single `fetch-and-inc` operation can repeatedly fail its CAS.

The above example illustrates an *optimistic* approach to synchronization: the `fetch-and-inc` operation completes quickly in the hopefully common case in which it does not encounter interference from a concurrent operation, but must employ more expensive techniques under contention (e.g., backoff).

* We use the term “nonblocking” broadly to include all progress conditions requiring that the failure or indefinite delay of a thread cannot prevent other threads from making progress, rather than as a synonym for “lock-free,” as some authors prefer.

```

bool CAS(L, E, N) {
    atomically {
        if (*L == E) {
            *L = N;
            return true;
        } else
            return false;
    }
}

```

FIGURE 48.2 The semantics of the CAS operation.

While the lock-free counter described above is simple, it has many of the same disadvantages that the original counter based on a single lock has: a sequential bottleneck and high contention for a single location. It is natural to attempt to apply similar techniques as those described above in order to improve the performance of this simple implementation. However, it is usually more difficult to incorporate such improvements into nonblocking implementations of concurrent data structures than blocking ones. Roughly, the reason for this is that a thread can use a lock to prevent other threads from “interfering” while it performs some sequence of actions. Without locks, we have to design our implementations to be correct despite the actions of concurrent operations; in current architectures, this often leads to the use of complicated and expensive techniques that undermine the improvements we are trying to incorporate. As discussed further in Section 48.1.7, transactional mechanisms make it much easier to design and modify efficient implementations of complex concurrent data structures. However, hardware support for such mechanisms does not yet exist.

48.1.4 Complexity Measures

A wide body of research is directed at analyzing the asymptotic complexity of concurrent data structures and algorithms in idealized models such as *parallel random access machines* [20–22]. However, there is less work on modeling such data structures in a realistic multiprocessor setting. There are many reasons for this, most of which have to do with the interplay of the architectural features of the hardware and the asynchronous execution of threads. Consider the combining tree example. Though we argued a speedup of $O(P/\log P)$ by counting instructions, this is not reflected in empirical studies [5,23]. Real-world behavior is dominated by other features discussed above, such as cost of contention, cache behavior, cost of universal synchronization operations (e.g., CAS), arrival rates of requests, effects of backoff delays, layout of the data structure in memory, and so on. These factors are hard to quantify in a single precise model spanning all current architectures. Complexity measures that capture some of these aspects have been proposed by Dwork et al. [24] and by Anderson and Yang [25]. While these measures provide useful insight into algorithm design, they cannot accurately capture the effects of all of the factors listed above. As a result, concurrent data structure designers compare their designs empirically by running them using micro-benchmarks on real machines and simulated architectures [5,7,26,27]. In the remainder of this chapter, we generally qualify data structures based on their empirically observed behavior and use simple complexity arguments only to aid intuition.

48.1.5 Correctness

It is easy to see that the behavior of the simple lock-based counter is “the same” as that of the sequential implementation. However, it is significantly more difficult to see this is also true for the combining tree. In general, concurrent data structure implementations are often subtle, and incorrect implementations are not uncommon. Therefore, it is important to be able to state and prove rigorously that a particular design correctly implements the required concurrent data structure. We cannot hope to achieve this without a precise way of specifying what “correct” means.

Data structure specifications are generally easier for sequential data structures. For example, we can specify the semantics of a sequential data structure by choosing a set of states, and providing a *transition function* that takes as arguments a state, an operation name and arguments to the operation, and returns a new state and a return value for the operation. Together with a designated initial state, the transition function specifies all acceptable sequences of operations on the data structure. The sequential semantics of the counter is specified as follows: The set of states for the counter is the set of integers, and the initial state is 0. The transition function for the `fetch-and-inc` operation adds one to the old state to obtain the new state, and the return value is the old state of the counter.

Operations on a sequential data structure are executed one-at-a-time in order, and we simply require that the resulting sequence of operations respects the sequential semantics specified as discussed above. However, with concurrent data structures, operations are not necessarily totally ordered. Correctness conditions for concurrent data structures generally require that *some* total order of

the operations exists that respects the sequential semantics. Different conditions are distinguished by their different requirements on this total ordering.

A common condition is Lamport's *sequential consistency* [28], which requires that the total order preserves the order of operations executed by each thread. Sequential consistency has a drawback from the software engineering perspective: a data structure implemented using sequentially consistent components may not be sequentially consistent itself.

A natural and widely used correctness condition that overcomes this problem is Herlihy and Wing's *linearizability* [29], a variation on the *serializability* [30] condition used for database transactions. Linearizability requires two properties: (1) that the data structure be sequentially consistent, and (2) that the total ordering which makes it sequentially consistent respect the *real-time ordering* among the operations in the execution. Respecting the real-time ordering means that if an operation O_1 finishes execution before another operation O_2 begins (so the operations are not concurrent with each other), then O_1 must be ordered before O_2 . Another way of thinking of this condition is that it requires us to be able to identify a distinct point within each operation's execution interval, called its *linearization point*, such that if we order the operations according to the order of their linearization points, the resulting order obeys the desired sequential semantics.

It is easy to see that the counter implementation based on a single lock is linearizable. The state of the counter is always stored in the variable x . We define the linearization point of each `fetch-and-inc` operation as the point at which it stores its incremented value to x . The linearizability argument for the CAS-based lock-free implementation is similarly simple, except that we use the semantics of the CAS instruction, rather than reasoning about the lock, to conclude that the counter is incremented by one each time it is modified.

For the combining tree, it is significantly more difficult to see that the implementation is linearizable because the state of the counter is incremented by more than one at a time, and because the increment for one `fetch-and-inc` operation may in fact be performed by another operation with which it has combined. We define the linearization points of `fetch-and-inc` operations on the combining-tree-based counter as follows. When a winner thread reaches the root of the tree and adds its accumulated value to the counter, we linearize each of the operations with which it has combined in sequence immediately after that point. The operations are linearized in the order of the return values that are subsequently distributed to those operations. While a detailed linearizability proof is beyond the scope of our presentation, it should be clear from this discussion that rigorous correctness proofs for even simple concurrent data structures can be quite challenging.

The intuitive appeal and modularity of linearizability makes it a popular correctness condition, and most of the concurrent data structure implementations we discuss in the remainder of this chapter are linearizable. However, in some cases, performance and scalability can be improved by satisfying a weaker correctness condition. For example, the *quiescent consistency* condition [31] drops the requirement that the total ordering of operations respects the real-time order, but requires that every operation executed after a quiescent state—one in which no operations are in progress—must be ordered after every operation executed before that quiescent state. Whether an implementation satisfying such a weak condition is useful is application-dependent. In contrast, a linearizable implementation is always usable, because designers can view it as atomic.

48.1.6 Verification Techniques

In general, to achieve a rigorous correctness proof for a concurrent data structure implementation, we need mathematical machinery for specifying correctness requirements, accurately modeling a concurrent data structure implementation, and ensuring that a proof that the implementation is correct is complete and accurate. Most linearizability arguments in the literature treat at least some of this machinery informally, and as a result, it is easy to miss cases, make incorrect inferences, etc. Rigorous proofs inevitably contain an inordinate amount of mundane detail about trivial properties, making them tedious to write and to read. Therefore, computer-assisted methods for verifying implementations are required. One approach is to use a *theorem prover* to prove a series of assertions which together imply that an implementation is correct. Another approach is to use *model checking* tools, which exhaustively check all possible executions of an implementation to ensure that each one meets specified correctness conditions. The theorem proving approach usually requires significant human insight, while model checking is limited by the number of states of an implementation that can be explored.

48.1.7 Tools of the Trade

Below we discuss three key types of tools one can use in designing concurrent data structures: locks, barriers, and transactional synchronization mechanisms. Locks and barriers are traditional low-level synchronization mechanisms that are used to restrict certain interleavings, making it easier to reason about implementations based on them. Transactional mechanisms seek to hide the tricky details of concurrency from programmers, allowing them to think in a more traditional sequential way.

```

void acquire(Lock *lock) {
    int delay = MIN_DELAY;
    while (true) {
        if (CAS(lock, UNOWNED, OWNED))
            return;
        sleep(random() % delay);
        if (delay < MAX_DELAY)
            delay = 2 * delay;
    }
}

void release(Lock *lock) {
    *lock = UNOWNED;
}

```

FIGURE 48.3 Exponential backoff lock.

48.1.7.1 Locks

As discussed earlier, locks are used to guarantee mutually exclusive access to (parts of) a data structure, in order to avoid “bad” interleavings. A key issue in designing a lock is what action to take when trying to acquire a lock already held by another thread. On uniprocessors, the only sensible option is to yield the processor to another thread. However, in multiprocessors, it may make sense to repeatedly attempt to acquire the lock, because the lock may soon be released by a thread executing on another processor. Locks based on this technique are called *spinlocks*. The choice between blocking and spinning is often a difficult one because it is hard to predict how long the lock will be held. When locks are supported directly by operating systems or threads packages, information such as whether the lock-holder is currently running can be used in making this decision.

A simple spinlock repeatedly uses a synchronization primitive such as compare-and-swap to atomically change the lock from unowned to owned. As mentioned earlier, if locks are not designed carefully, such spinning can cause heavy contention for the lock, which can have a severe impact on performance. A common way to reduce such contention is to use *exponential backoff* [2]. In this approach, which is illustrated in Figure 48.3, a thread that is unsuccessful in acquiring the lock waits some time before retrying; repeated failures cause longer waiting times, with the idea that threads will “spread themselves out” in time, resulting in lower contention and less memory traffic due to failed attempts.

Exponential backoff has the disadvantage that the lock can be unowned, but all threads attempting to acquire it have backed off too far, so none of them is making progress. One way to overcome this is to have threads form a queue and have each thread that releases the lock pass ownership of the lock to the next queued thread. Locks based on this approach are called *queuelocks*. Anderson [32] and Graunke and Thakkar [33] introduce array-based queuelocks, and these implementations are improved upon by the list-based MCS queue locks of Mellor-Crummey and Scott [7] and the CLH queue locks of Craig and Landin and Hagersten [34,35].

Threads using CLH locks form a virtual linked list of nodes, each containing a `done` flag; a thread enters the critical section only after the `done` flag of the node preceding its own node in the list is raised. The lock object has a pointer to the node at the tail of the list, the last one to join it. To acquire the lock, a thread creates a node, sets its `done` flag to false indicate that it has not yet released the critical section, and uses a synchronization primitive such as CAS to place its own node at the tail of the list while determining the node of its predecessor. It then spins on the `done` flag of the predecessor node. Note that each thread spins on a different memory location. Thus, in a cache-based architecture, when a thread sets its `done` flag to inform the next thread in the queue that it can enter the critical section, the `done` flags on which all other threads are spinning are not modified, so those threads continue to spin on a local cache line, and do not produce additional memory traffic. This significantly reduces contention and improves scalability in such systems. However, if this algorithm is used in a non-coherent NUMA machine, threads will likely have to spin on remote memory locations, again causing excessive memory traffic. The MCS queuelock [7] overcomes this problem by having each thread spin on a `done` flag in its *own* node. This way, nodes can be allocated in local memory, eliminating the problem.

There are several variations on standard locks that are of interest to the data structure designer in some circumstances. The queuelock algorithms discussed above have more advanced *abortable* versions that allow threads to give up on waiting to acquire the lock, for example, if they are delayed beyond some limit in a real-time application [36,37], or if they need to recover from deadlock. The algorithms of [36] provide an abort that is nonblocking. Finally [27], presents *preemption-safe* locks, which attempt to reduce the negative performance effects of preemption by ensuring that a thread that is in the queue but preempted does not prevent the lock from being granted to another running thread.

In many data structures it is desirable to have locks that allow concurrent readers. Such *reader-writer* locks allow threads that only read data in the critical section (but do not modify it) to access the critical section exclusively from the writers but concurrently with each other. Various algorithms have been suggested for this problem. The reader-writer queuelock algorithms

of Mellor-Crummey and Scott [38] are based on MCS queuelocks and use read counters and a special pointer to writer nodes. In Reference 39 a version of these algorithms is presented in which readers remove themselves from the lock's queue. This is done by keeping a doubly-linked list of queued nodes, each having its own simple “mini-lock.” Readers remove themselves from the queuelock list by acquiring mini-locks of their neighboring nodes and redirecting the pointers of the doubly-linked list. The above-mentioned real-time queuelock algorithms of Reference 36 provide a similar ability without locking nodes.

The reader-writer lock approach can be extended to arbitrarily many operation types through a construct called *group mutual exclusion* or *room synchronization*. The idea is that operations are partitioned into groups, such that operations in the same group can execute concurrently with each other, but operations in different groups must not. An interesting application of this approach separates push and pop operations on a stack into different groups, allowing significant simplifications to the implementations of those operations because they do not have to deal with concurrent operations of different types [40]. Group mutual exclusion was introduced by Joung [41]. Implementations based on mutual exclusion locks or *fetch-and-inc* counters appear in References 40,42.

More complete and detailed surveys of the literature on locks can be found in References 43,44.

48.1.7.2 Barriers

A barrier is a mechanism that collectively halts threads at a given point in their code, and allows them to proceed only when all threads have arrived at that point. The use of barriers arises whenever access to a data structure or application is layered into phases whose execution should not overlap in time. For example, repeated iterations of a numerical algorithm that converges by iterating a computation on the same data structure or the marking and sweeping phases of a parallel garbage collector.

One simple way to implement a barrier is to use a counter that is initialized to the total number of threads: Each thread decrements the counter upon reaching the barrier, and then spins, waiting for the counter to become zero before proceeding. Even if we use the techniques discussed earlier to implement a scalable counter, this approach still has the problem that waiting threads produce contention. For this reason, specialized barrier implementations have been developed that arrange for each thread to spin on a different location [45–47]. Alternatively, a barrier can be implemented using a *diffusing computation* tree in the style of Dijkstra and Scholten [48]. In this approach, each thread is the owner of one node in a binary tree. Each thread awaits the arrival of its children, then notifies its parent that it has arrived. Once all threads have arrived, the root of the tree releases all threads by disseminating the release information down the tree.

48.1.7.3 Transactional Synchronization Mechanisms

A key use of locks in designing concurrent data structures is to allow threads to modify multiple memory locations atomically, so that no thread can observe partial results of an update to the locations. Transactional synchronization mechanisms are tools that allow the programmer to treat sections of code that access multiple memory locations as a single atomic step. This substantially simplifies the design of correct concurrent data structures because it relieves the programmer of the burden of deciding which locks should be held for which memory accesses and of preventing deadlock.

As an example of the benefits of transactional synchronization, consider Figure 48.4, which shows a concurrent queue implementation achieved by requiring operations of a simple sequential implementation to be executed atomically. Such atomicity could be ensured either by using a global mutual exclusion lock, or via a transactional mechanism. However, the lock-based

```

typedef struct qnode_s { qnode_s *next; valuetype value; } qnode_t;
shared variables:
// initially null
qnode_t *head, *tail;

void enqueue(qnode_t *n) {
    atomically {
        if (tail == null)
            tail = head = n;
        else {
            tail->next = n;
            tail = n;
        }
    }
}

qnode_t * dequeue() {
    atomically {
        if (head == null)
            return null;
        else {
            n = head;
            head = head->next;
            if (head == null)
                tail = null;
            return n;
        }
    }
}

```

FIGURE 48.4 A concurrent shared FIFO queue.

approach prevents concurrent enqueue and dequeue operations from executing in parallel. In contrast, a good transactional mechanism will allow them to do so in all but the empty state because when the queue is not empty, concurrent enqueue and dequeue operations do not access any memory locations in common.

The use of transactional mechanisms for implementing concurrent data structures is inspired by the widespread use of transactions in database systems. However, the problem of supporting transactions over shared memory locations is different from supporting transactions over databases elements stored on disk. Thus, more lightweight support for transactions is possible in this setting.

Kung and Robinson's *optimistic concurrency control* (OCC) [49] is one example of a transactional mechanism for concurrent data structures. OCC uses a global lock, which is held only for a short time at the end of a transaction. Nonetheless, the lock is a sequential bottleneck, which has a negative impact on scalability. Ideally, transactions should be supported without the use of locks, and transactions that access disjoint sets of memory locations should not synchronize with each other at all.

Transactional support for multiprocessor synchronization was originally suggested by Herlihy and Moss, who also proposed a hardware-based *transactional memory* mechanism for supporting it [50]. Recent extensions to this idea include *lock elision* [51,52], in which the hardware automatically translates critical sections into transactions, with the benefit that two critical sections that do not in fact conflict with each other can be executed in parallel. For example, lock elision could allow concurrent enqueue and dequeue operations of the above queue implementation to execute in parallel, even if the atomicity is implemented using locks. To date, hardware support for transactional memory has not been built.

Various forms of *software transactional memory* have been proposed by Shavit and Touitou [53], Harris et al. [54], Herlihy et al. [11], and Harris and Fraser [55].

Transactional mechanisms can easily be used to implement most concurrent data structures, and when efficient and robust transactional mechanisms become widespread, this will likely be the preferred method. In the following sections, we mention implementations based on transactional mechanisms only when no direct implementation is known.

48.2 Shared Counters and Fetch-and- ϕ Structures

Counters have been widely studied as part of a broader class of *fetch-and- ϕ* coordination structures, which support operations that fetch the current value of a location and apply some function from an allowable set ϕ to its contents. As discussed earlier, simple lock-based implementations of *fetch-and- ϕ* structures such as counters suffer from contention and sequential bottlenecks. Below we describe some approaches to overcoming these problems.

48.2.1 Combining

The combining tree technique was originally invented by Gottlieb et al. [4] to be used in the hardware switches of processor-to-memory networks. In Section 48.1.2 we discussed a software version of this technique, first described by Goodman et al. [3] and Yew et al. [6], for implementing a *fetch-and-add* counter. (The algorithm in Reference 6 has a slight bug; see Reference 5.) This technique can also be used to implement *fetch-and- ϕ* operations for a variety of sets of combinable operations, including arithmetic and boolean operations, and synchronization operations such as *load*, *store*, *swap*, *test-and-set*, etc. [56].

As explained earlier, scalability is achieved by sizing the tree such that there is one leaf node per thread. Under maximal load, the throughput of such a tree is proportional to $O(P/\log P)$ operations per time unit, offering a significant speedup. Though it is possible to construct trees with fan-out greater than two in order to reduce tree depth, that would sacrifice the simplicity of the nodes and, as shown by Shavit and Zemach [57], will most likely result in reduced performance. Moreover, Herlihy et al. [5] have shown that combining trees are extremely sensitive to changes in the arrival rate of requests: as the load decreases, threads must still pay the price of traversing the tree while attempting to combine, but the likelihood of combining is reduced because of the reduced load.

Shavit and Zemach overcome the drawbacks of the static combining tree structures by introducing combining funnels [57]. A *combining funnel* is a linearizable *fetch-and- ϕ* structure that allows combining trees to form dynamically, adapting its overall size based on load patterns. It is composed of a (typically small) number of *combining layers*. Each such layer is implemented as a *collision array* in memory. Threads pass through the funnel layer by layer, from the first (widest) to the last (narrowest). These layers are used by threads to locate each other and combine their operations. As threads pass through a layer, they read a thread ID from a randomly chosen array element, and write their own in its place. They then attempt to combine with the thread whose ID they read. A successful combination allows threads to exchange information, allowing some to continue to the next layer, and others to await their return with the resulting value. Combining funnels can also support the *elimination* technique (described in Section 48.3) to allow two operations to complete without accessing the central data structure in some cases.

48.2.2 Counting Networks

Combining structures provide scalable and linearizable fetch-and- ϕ operations. However, they are blocking. An alternative approach to parallelizing a counter that overcomes this problem is to have multiple counters instead of a single one, and to use a counting network to coordinate access to the separate counters so as to avoid problems such as duplicated or omitted values. *Counting networks*, introduced by Aspnes et al. [31], are a class of data structures for implementing, in a highly concurrent and nonblocking fashion, a restricted class of fetch-and- ϕ operations, the most important of which is `fetch-and-inc`.

Counting networks, like sorting networks [58], are acyclic networks constructed from simple building blocks called balancers. In its simplest form, a *balancer* is a computing element with two input wires and two output wires. Tokens arrive on the balancer's input wires at arbitrary times, and are output on its output wires in a balanced way. Given a stream of input tokens, a balancer alternates sending one token to the top output wire, and one to the bottom, effectively balancing the number of tokens between the two wires.

We can wire balancers together to form a network. The *width* of a network is its number of output wires (wires that are not connected to an input of any balancer). Let y_0, \dots, y_{w-1} respectively represent the number of tokens output on each of the output wires of a network of width w . A *counting network* is an acyclic network of balancers whose outputs satisfy the following *step property*:

In any quiescent state, $0 \leq y_i - y_j \leq 1$ for any $i < j$.

Figure 48.5 shows a sequence of tokens traversing a counting network of width four based on Batcher's Bitonic sorting network structure [59]. The horizontal lines are wires and the vertical lines are balancers, each connected to two input and output wires at the dotted points. Tokens (numbered 1 through 5) traverse the balancers starting on arbitrary input wires and accumulate on specific output wires meeting the desired step-property. Aspnes et al. [31] have shown that every counting network has a layout isomorphic to a sorting network, but not every sorting network layout is isomorphic to a counting network.

On a shared memory multiprocessor, balancers are records, and wires are pointers from one record to another. Threads performing increment operations traverse the data structure from some input wire (either preassigned or chosen at random) to some output wire, each time shepherding a new token through the network.

The counting network distributes input tokens to output wires while maintaining the step property stated above. Counting is done by adding a local counter to each output wire, so that tokens coming out of output wire i are assigned numbers $i, i+w, \dots, i+(y_i-1)w$. Because threads are distributed across the counting network, there is little contention on the balancers, and the even distribution on the output wires lowers the load on the shared counters. However, as shown by Shavit and Zemach [23], the dynamic patterns through the networks increase cache miss rates and make optimized layout almost impossible.

There is a significant body of literature on counting networks, much of which is surveyed by Herlihy and Busch [60]. An empirical comparison among various counting techniques can be found in Reference 5. Aharonson and Attiya [61] and Felten et al. [62] study counting networks with arbitrary fan-in and fan-out. Shavit and Touitou [63] show how to perform decrements on counting network counters by introducing the notion of "anti-tokens" and elimination. Busch and Mavronicolas [64] provide a combinatorial classification of the various properties of counting networks. Randomized counting networks are introduced by Aiello et al. [65] and fault-tolerant networks are presented by Riedel and Bruck [66].

The classical counting network structures in the literature are lock-free but not linearizable, they are only quiescently consistent. Herlihy et al. [67] show the tradeoffs involved in making counting networks linearizable.

Klugerman and Plaxton present an optimal $\log w$ -depth counting network [68]. However, this construction is not practical, and all practical counting network implementations have $\log^2 w$ depth. Shavit and Zemach introduce *diffracting trees* [23], improved counting networks made of balancers with one input and two output wires laid out as a binary tree. The simple balancers of the counting network are replaced by more sophisticated *diffracting balancers* that can withstand high loads by using a randomized collision array approach, yielding lower depth counting networks with significantly improved throughput. An adaptive diffracting tree that adapts its size to load is presented in References 69.

48.3 Stacks and Queues

Stacks and queues are among the simplest sequential data structures. Numerous issues arise in designing concurrent versions of these data structures, clearly illustrating the challenges involved in designing data structures for shared-memory multiprocessors.

48.3.1 Stacks

A concurrent *stack* is a data structure linearizable to a sequential stack that provides `push` and `pop` operations with the usual *LIFO* semantics. Various alternatives exist for the behavior of these data structures in full or empty states, including returning a special value indicating the condition, raising an exception, or blocking.

Michael and Scott present several linearizable lock-based concurrent stack implementations: they are based on sequential linked lists with a top pointer and a global lock that controls access to the stack [27]. They typically scale poorly because even if one reduces contention on the lock, the top of the stack is a sequential bottleneck. Combining funnels [57] have been used to implement a linearizable stack that provides parallelism under high load. As with all combining structures, it is blocking, and it has a high overhead which makes it unsuitable for low loads.

Treiber [70] was the first to propose a lock-free concurrent stack implementation. He represented the stack as a singly-linked list with a top pointer and used CAS to modify the value of the top pointer atomically. Michael and Scott [27] compare the performance of Treiber's stack to an optimized nonblocking algorithm based on Herlihy's methodology [71], and several lock-based stacks (such as an MCS lock [7]) in low load situations. They concluded that Treiber's algorithm yields the best overall performance, and that this performance gap increases as the degree of multiprogramming grows. However, because the top pointer is a sequential bottleneck, even with an added backoff mechanism to reduce contention, the Treiber stack offers little scalability as concurrency increases [72].

Hendler et al. [72] observe that any stack implementation can be made more scalable using the *elimination* technique of Shavit and Touitou [63]. Elimination allows pairs of operations with reverse semantics—like pushes and pops on a stack—to complete without any central coordination, and therefore substantially aids scalability. The idea is that if a `pop` operation can find a concurrent `push` operation to “partner” with, then the `pop` operation can take the `push` operation’s value, and both operations can return immediately. The net effect of each pair is the same as if the `push` operation was followed immediately by the `pop` operation, in other words, they eliminate each other’s effect on the state of the stack. Elimination can be achieved by adding a collision array from which each operation chooses a location at random, and then attempts to coordinate with another operation that concurrently chose the same location [63]. The number of eliminations grows with concurrency, resulting in a high degree of parallelism. This approach, especially if the collision array is used as an adaptive backoff mechanism on the shared stack, introduces a high degree of parallelism with little contention [72], and delivers a scalable lock-free linearizable stack.

There is a subtle point in the Treiber stack used in the implementations above that is typical of many CAS-based algorithms. Suppose several concurrent threads all attempt a `pop` operation that removes the first element, located in some node “A,” from the list by using a CAS to redirect the head pointer to point to a previously-second node “B.” The problem is that it is possible for the list to change completely just before a particular `pop` operation attempts its CAS, so that by the time it does attempt it, the list has the node “A” as the first node as before, but the rest of the list including “B” is in a completely different order. This CAS of the head pointer from “A” to “B” may now succeed, but “B” might be anywhere in the list and the stack will behave incorrectly. This is an instance of the “ABA” problem [73], which plagues many CAS-based algorithms. To avoid this problem, Treiber augments the head pointer with a version number that is incremented every time the head pointer is changed. Thus, in the above scenario, the changes to the stack would cause the CAS to fail, thereby eliminating the ABA problem.*

48.3.2 Queues

A concurrent *queue* is a data structure linearizable to a sequential queue that provides `enqueue` and `dequeue` operations with the usual *FIFO* semantics.

Michael and Scott [27] present a simple lock-based queue implementation that improves on the naive single-lock approach by having separate locks for the head and tail pointers of a linked-list-based queue. This allows an `enqueue` operation to execute in parallel with a `dequeue` operation (provided we avoid false sharing by placing the head and tail locks in separate cache lines). This algorithm is quite simple, with one simple trick: a “dummy” node is always in the queue, which allows the implementation to avoid acquiring both the head and tail locks in the case that the queue is empty, and therefore it avoids deadlock.

* Note that the version number technique does not technically eliminate the ABA problem because the version number can wrap around; see Reference 74 for a discussion of the consequences of this point in practice, and also a “bounded tag” algorithm that eliminates the problem entirely, at some cost in space and time.

It is a matter of folklore that one can implement an array-based lock-free queue for a single enqueuer thread and a single dequeuer thread using only load and store operations [75]. A linked-list-based version of this algorithm appears in References 76. Herlihy and Wing [29] present a lock-free array-based queue that works if one assumes an unbounded size array. A survey in Reference 27 describes numerous flawed attempts at devising general (multiple enqueuers, multiple dequeuers) nonblocking queue implementations. It also discusses some correct implementations that involve much more overhead than the ones discussed below.

Michael and Scott [27] present a linearizable CAS-based lock-free queue with parallel access to both ends. The structure of their algorithm is very simple and is similar to the two-lock algorithm mentioned above: it maintains head and tail pointers, and always keeps a dummy node in the list. To avoid using a lock, the `enqueue` operation adds a new node to the end of the list using CAS, and then uses CAS to update the tail pointer to reflect the addition. If the `enqueue` is delayed between these two steps, another `enqueue` operation can observe the tail pointer “lagging” behind the end of the list. A simple *helping technique* [71] is used to recover from this case, ensuring that the tail pointer is always behind the end of the list by at most one element.

While this implementation is simple and efficient enough to be used in practice, it does have a disadvantage. Operations can access nodes already removed from the list, and therefore the nodes cannot be freed. Instead, they are put into a *freelist*—a list of nodes stored for reuse by future `enqueue` operations—implemented using Treiber’s stack. This use of a freelist has the disadvantage that the space consumed by the nodes in the freelist cannot be freed for arbitrary reuse. Herlihy et al. [77] and Michael [78] have presented nonblocking memory management techniques that overcome this disadvantage.

It is interesting to note that the elimination technique is not applicable to queues: we cannot simply pass a value from an `enqueue` operation to a concurrent `dequeue` operation, because this would not respect the FIFO order with respect to other values in the queue.

48.3.3 Deques

A concurrent double-ended queue (*deque*) is a linearizable concurrent data structure that generalizes concurrent stacks and queues by allowing pushes and pops at both ends [79]. (See Chapter 2 for an introduction to stacks, queues and deques.) As with queues, implementations that allow operations on both ends to proceed in parallel without interfering with each other are desirable.

Lock-based deques can be implemented easily using the same two-lock approach used for queues. Given the relatively simple lock-free implementations for stacks and queues, it is somewhat surprising that there is no known lock-free deque implementation that allows concurrent operations on both ends. Martin et al. [80] provide a summary of concurrent deque implementations, showing that, even using nonconventional two-word synchronization primitives such as *double-compare-and-swap* (DCAS) [81], it is difficult to design a lock-free deque. The only known nonblocking deque implementation for current architectures that supports noninterfering operations at opposite ends of the deque is an obstruction-free CAS-based implementation due to Herlihy et al. [10].

48.4 Pools

Much of the difficulty in implementing efficient concurrent stacks and queues arises from the ordering requirements on when an element that has been inserted can be removed. A concurrent *pool* [82] is a data structure that supports `insert` and `delete` operations, and allows a `delete` operation to remove *any* element that has been inserted and not subsequently deleted. This weaker requirement offers opportunities for improving scalability.

A high-performance pool can be built using any quiescently consistent counter implementation [23,31]. Elements are placed in an array, and a `fetch-and-inc` operation is used to determine in which location an `insert` operation stores its value, and similarly from which location a `delete` operation takes its value. Each array element contains a full/empty bit or equivalent mechanism to indicate if the element to be removed has already been placed in the location. Using such a scheme, any one of the combining tree, combining funnel, counting network, or diffracting tree approaches described above can be used to create a high throughput shared pool by parallelizing the main bottlenecks: the shared counters. Alternatively, a “stack like” pool can be implemented by using a counter that allows increments and decrements, and again using one of the above techniques to parallelize it.

Finally, the elimination technique discussed earlier is applicable to pools constructed using combining funnels, counting networks, or diffracting trees: if `insert` and `delete` operations meet in the tree, the `delete` can take the value being inserted by the `insert` operation, and both can leave without continuing to traverse the structure. This technique provides high performance under high load.

The drawback of all these implementations is that they perform rather poorly under low load. Moreover, when used for work-load distribution [26,83,84], they do not allow us to exploit locality information, as pools designed specifically for work-load distribution do.

Workload distribution (or *load balancing*) algorithms involve a collection of pools of units of work to be done; each pool is local to a given processor. Threads create work items and place them in local pools, employing a load balancing algorithm to ensure that the number of items in the pools is balanced. This avoids the possibility that some processors are idle while others still have work in their local pools. There are two general classes of algorithms of this type: *work sharing* [76,84] and *work stealing* [26,83]. In a work sharing scheme, each processor attempts to continuously offload work from its pool to other pools. In work stealing, a thread that has no work items in its local pool steals work from other pools. Both classes of algorithms typically use randomization to select the pool with which to balance or the target pool for stealing.

The classical work stealing algorithm is due to Arora et al. [26]. It is based on a lock-free construction of a *deque* that allows operations by only one thread (the thread to which the pool is local) at one end of the deque, allowing only pop operations at the other end, and allowing concurrent pop operations at that end to “abort” if they interfere. A deque with these restrictions is suitable for work stealing, and the restrictions allow a simple implementation in which the local thread can insert and delete using simple low-cost load and store operations, resorting to a more expensive CAS operation only when it competes with the remote deleters for the last remaining item in the queue.

It has been shown that in some cases it is desirable to steal more than one item at a time [85,86]. A nonblocking multiple-item work-stealing algorithm due to Helder and Shavit appears in References 87. It has also been shown that in some cases it is desirable to use affinity information of work items in deciding which items to steal. A locality-guided work stealing algorithm due to Acar et al. appears in References 88.

48.5 Linked Lists

Consider implementations of concurrent search structures supporting `insert`, `delete`, and `search` operations. If these operations deal only with a key value, then the resulting data structure is a *set*; if a data value is associated with each key, we have a *dictionary* [58]. These are closely related data structures, and a concurrent set implementation can often be adapted to implement a dictionary. In the next three sections, we concentrate on implementing sets using different structures: linked lists, hash tables, and trees.

Suppose we use a linked list to implement a set. Apart from globally locking the linked list to prevent concurrent manipulation, the most popular approach to concurrent lock-based linked lists is *hand-over-hand locking* (sometimes called *lock coupling*) [89,90]. In this approach, each node has an associated lock. A thread traversing the linked list releases a node’s lock only after acquiring the lock of the next node in the list, thus preventing overtaking which may cause unnoticed removal of a node. This approach reduces lock granularity but significantly limits concurrency because insertions and deletions at disjoint list locations may delay each other.

One way to overcome this problem is to design lock-free linked lists. The difficulty in implementing a lock-free ordered linked list is ensuring that during an insertion or deletion, the adjacent nodes are still valid, that is, they are still in the list and are still adjacent. As Figure 48.6 shows, designing such lock-free linked lists is not a straightforward matter.

The first CAS-based lock-free linked list is due to Valois [91], who uses a special auxiliary node in front of every regular node to prevent the undesired phenomena depicted in Figure 48.6. Valois’s algorithm is correct when combined with a memory management solution due to Michael and Scott [92], but this solution is not practical. Harris [93] presents a lock-free list that

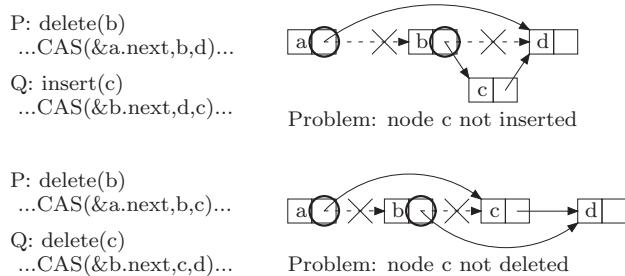

FIGURE 48.6 CAS-based list manipulation is hard. In both examples, P is deleting b from the list (the examples slightly abuse CAS notation). In the upper example, Q is trying to insert c into the list, and in the lower example, Q is trying to delete c from the list. Circled locations indicate the target addresses of the CAS operations; crossed out pointers are the values before the CAS succeeds.

uses a special “deleted” bit that is accessed atomically with node pointers in order to signify that a node has been deleted; this scheme is applicable only in garbage collected environments. Michael [94] overcomes this disadvantage by modifying Harris’s algorithm to make it compatible with memory reclamation methods [77,78].

48.6 Hash Tables

A typical extensible hash table is a resizable array of buckets, each holding an expected constant number of elements, and thus requiring on average a constant time for `insert`, `delete` and `search` operations [58]. The principal cost of *resizing*—the redistribution of items between old and new buckets—is amortized over all table operations, thus keeping the cost of operations constant on average. Here resizing means extending the table, as it has been shown that as a practical matter, hash tables need only increase in size [95]. See Chapter 9 for more on hash tables.

Michael [94] shows that a concurrent non-extensible hash table can be achieved by placing a read-write lock on every bucket in the table. However, to guarantee good performance as the number of elements grows, hash tables must be extensible [96].

In the eighties, Ellis [97] and others [95,98] extended the work of Fagin et al. [96] by designing an extensible concurrent hash table for distributed databases based on two-level locking schemes. A recent extensible hash algorithm by Lea [99] is known to be highly efficient in non-multiprogrammed environments [100]. It is based on a version of Litwin’s sequential linear hashing algorithm [101]. It uses a locking scheme that involves a small number of high-level locks rather than a lock per bucket, and allows concurrent searches while resizing the table, but not concurrent inserts or deletes. Resizing is performed as a global restructuring of all buckets when the table size needs to be doubled.

Lock-based extensible hash-table algorithms suffer from all of the typical drawbacks of blocking synchronization, as discussed earlier. These problems become more acute because of the elaborate “global” process of redistributing the elements in all the hash table’s buckets among newly added buckets. Lock-free extensible hash tables are thus a matter of both practical and theoretical interest.

As described in Section 48.5, Michael [94] builds on the work of Harris [93] to provide an effective CAS-based lock-free linked list implementation. He then uses this as the basis for a lock-free hash structure that performs well in multiprogrammed environments: a fixed-sized array of hash buckets, each implemented as a lock-free list. However, there is a difficulty in making a lock-free array of lists extensible since it is not obvious how to redistribute items in a lock-free manner when the bucket array grows. Moving an item between two bucket lists seemingly requires two CAS operations to be performed together atomically, which is not possible on current architectures.

Greenwald [102] shows how to implement an extensible hash table using his *two-handed emulation* technique. However, this technique employs a DCAS synchronization operation, which is not available on current architectures, and introduces excessive amounts of work during global resizing operations.

Shalev and Shavit [100] introduce a lock-free extensible hash table which works on current architectures. Their key idea is to keep the items in a single lock-free linked list instead of a list per bucket. To allow operations fast access to the appropriate part of the list, the Shalev-Shavit algorithm maintains a resizable array of “hints” (pointers into the list); operations use the hints to find a point in the list that is close to the relevant position, and then follow list pointers to find the position. To ensure a constant number of steps per operation on average, finer grained hints must be added as the number of elements in the list grows. To allow these hints to be installed simply and efficiently, the list is maintained in a special *recursive split ordering*. This technique allows new hints to be installed incrementally, thereby eliminating the need for complicated mechanisms for atomically moving items between buckets, or reordering the list.

48.7 Search Trees

A concurrent implementation of any search tree (See Chapters 3 and 11 for more on sequential search trees) can be achieved by protecting it using a single exclusive lock. Concurrency can be improved somewhat by using a reader-writer lock to allow all read-only (`search`) operations to execute concurrently with each other while holding the lock in *shared mode*, while update (`insert` or `delete`) operations exclude all other operations by acquiring the lock in *exclusive mode*. If update operations are rare, this may be acceptable, but with even a moderate number of updates, the exclusive lock for update operations creates a sequential bottleneck that degrades performance substantially. By using fine-grained locking strategies—for example by using one lock per node, rather than a single lock for the entire tree—we can improve concurrency further.

Kung and Lehman [103] present a concurrent binary search tree implementation in which update operations hold only a constant number of node locks at a time, and these locks only exclude other update operations: search operations are never blocked. However, this implementation makes no attempt to keep the search tree balanced. In the remainder of this section, we focus on balanced search trees, which are considerably more challenging.

As a first step towards more fine-grained synchronization in balanced search tree implementations, we can observe that it is sufficient for an operation to hold an exclusive lock on the subtree in which it causes any modifications. This way, update operations that modify disjoint subtrees can execute in parallel. We briefly describe some techniques in this spirit in the context of B^+ -trees. Recall that in B^+ -trees, all keys and data are stored in leaf nodes; internal nodes only maintain routing information to direct operations towards the appropriate leaf nodes. Furthermore, an insertion into a leaf may require the leaf to be split, which may in turn require a new entry to be added to the leaf's parent, which itself may need to be split to accommodate the new entry. Thus, an insertion can potentially result in modifying all nodes along the path from the root to the leaf. However, such behavior is rare, so it does not make sense to exclusively lock the whole path just in case this occurs.

As a first step to avoiding such conservative locking strategies, we can observe that if an `insert` operation passes an internal B^+ -tree node that is not full, then the modifications it makes to the tree cannot propagate past that node. In this case, we say that the node is *safe* with respect to the `insert` operation. If an update operation encounters a safe node while descending the tree acquiring exclusive locks on each node it traverses, it can safely release the locks on all ancestors of that node, thereby improving concurrency by allowing other operations to traverse those nodes [104,105]. Because `search` operations do not modify the tree, they can descend the tree using lock coupling: as soon as a lock has been acquired on a child node, the lock on its parent can be released. Thus, `search` operations hold at most two locks (in shared mode) at any point in time, and are therefore less likely to prevent progress by other operations.

This approach still requires each update operation to acquire an exclusive lock on the root node, and to hold the lock while reading a child node, potentially from disk, so the root is still a bottleneck. We can improve on this approach by observing that most update operations will not need to split or merge the leaf node they access, and will therefore eventually release the exclusive locks on all of the nodes traversed on the way to the leaf. This observation suggests an “optimistic” approach in which we descend the tree acquiring the locks in shared mode, acquiring only the leaf node exclusively [89]. If the leaf does not need to be split or merged, the update operation can complete immediately; in the rare cases in which changes do need to propagate up the tree, we can release all of the locks and then retry with the more pessimistic approach described above. Alternatively, we can use reader-writer locks that allow locks held in a shared mode to be “upgraded” to exclusive mode. This way, if an update operation discovers that it does need to modify nodes other than the leaf, it can upgrade locks it already holds in shared mode to exclusive mode, and avoid completely restarting the operation from the top of the tree [89]. Various combinations of the above techniques can be used because nodes near the top of the tree are more likely to conflict with other operations and less likely to be modified, while the opposite is true of nodes near the leaves [89].

As we employ some of the more sophisticated techniques described above, the algorithms become more complicated, and it becomes more difficult to avoid deadlock, resulting in even further complications. Nonetheless, all of these techniques maintain the invariant that operations exclusively lock the subtrees that they modify, so operations do not encounter states that they would not encounter in a sequential implementation. Significant improvements in concurrency and performance can be made by relaxing this requirement, at the cost of making it more difficult to reason that the resulting algorithms are correct.

A key difficulty we encounter when we attempt to relax the strict subtree locking schemes is that an operation descending the tree might follow a pointer to a child node that is no longer the correct node because of a modification by a concurrent operation. Various techniques have been developed that allow operations to recover from such “confusion,” rather than strictly avoiding it.

An important example in the context of B^+ -trees is due to Lehman and Yao [106], who define B^{link} -trees: B^+ -trees with “links” from each node in the tree to its right neighbor at the same level of the tree. These links allow us to “separate” the splitting of a node from modifications to its parent to reflect the splitting. Specifically, in order to split a node n , we can create a new node n' to its right, and install a link from n to n' . If an operation that is descending the tree reaches node n while searching for a key position that is now covered by node n' due to the split, the operation can simply follow the link from n to n' to recover. This allows a node to be split without preventing access by concurrent operations to the node's parent. As a result, update operations do not need to simultaneously lock the entire subtree they (potentially) modify. In fact, in the Lehman-Yao algorithm, update operations as well as `search` operations use the lock coupling technique so that no operation ever holds more than two locks at a time, which significantly improves concurrency. This technique has been further refined, so that operations never hold more than one lock at a time [107].

Lehman and Yao do not address how nodes can be merged, instead allowing `delete` operations to leave nodes underfull. They argue that in many cases `delete` operations are rare, and that if space utilization becomes a problem, the tree can occasionally be reorganized in “batch” mode by exclusively locking the entire tree. Lanin and Shasha [108] incorporate merging into the `delete` operations, similarly to how `insert` operations split overflowed nodes in previous implementations. Similar to the Lehman-Yao link technique, these implementations use links to allow recovery by operations that have mistakenly reached a node that has been evacuated due to node merging.

In all of the algorithms discussed above, the maintenance operations such as node splitting and merging (where applicable) are performed as part of the regular update operations. Without such tight coupling between the maintenance operations and

the regular operations that necessitate them, we cannot guarantee strict balancing properties. However, if we relax the balance requirements, we can separate the tree maintenance work from the update operations, resulting in a number of advantages that outweigh the desire to keep search trees strictly balanced. As an example, the B^{link} -tree implementation in References 107 supports a *compression process* that can run concurrently with regular operations to merge nodes that are underfull. By separating this work from the regular update operations, it can be performed concurrently by threads running on different processors, or in the background.

The idea of separating rebalancing work from regular tree operations was first suggested for red-black trees [109], and was first realized in References 110 for AVL trees [111] supporting `insert` and `search` operations. An implementation that also supports `delete` operations is provided in References 112. These implementations improve concurrency by breaking balancing work down into small, local tree transformations that can be performed independently. Analysis in References 113 shows that with some modifications, the scheme of Reference 112 guarantees that each update operation causes at most $O(\log N)$ rebalancing operations for an N -node AVL tree. Similar results exist for B-trees [112,114] and red-black trees [115,116].

The only nonblocking implementations of balanced search trees have been achieved using Dynamic Software Transactional Memory mechanisms [11,117]. These implementations use transactions translated from sequential code that performs rebalancing work as part of regular operations.

The above brief survey covers only basic issues and techniques involved with implementing concurrent search trees. To mention just a few of the numerous improvements and extensions in the literature, [118] addresses practical issues for the use of B^+ -trees in commercial database products, such as recovery after failures; [119] presents concurrent implementations for *generalized search trees* (GiSTs) that facilitate the design of search trees without repeating the delicate work involved with concurrency control; and [120,121] present several types of trees that support the efficient insertion and/or deletion of a group of values. Pugh [122] presents a concurrent version of his skip list randomized search structure [123]. *Skip lists* are virtual tree structures consisting of multiple layers of linked lists. The expected search time in a skip list is logarithmic in the number of elements in it. The main advantage of skip lists is that they do not require rebalancing: insertions are done in a randomized fashion that keeps the search tree balanced.

Empirical and analytical evaluations of concurrent search trees and other data structures can be found in References 124,125.

48.8 Priority Queues

A concurrent *priority queue* is a data structure linearizable to a sequential priority queue that provides `insert` and `delete-min` operations with the usual priority queue semantics. (See Part II of this handbook for more on sequential priority queues.)

48.8.1 Heap-Based Priority Queues

Many of the concurrent priority queue constructions in the literature are linearizable versions of the heap structures described earlier in this book. Again, the basic idea is to use fine-grained locking of the individual heap nodes to allow threads accessing different parts of the data structure to do so in parallel where possible. A key issue in designing such concurrent heaps is that traditionally `insert` operations proceed from the bottom up and `delete-min` operations from the top down, which creates potential for deadlock. Biswas and Brown [126] present such a lock-based heap algorithm assuming specialized “cleanup” threads to overcome deadlocks. Rao and Kumar [127] suggest to overcome the drawbacks of [126] using an algorithm that has both `insert` and `delete-min` operations proceed from the top down. Ayani [128] improved on their algorithm by suggesting a way to have consecutive insertions be performed on opposite sides of the heap. Jones [129] suggests a scheme similar to [127] based on a skew heap.

Hunt et al. [130] present a heap-based algorithm that overcomes many of the limitations of the above schemes, especially the need to acquire multiple locks along the traversal path in the heap. It proceeds by locking for a short duration a variable holding the size of the heap and a lock on either the first or last element of the heap. In order to increase parallelism, insertions traverse the heap bottom-up while deletions proceed top-down, without introducing deadlocks. Insertions also employ a left-right technique as in References 128 to allow them to access opposite sides on the heap and thus minimize interference.

On a different note, Huang and Weihl [131] show a concurrent priority queue based on a concurrent version of Fibonacci Heaps [132].

Nonblocking linearizable heap-based priority queue algorithms have been proposed by Herlihy [71], Barnes [133], and Israeli and Rappoport [134]. Sundell and Tsigas [135] present a lock-free priority queue based on a lock-free version of Pugh’s concurrent skip list [122].

48.8.2 Tree-Based Priority Pools

Huang and Weihl [131] and Johnson [136] describe concurrent *priority pools*: priority queues with relaxed semantics that do not guarantee linearizability of the `delete-min` operations. Their designs are both based on a modified concurrent B^+ -tree implementation. Johnson introduces a “delete bin” that accumulates values to be deleted and thus reduces the load when performing concurrent `delete-min` operations. Shavit and Zemach [137] show a similar pool based on Pugh’s concurrent skiplist [122] with an added “delete bin” mechanism based on [136]. Typically, the weaker pool semantics allows for increased concurrency. In References 137 they further show that if the size of the set of allowable keys is bounded (as is often the case in operating systems) a priority pool based on a binary tree of combining funnel nodes can scale to hundreds (as opposed to tens) of processors.

48.9 Summary

We have given an overview of issues related to the design of concurrent data structures for shared-memory multiprocessors, and have surveyed some of the important contributions in this area. Our overview clearly illustrates that the design of such data structures provides significant challenges, and as of this writing, the maturity of concurrent data structures falls well behind that of sequential data structures. However, significant progress has been made towards understanding key issues and developing new techniques to facilitate the design of effective concurrent data structures; we are particularly encouraged by renewed academic and industry interest in stronger hardware support for synchronization. Given new understanding, new techniques, and stronger hardware support, we believe significant advances in concurrent data structure designs are likely in the coming years.

49.1 Introduction

An Internet router classifies incoming packets into flows[‡] utilizing information contained in packet headers and a table of (classification) rules. This table is called the *rule table* (equivalently, *router table*). The packet-header information that is used to perform the classification is some subset of the source and destination addresses, the source and destination ports, the protocol, protocol flags, type of service, and so on. The specific header information used for packet classification is governed by the rules in the rule table. Each rule-table rule is a pair of the form (F, A) , where F is a filter and A is an action. The action component of a rule specifies what is to be done when a packet that satisfies the rule filter is received. Sample actions are drop the packet, forward the packet along a certain output link, and reserve a specified amount of bandwidth. A rule filter F is a tuple that is comprised of one or more fields. In the simplest case of destination-based packet forwarding, F has a single field, which is a destination (address) prefix and A is the next hop for packets whose destination address has the specified prefix. For example, the rule $(01^*, a)$ states that the next hop for packets whose destination address (in binary) begins with 01 is a . IP (Internet Protocol) multicasting uses rules in which F is comprised of the two fields source prefix and destination prefix; QoS routers may use five-field rule filters (source-address prefix, destination-address prefix, source-port range, destination-port range, and protocol); and firewall filters may have one or more fields.

In the d -dimensional packet classification problem, each rule has a d -field filter. In this chapter, we are concerned solely with 1-dimensional packet classification. It should be noted, that data structures for multidimensional packet classification are usually built on top of data structures for 1-dimensional packet classification. Therefore, the study of data structures for 1-dimensional packet classification is fundamental to the design and development of data structures for d -dimensional, $d > 1$, packet classification.

For the 1-dimensional packet classification problem, we assume that the single field in the filter is the destination field and that the action is the next hop for the packet. With these assumptions, 1-dimensional packet classification is equivalent to the destination-based packet forwarding problem. Henceforth, we shall use the terms rule table and router table to mean tables in which the filters have a single field, which is the destination address. This single field of a filter may be specified in one of two ways:

1. *As a range.* For example, the range $[35, 2096]$ matches all destination addresses d such that $35 \leq d \leq 2096$.
2. *As an address/mask pair.* Let x_i denote the i th bit of x . The address/mask pair a/m matches all destination addresses d for which $d_i = a_i$ for all i for which $m_i = 1$. That is, a 1 in the mask specifies a bit position in which d and a must agree, while a 0

† We have used this author's affiliation from the first edition of this handbook, but note that this may have changed since then.

‡ A **flow** is a set of packets that are to be treated similarly for routing purposes.

Prefix Name	Prefix	Range Start	Range Finish
P1	*	0	31
P2	0101*	10	11
P3	100*	16	19
P4	1001*	18	19
P5	10111	23	23

FIGURE 49.1 Prefixes and their ranges.

in the mask specifies a don't care bit position. For example, the address/mask pair 101100/011101 matches the destination addresses 101100, 101110, 001100, and 001110.

When all the 1-bits of a mask are to the left of all 0-bits, the address/mask pair specifies an address prefix. For example, 101100/110000 matches all destination addresses that have the prefix 10 (i.e., all destination addresses that begin with 10). In this case, the address/mask pair is simply represented as the prefix 10^* , where the * denotes a sequence of don't care bits. If W is the length, in bits, of a destination address, then the * in 10^* represents all sequences of $W - 2$ bits. In IPv4 the address and mask are both 32 bits, while in IPv6 both of these are 128 bits.

Notice that every prefix may be represented as a range. For example, when $W = 6$, the prefix 10^* is equivalent to the range [32,47]. A range that may be specified as a prefix for some W is called a *prefix range*. The specification 101100/011101 may be abbreviated to ?011?0, where ? denotes a don't-care bit. This specification is not equivalent to any single range. Also, the range specification [3,6] isn't equivalent to any single address/mask specification.

Figure 49.1 shows a set of five prefixes together with the start and finish of the range for each. This figure assumes that $W = 5$. The prefix P1 = *, which matches all legal destination addresses, is called the *default* prefix.

Suppose that our router table is comprised of five rules R1–R5 and that the filters for these five rules are P1–P5, respectively. Let N1–N5, respectively, be the next hops for these five rules. The destination address 18 is matched by rules R1, R3, and R5 (equivalently, by prefixes P1, P3, and P5). So, N1, N3, and N5 are candidates for the next hop for incoming packets that are destined for address 18. Which of the matching rules (and associated action) should be selected? When more than one rule matches an incoming packet, a *tie* occurs. To select one of the many rules that may match an incoming packet, we use a *tie breaker*.

Let RS be the set of rules in a rule table and let FS be the set of filters associated with these rules. $rules(d, RS)$ (or simply $rules(d)$ when RS is implicit) is the subset of rules of RS that match/cover the destination address d . $filters(d, FS)$ and $filters(d)$ are defined similarly. A tie occurs whenever $|rules(d)| > 1$ (equivalently, $|filters(d)| > 1$).

Three popular tie breakers are:

1. *First matching rule in table*. The rule table is assumed to be a linear list [1] of rules with the rules indexed 1 through n for an n -rule table. The action corresponding to the first rule in the table that matches the incoming packet is used. In other words, for packets with destination address d , the rule of $rules(d)$ that has least index is selected.

For our example router table corresponding to the five prefixes of Figure 49.1, rule R1 is selected for every incoming packet, because P1 matches every destination address. When using the first-matching-rule criteria, we must index the rules carefully. In our example, P1 should correspond to the last rule so that every other rule has a chance to be selected for at least one destination address.

2. *Highest-priority rule*. Each rule in the rule table is assigned a priority. From among the rules that match an incoming packet, the rule that has highest priority wins is selected. To avoid the possibility of a further tie, rules are assigned different priorities (it is actually sufficient to ensure that for every destination address d , $rules(d)$ does not have two or more highest-priority rules).

Notice that the first-matching-rule criteria is a special case of the highest-priority criteria (simply assign each rule a priority equal to the negative of its index in the linear list).

3. *Most-specific-rule matching*. The filter $F1$ is **more specific** than the filter $F2$ iff $F2$ matches all packets matched by $F1$ plus at least one additional packet. So, for example, the range [2, 4] is more specific than [1, 6], and [5, 9] is more specific than [5, 12]. Since [2, 4] and [8, 14] are disjoint (i.e., they have no address in common), neither is more specific than the other. Also, since [4, 14] and [6, 20] intersect,^{*} neither is more specific than the other. The prefix 110^* is more specific than the prefix 11^* .

^{*} Two ranges $[u, v]$ and $[x, y]$ intersect iff $u < x \leq v < y \vee x < u \leq y < v$.

In most-specific-rule matching, ties are broken by selecting the matching rule that has the most specific filter. When the filters are destination prefixes, the most-specific-rule that matches a given destination d is the longest^{*} prefix in $\text{filters}(d)$. Hence, for prefix filters, the most-specific-rule tie breaker is equivalent to the longest-matching-prefix criteria used in router tables. For our example rule set, when the destination address is 18, the longest matching-prefix is P4. When the filters are ranges, the most-specific-rule tie breaker requires us to select the most specific range in $\text{filters}(d)$. Notice also that most-specific-range matching is a special case of the highest-priority rule. For example, when the filters are prefixes, set the prefix priority equal to the prefix length. For the case of ranges, the range priority equals the negative of the range size.

In a *static* rule table, the rule set does not vary in time. For these tables, we are concerned primarily with the following metrics:

1. *Time required to process an incoming packet.* This is the time required to search the rule table for the rule to use.
2. *Preprocessing time.* This is the time to create the rule-table data structure.
3. *Storage requirement.* That is, how much memory is required by the rule-table data structure?

In practice, rule tables are seldom truly static. At best, rules may be added to or deleted from the rule table infrequently. Typically, in a “static” rule table, inserts/deletes are batched and the rule-table data structure reconstructed as needed.

In a *dynamic* rule table, rules are added/deleted with some frequency. For such tables, inserts/deletes are not batched. Rather, they are performed in real time. For such tables, we are concerned additionally with the time required to insert/delete a rule. For a dynamic rule table, the initial rule-table data structure is constructed by starting with an empty data structures and then inserting the initial set of rules into the data structure one by one. So, typically, in the case of dynamic tables, the preprocessing metric, mentioned above, is very closely related to the insert time.

In this paper, we focus on data structures for static and dynamic router tables (1-dimensional packet classification) in which the filters are either prefixes or ranges.

49.2 Longest Matching-Prefix

49.2.1 Linear List

In this data structure, the rules of the rule table are stored as a linear list^[1] L . Let $LMP(d)$ be the longest matching-prefix for address d . $LMP(d)$ is determined by examining the prefixes in L from left to right; for each prefix, we determine whether or not that prefix matches d ; and from the set of matching prefixes, the one with longest length is selected. To insert a rule q , we first search the list L from left to right to ensure that L doesn’t already have a rule with the same filter as does q . Having verified this, the new rule q is added to the end of the list. Deletion is similar. The time for each of the operations determine $LMP(d)$, insert a rule, delete a rule is $O(n)$, where n is the number of rules in L . The memory required is also $O(n)$.

Note that this data structure may be used regardless of the form of the filter (i.e., ranges, Boolean expressions, etc.) and regardless of the tie breaker in use. The time and memory complexities are unchanged.

Although the linear list is not a suitable data structure for a purely software implementation of a router table with a large number of prefixes, it leads to a very practical solution using TCAMs (ternary content-addressable memories) [2,3]. Each memory cell of a TCAM may be set to one of three states 0, 1, and don’t care. The prefixes of a router table are stored in a TCAM in descending order of prefix length. Assume that each word of the TCAM has 32 cells. The prefix 10^* is stored in a TCAM word as $10????\dots?$, where $?$ denotes a don’t care and there are 30 $?$ s in the given sequence. To do a longest-prefix match, the destination address is matched, in parallel, against every TCAM entry and the first (i.e., longest) matching entry reported by the TCAM arbitration logic. So, using a TCAM and a sorted-by-length linear list, the longest matching-prefix can be determined in $O(1)$ time. A prefix may be inserted or deleted in $O(W)$ time, where W is the length of the longest prefix [2].[†] For example, an insert of a prefix of length 3 (say) can be done by relocating the first prefix of length 1 to the end of the list; filling the vacated slot with the first prefix of length 2; and finally filling this newly vacated spot with the prefix of length 3 that is to be inserted.

Despite the simplicity and efficiency of using TCAMs, TCAMs present problems in real applications [4]. For example, TCAMs consume a lot of power and board area.

49.2.2 End-Point Array

Lampson, Srinivasan, and Varghese [5] have proposed a data structure in which the end points of the ranges defined by the prefixes are stored in ascending order in an array. $LMP(d)$ is found by performing a binary search on this ordered array of end points.

^{*} The length of a prefix is the number of bits in that prefix (note that the $*$ is not used in determining prefix length). The length of P1 is 0 and that of P2 is 4.

[†] More precisely, W may be defined to be the number of different prefix lengths in the table.

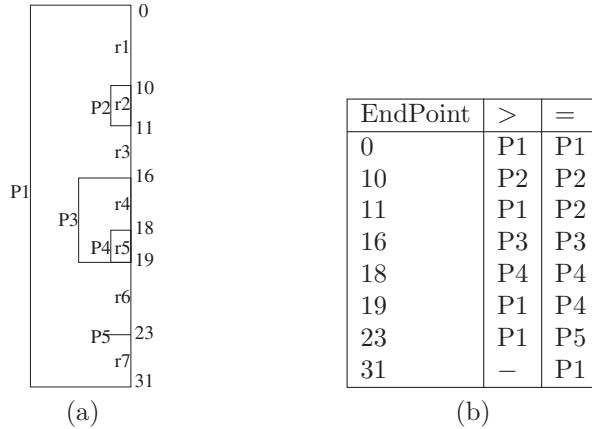

FIGURE 49.2 (a) Pictorial representation of prefixes and ranges (b) Array for binary search.

Prefixes and their ranges may be drawn as nested rectangles as in Figure 49.2a, which gives the pictorial representation of the five prefixes of Figure 49.1.

In the data structure of Lampson et al. [5], the distinct range end-points are stored in ascending order as in Figure 49.2b. The distinct end-points (range start and finish points) for the prefixes of Figure 49.1 are $[0, 10, 11, 16, 18, 19, 23, 31]$. Let r_i , $1 \leq i \leq q \leq 2n$ be the distinct range end-points for a set of n prefixes. Let $r_{q+1} = \infty$. With each distinct range end-point, r_i , $1 \leq i \leq q$, the array stores $LMP(d)$ for d such that (a) $r_i < d < r_{i+1}$ (this is the column labeled “>” in Figure 49.2b and (b) $r_i = d$ (column labeled “=”)). Now, $LMP(d)$, $r_1 \leq d \leq r_q$ can be determined in $O(\log n)$ time by performing a binary search to find the unique i such that $r_i \leq d < r_{i+1}$. If $r_i = d$, $LMP(d)$ is given by the “=” entry; otherwise, it is given by the “>” entry. For example, since $d = 20$ satisfies $19 \leq d < 23$ and since $d \neq 19$, the “>” entry of the end point 19 is used to determine that $LMP(20)$ is P1.

As noted by Lampson et al. [5], the range end-point table can be built in $O(n)$ time (this assumes that the end points are available in ascending order). Unfortunately, as stated in Reference 5, updating the range end-point table following the insertion or deletion of a prefix also takes $O(n)$ time because $O(n)$ “>” and/or “=” entries may change. Although Lampson et al. [5] provide ways to reduce the complexity of the search for the LMP by a constant factor, these methods do not result in schemes that permit prefix insertion and deletion in $O(\log n)$ time.

It should be noted that the end-point array may be used even when ties are broken by selecting the first matching rule or the highest-priority matching rule. Further, the method applies to the case when the filters are arbitrary ranges rather than simply prefixes. The complexity of the preprocessing step (i.e., creation of the array of ordered end-points) and the search for the rule to use is unchanged. Further, the memory requirements are the same, $O(n)$ for an n -rule table, regardless of the tie breaker and whether the filters are prefixes or general ranges.

49.2.3 Sets of Equal-Length Prefixes

Waldvogel et al. [6] have proposed a data structure to determine $LMP(d)$ by performing a binary search on prefix length. In this data structure, the prefixes in the router table T are partitioned into the sets S_0, S_1, \dots such that S_i contains all prefixes of T whose length is i . For simplicity, we assume that T contains the default prefix. *So, $S_0 = \{ *\}$. Next, each S_i is augmented with markers that represent prefixes in S_j such that $j > i$ and i is on the binary search path to S_j . For example, suppose that the length of the longest prefix of T is 32 and that the length of $LMP(d)$ is 22. To find $LMP(d)$ by a binary search on length, we will first search S_{16} for an entry that matches the first 16 bits of d . This search^{*} will need to be successful for us to proceed to a larger length. The next search will be in S_{24} . This search will need to fail. Then, we will search S_{20} followed by S_{22} . So, the path followed by a binary search on length to get to S_{22} is S_{16}, S_{24}, S_{20} , and S_{22} . For this to be followed, the searches in S_{16}, S_{20} , and S_{22} must succeed while that in S_{24} must fail. Since the length of $LMP(d)$ is 22, T has no matching prefix whose length is more than 22. So, the search in S_{24} is guaranteed to fail. Similarly, the search in S_{22} is guaranteed to succeed. However, the searches in S_{16} and S_{20} will succeed iff T has matching prefixes of length 16 and 20. To ensure success, every length 22 prefix P places a marker in S_{16} and S_{20} , the marker in S_{16} is the first 16 bits of P and that in S_{20} is the first 20 bits in P . Note that a marker M is placed in S_i only if S_i doesn't contain a prefix equal to M . Notice also that for each i , the binary search path to S_i has $O(\log l_{\max}) = O(\log W)$, where l_{\max} is the

* When searching S_i , only the first i bits of d are used, because all prefixes in S_i have exactly i bits.

length of the longest prefix in T , S_i s on it. So, each prefix creates $O(\log W)$ markers. With each marker M in S_i , we record the longest prefix of T that matches M (the length of this longest matching-prefix is necessarily smaller than i).

To determine $LMP(d)$, we begin by setting $leftEnd = 0$ and $rightEnd = l_{max}$. The repetitive step of the binary search requires us to search for an entry in S_m , where $m = \lfloor (leftEnd + rightEnd)/2 \rfloor$, that equals the first m bits of d . If S_m does not have such an entry, set $rightEnd = m - 1$. Otherwise, if the matching entry is the prefix P , P becomes the longest matching-prefix found so far. If the matching entry is the marker M , the prefix recorded with M is the longest matching-prefix found so far. In either case, set $leftEnd = m + 1$. The binary search terminates when $leftEnd > rightEnd$.

One may easily establish the correctness of the described binary search. Since, each prefix creates $O(\log W)$ markers, the memory requirement of the scheme is $O(n \log W)$. When each set S_i is represented as a hash table, the data structure is called SELPH (sets of equal length prefixes using hash tables). The expected time to find $LMP(d)$ is $O(\log W)$ when the router table is represented as an SELPH. When inserting a prefix, $O(\log W)$ markers must also be inserted. With each marker, we must record a longest-matching prefix. The expected time to find these longest matching-prefixes is $O(\log^2 W)$. In addition, we may need to update the longest-matching prefix information stored with the $O(n \log W)$ markers at lengths greater than the length of the newly inserted prefix. This takes $O(n \log^2 W)$ time. So, the expected insert time is $O(n \log^2 W)$. When deleting a prefix P , we must search all hash tables for markers M that have P recorded with them and then update the recorded prefix for each of these markers. For hash tables with a bounded loading density, the expected time for a delete (including marker-prefix updates) is $O(n \log^2 W)$. Waldvogel et al. [6] have shown that by inserting the prefixes in ascending order of length, an n -prefix SELPH may be constructed in $O(n \log^2 W)$ time.

When each set is represented as a balanced search tree (see Chapter 11), the data structure is called SELPT. In an SELPT, the time to find $LMP(d)$ is $O(\log n \log W)$; the insert time is $O(n \log n \log^2 W)$; the delete time is $O(n \log n \log^2 W)$; and the time to construct the data structure for n prefixes is $O(W + n \log n \log^2 W)$.

In the full version of [6], Waldvogel et al. show that by using a technique called marker partitioning, the SELPH data structure may be modified to have a search time of $O(\alpha + \log W)$ and an insert/delete time of $O(\alpha \sqrt{n} W \log W)$, for any $\alpha > 1$.

Because of the excessive insert and delete times, the sets of equal-length prefixes data structure is suitable only for static router tables. Note that in an actual implementation of SELPH or SELPT, we need only keep the non-empty S_i s and do a binary search over the collection of non-empty S_i s. Srinivasan and Varghese [7] have proposed the use of controlled prefix-expansion to reduce the number of non-empty sets S_i . The details of their algorithm to reduce the number of lengths are given in Reference 8. The complexity of their algorithm is $O(nW^2)$, where n is the number of prefixes, and W is the length of the longest prefix. The algorithm of [8] does not minimize the storage required by the prefixes and markers for the resulting set of prefixes. Kim and Sahni [9] have developed an algorithm that minimizes storage requirement but takes $O(nW^3 + kW^4)$ time, where k is the desired number of non-empty S_i s. Additionally, Kim and Sahni [9] propose improvements to the heuristic of [8].

We note that Waldvogel's scheme is very similar to the k -ary search-on-length scheme developed by Berg et al. [10] and the binary search-on-length schemes developed by Willard [11]. Berg et al. [10] use a variant of stratified trees [12] for one-dimensional point location in a set of n disjoint ranges. Willard [11] modified stratified trees and proposed the y-fast trie data structure to search a set of disjoint ranges. By decomposing filter ranges that are not disjoint into disjoint ranges, the schemes of [10,11] may be used for longest-prefix matching in static router tables. The asymptotic complexity for a search using the schemes of [10,11] is the same as that of Waldvogel's scheme. The decomposition of overlapping ranges into disjoint ranges is feasible for static router tables but not for dynamic router tables because a large range may be decomposed into $O(n)$ disjoint small ranges.

49.2.4 Tries

49.2.4.1 1-Bit Tries

A 1-bit trie is a tree-like structure in which each node has a left child, left data, right child, and right data field. Nodes at level^{*} $l - 1$ of the trie store prefixes whose length is l . If the rightmost bit in a prefix whose length is l is 0, the prefix is stored in the left data field of a node that is at level $l - 1$; otherwise, the prefix is stored in the right data field of a node that is at level $l - 1$. At level i of a trie, branching is done by examining bit i (bits are numbered from left to right beginning with the number 0) of a prefix or destination address. When bit i is 0, we move into the left subtree; when the bit is 1, we move into the right subtree. Figure 49.3a gives the prefixes in the 8-prefix example of [7], and Figure 49.3b shows the corresponding 1-bit trie. The prefixes in Figure 49.3a are numbered and ordered as in Reference 7.

The 1-bit tries described here are an extension of the 1-bit tries described in Reference 1. The primary difference being that the 1-bit tries of [1] are for the case when no key is a prefix of another. Since in router-table applications, this condition isn't satisfied, the 1-bit trie representation of [1] is extended so that keys of length l are stored in nodes at level $l - 1$ of the trie. Note that at most

^{*} Level numbers are assigned beginning with 0 for the root level.

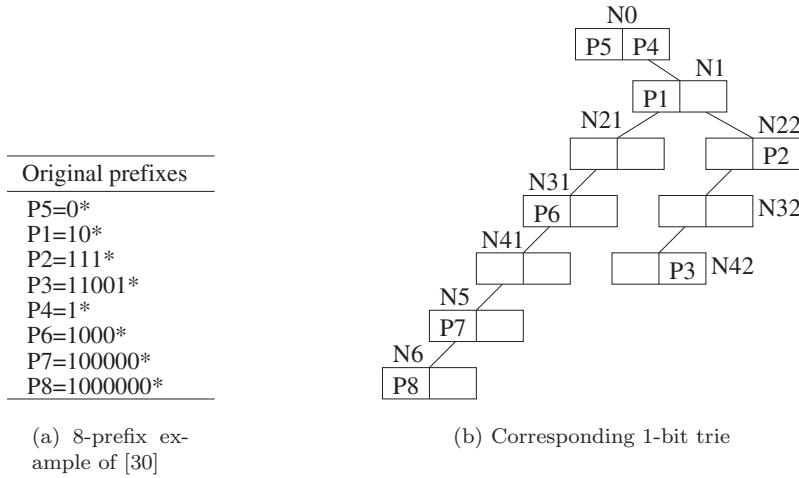

FIGURE 49.3 Prefixes and corresponding 1-bit trie.

two keys may be stored in a node; one of these has bit l equal to 0 and other has this bit equal to 1. In this extension, every node of the 1-bit trie has 2 child pointers and 2 data fields. The height of a 1-bit trie is $O(W)$.

For any destination address d , all prefixes that match d lie on the search path determined by the bits of d . By following this search path, we may determine the longest matching-prefix, the first prefix in the table that matches d , as well as the highest-priority matching-prefix in $O(W)$ time. Further, prefixes may be inserted/deleted in $O(W)$ time. The memory required by the 1-bit trie is $O(nW)$.

IPv4 backbone routers may have more than 100 thousand prefixes. Even though the prefixes in a backbone router may have any length between 0 and W , there is a concentration of prefixes at lengths 16 and 24, because in the early days of the Internet, Internet address assignment was done by classes. All addresses in a class B network have the same first 16 bits, while addresses in the same class C network agree on the first 24 bits. Addresses in class A networks agree on their first 8 bits. However, there can be at most 256 class A networks (equivalently, there can be at most 256 8-bit prefixes in a router table). For our backbone routers that occur in practice [13], the number of nodes in a 1-bit trie is between $2n$ and $3n$. Hence, in practice, the memory required by the 1-bit-trie representation is $O(n)$.

49.2.4.2 Fixed-Stride Tries

Since the trie of Figure 49.3b has a height of 6, a search into this trie may make up to 7 memory accesses, one access for each node on the path from the root to a node at level 6 of the trie. The total memory required for the 1-bit trie of Figure 49.3b is 20 units (each node requires 2 units, one for each pair of (child, data) fields).

When 1-bit tries are used to represent IPv4 router tables, the trie height may be as much as 31. A lookup in such a trie takes up to 32 memory accesses.

Degermark et al. [14] and Srinivasan and Varghese [7] have proposed the use of fixed-stride tries to enable fast identification of the longest matching prefix in a router table. The *stride* of a node is defined to be the number of bits used at that node to determine which branch to take. A node whose stride is s has 2^s child fields (corresponding to the 2^s possible values for the s bits that are used) and 2^s data fields. Such a node requires 2^s memory units. In a *fixed-stride trie* (FST), all nodes at the same level have the same stride; nodes at different levels may have different strides.

Suppose we wish to represent the prefixes of Figure 49.3a using an FST that has three levels. Assume that the strides are 2, 3, and 2. The root of the trie stores prefixes whose length is 2; the level one nodes store prefixes whose length is 5 ($2 + 3$); and level three nodes store prefixes whose length is 7 ($2 + 3 + 2$). This poses a problem for the prefixes of our example, because the length of some of these prefixes is different from the storeable lengths. For instance, the length of P5 is 1. To get around this problem, a prefix with a nonpermissible length is expanded to the next permissible length. For example, $P5 = 0^*$ is expanded to $P5a = 00^*$ and $P5b = 01^*$. If one of the newly created prefixes is a duplicate, natural dominance rules are used to eliminate all but one occurrence of the prefix. For instance, $P4 = 1^*$ is expanded to $P4a = 10^*$ and $P4b = 11^*$. However, $P1 = 10^*$ is to be chosen over $P4a = 10^*$, because $P1$ is a longer match than $P4$. So, $P4a$ is eliminated. Because of the elimination of duplicate prefixes from the expanded prefix set, all prefixes are distinct. Figure 49.4a shows the prefixes that result when we expand the prefixes of Figure 49.3 to lengths 2, 5, and 7. Figure 49.4b shows the corresponding FST whose height is 2 and whose strides are 2, 3, and 2.

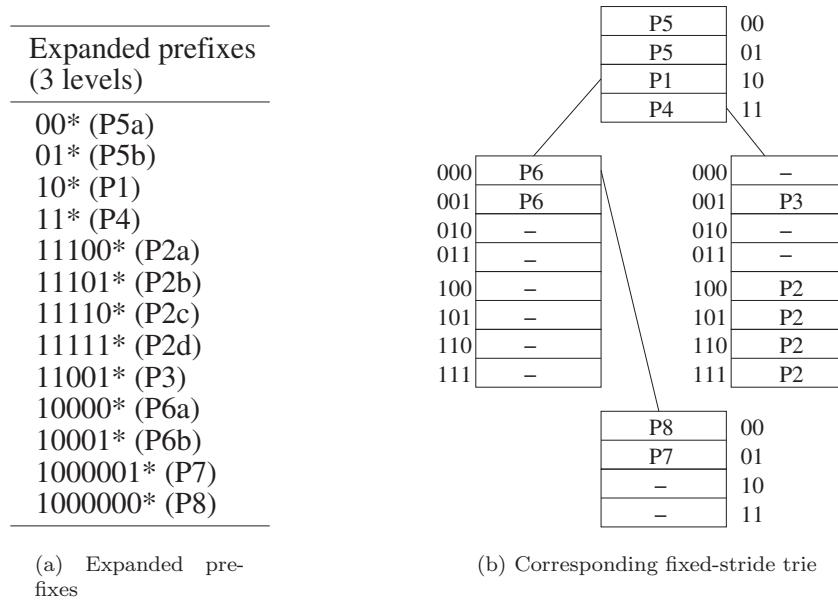

FIGURE 49.4 Prefix expansion and fixed-stride trie.

Since the trie of Figure 49.4b can be searched with at most 3 memory references, it represents a time performance improvement over the 1-bit trie of Figure 49.3b, which requires up to 7 memory references to perform a search. However, the space requirements of the FST of Figure 49.4b are more than that of the corresponding 1-bit trie. For the root of the FST, we need 8 fields or 4 units; the two level 1 nodes require 8 units each; and the level 3 node requires 4 units. The total is 24 memory units.

We may represent the prefixes of Figure 49.3a using a one-level trie whose root has a stride of 7. Using such a trie, searches could be performed making a single memory access. However, the one-level trie would require $2^7 = 128$ memory units.

For IPv4 prefix sets, Degermark et al. [14] propose the use of a three-level trie in which the strides are 16, 8, and 8. They propose encoding the nodes in this trie using bit vectors to reduce memory requirements. The resulting data structure requires at most 12 memory accesses. However, inserts and deletes are quite expensive. For example, the insertion of the prefix 1* changes up to 2^{15} entries in the trie's root node. All of these changes may propagate into the compacted storage scheme of [14].

Lampson et al. [5] have proposed the use of hybrid data structures comprised of a stride-16 root and an auxiliary data structure for each of the subtrees of the stride-16 root. This auxiliary data structure could be the end-point array of Section 49.2.2 (since each subtree is expected to contain only a small number of prefixes, the number of end points in each end-point array is also expected to be quite small). An alternative auxiliary data structure suggested by Lampson et al. [5] is a 6-way search tree for IPv4 router tables. In the case of these 6-way trees, the keys are the remaining up to 16 bits of the prefix (recall that the stride-16 root consumes the first 16 bits of a prefix). For IPv6 prefixes, a multicolumn scheme is suggested [5]. None of these proposed structures is suitable for a dynamic table.

In the *fixed-stride trie optimization* (FSTO) problem, we are given a set P of prefixes and an integer k . We are to select the strides for a k -level FST in such a manner that the k -level FST for the given prefixes uses the smallest amount of memory.

For some P , a k -level FST may actually require more space than a $(k - 1)$ -level FST. For example, when $P = \{00*, 01*, 10*, 11*\}$, the unique 1-level FST for P requires 4 memory units while the unique 2-level FST (which is actually the 1-bit trie for P) requires 6 memory units. Since the search time for a $(k - 1)$ -level FST is less than that for a k -level tree, we would actually prefer $(k - 1)$ -level FSTs that take less (or even equal) memory over k -level FSTs. Therefore, in practice, we are really interested in determining the best FST that uses at most k levels (rather than exactly k levels). The *modified MSTO* problem (MFSTO) is to determine the best FST that uses at most k levels for the given prefix set P .

Let O be the 1-bit trie for the given set of prefixes, and let F be any k -level FST for this prefix set. Let s_0, \dots, s_{k-1} be the strides for F . We shall say that level 0 of F covers levels $0, \dots, s_0 - 1$ of O , and that level j , $0 < j < k$ of F covers levels a, \dots, b of O , where $a = \sum_{q=0}^{j-1} s_q$ and $b = \sum_{q=0}^j s_q - 1$. So, level 0 of the FST of Figure 49.4b covers levels 0 and 1 of the 1-bit trie of Figure 49.3b. Level 1 of this FST covers levels 2, 3, and 4 of the 1-bit trie of Figure 49.3b; and level 2 of this FST covers levels 5 and 6 of the 1-bit trie. We shall refer to levels $e_u = \sum_{q=0}^u s_q$, $0 \leq u < k$ as the *expansion levels* of O . The expansion levels defined by the FST of Figure 49.4b are 0, 2, and 5.

Let $\text{nodes}(i)$ be the number of nodes at level i of the 1-bit trie O . For the 1-bit trie of Figure 49.3a, $\text{nodes}(0:6) = [1, 1, 2, 2, 2, 1, 1]$. The memory required by F is $\sum_0^{k-1} \text{nodes}(e_q) * 2^{s_q}$. For example, the memory required by the FST of Figure 49.4b is $\text{nodes}(0) * 2^2 + \text{nodes}(2) * 2^3 + \text{nodes}(5) * 2^2 = 24$.

Let $C(j, r)$ be the cost of the best FST that uses *at most* r expansion levels. A simple dynamic programming recurrence for C is [13]:

$$C(j, r) = \min_{m \in \{-1..j-1\}} \{C(m, r-1) + \text{nodes}(m+1) * 2^{j-m}\}, \quad j \geq 0, r > 1 \quad (49.1)$$

$$C(-1, r) = 0 \text{ and } C(j, 1) = 2^{j+1}, \quad j \geq 0 \quad (49.2)$$

Let $M(j, r)$, $r > 1$, be the smallest m that minimizes

$$C(m, r-1) + \text{nodes}(m+1) * 2^{j-m},$$

in Equation 49.1.

Theorem 49.1

(Sahni and Kim [13]) $\forall (j \geq 0, k > 2) [M(j, k) \geq \max\{M(j-1, k), M(j, k-1)\}]$.

Theorem 49.1 results in an algorithm to compute $C(W-1, k)$ in $O(kW^2)$. Using the computed M values, the strides for the OFST that uses at most k expansion levels may be determined in an additional $O(k)$ time. Although the resulting algorithm has the same asymptotic complexity as does the optimization algorithm of Srinivasan and Varghese [7], experiments conducted by Sahni and Kim [13] using real IPv4 prefix-data-sets indicate that the algorithm based on Theorem 49.1 runs 2 to 4 times as fast.

Basu and Narliker [15] consider implementing FST router tables on a pipelined architecture. Each level of the FST is assigned to a unique pipeline stage. The optimization problem to be solved in this application requires an FST that has a number of levels no more than the number of pipeline stages, the memory required per level should not exceed the available per stage memory, and the total memory required is minimum subject to the stated constraints.

49.2.4.3 Variable-Stride Tries

In a *variable-stride trie* (VST) [7], nodes at the same level may have different strides. Figure 49.5 shows a two-level VST for the 1-bit trie of Figure 49.3. The stride for the root is 2; that for the left child of the root is 5; and that for the root's right child is 3. The memory requirement of this VST is 4 (root) + 32 (left child of root) + 8 (right child of root) = 44.

Since FSTs are a special case of VSTs, the memory required by the best VST for a given prefix set P and number of expansion levels k is less than or equal to that required by the best FST for P and k . Despite this, FSTs may be preferred in certain router applications “because of their simplicity and slightly faster search time” [7].

Let r -VST be a VST that has at most r levels. Let $\text{Opt}(N, r)$ be the cost (i.e., memory requirement) of the best r -VST for a 1-bit trie whose root is N . Nilsson and Karlsson [16] propose a greedy heuristic to construct optimal VSTs. The resulting VSTs are known as LC-tries (level-compressed tries) and were first proposed in a more general context by Andersson and Nilsson [17]. An LC-tries obtained from a 1-bit trie by replacing full subtrees of the 1-bit trie by single multibit nodes. This replacement is done by examining the 1-bit trie top to bottom (i.e., from root to leaves). Srinivasan and Varghese [7], have obtained the following dynamic programming recurrence for $\text{Opt}(N, r)$.

$$\text{Opt}(N, r) = \min_{s \in \{1..1+\text{height}(N)\}} \left\{ 2^s + \sum_{M \in D_s(N)} \text{Opt}(M, r-1) \right\}, \quad r > 1 \quad (49.3)$$

where $D_s(N)$ is the set of all descendants of N that are at level s of N . For example, $D_1(N)$ is the set of children of N and $D_2(N)$ is the set of grandchildren of N . $\text{height}(N)$ is the maximum level at which the trie rooted at N has a node. For example, in Figure 49.3b, the height of the trie rooted at N1 is 5. When $r = 1$,

$$\text{Opt}(N, 1) = 2^{1+\text{height}(N)} \quad (49.4)$$

Srinivasan and Varghese [7], describe a way to determine $\text{Opt}(R, k)$ using Equations 49.4 and 49.5. The complexity of their algorithm is $O(p * W * k)$, where p is the number of nodes in the 1-bit trie for the prefixes ($p = O(n)$ for realistic router tables). Sahni and Kim [18] provide an alternative way to compute $\text{Opt}(R, k)$ in $O(pWk)$ time. The algorithm of [18], however, performs fewer operations and has fewer cache misses. When the cost of operations dominates the run time, the algorithm of [18] is

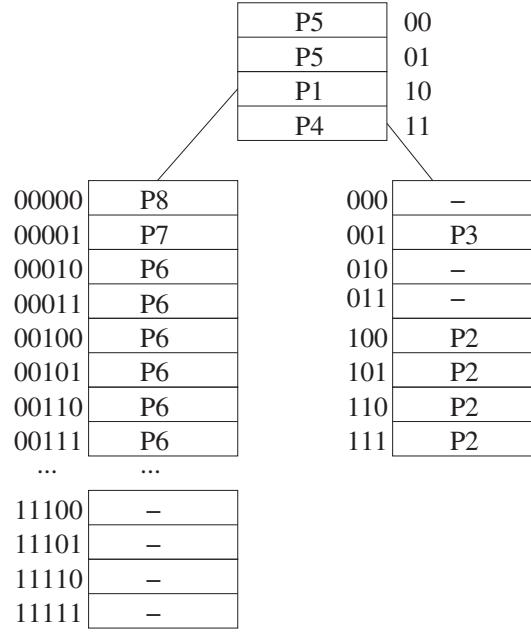

FIGURE 49.5 Two-level VST for prefixes of Figure 49.3a.

expected to be about 6 times as fast as that of [7] (for available router databases). When cache miss time dominates the run time, the algorithm of [18] could be 12 times as fast when $k=2$ and 42 times as fast when $k=7$.

We describe the formulation used in Reference 18. Let

$$Opt(N, s, r) = \sum_{M \in D_s(N)} Opt(M, r), \quad s > 0, \quad r > 1,$$

and let $Opt(N, 0, r) = Opt(N, r)$. From Equations 49.4 and 49.5, it follows that:

$$Opt(N, 0, r) = \min_{s \in \{1 \dots 1 + height(N)\}} \{2^s + Opt(N, s, r - 1)\}, \quad r > 1 \quad (49.5)$$

and

$$Opt(N, 0, 1) = 2^{1 + height(N)}. \quad (49.6)$$

For $s > 0$ and $r > 1$, we get

$$\begin{aligned} Opt(N, s, r) &= \sum_{M \in D_s(N)} Opt(M, r) \\ &= Opt(LeftChild(N), s - 1, r) \\ &\quad + Opt(RightChild(N), s - 1, r). \end{aligned} \quad (49.7)$$

For Equation 49.9, we need the following initial condition:

$$Opt(null, *, *) = 0 \quad (49.8)$$

With the assumption that the number of nodes in the 1-bit trie is $O(n)$, we see that the number of $Opt(*, *, *)$ values is $O(nWk)$. Each $Opt(*, *, *)$ value may be computed in $O(1)$ time using Equations 49.7 through 49.11 provided the Opt values are computed in postorder. Therefore, we may compute $Opt(R, k) = Opt(R, 0, k)$ in $O(pWk)$ time. The algorithm of [18] requires $O(W^2k)$ memory for the $Opt(*, *, *)$ values. To see this, notice that there can be at most $W + 1$ nodes N whose $Opt(N, *, *)$ values must be retained at any given time, and for each of these at most $W + 1$ nodes, $O(Wk)$ $Opt(N, *, *)$ values must be retained. To determine the optimal strides, each node of the 1-bit trie must store the stride s that minimizes the right side of Equation 49.7 for each value of r . For this purpose, each 1-bit trie node needs $O(k)$ space. Since the 1-bit trie has $O(n)$ nodes in practice, the memory requirements of the 1-bit trie are $O(nk)$. The total memory required is, therefore, $O(nk + W^2k)$.

In practice, we may prefer an implementation that uses considerably more memory. If we associate a cost array with each of the p nodes of the 1-bit trie, the memory requirement increases to $O(pWk)$. The advantage of this increased memory implementation is that the optimal strides can be recomputed in $O(W^2k)$ time (rather than $O(pWk)$) following each insert or delete of a prefix. This is so because, the $Opt(N, *, *)$ values need be recomputed only for nodes along the insert/delete path of the 1-bit trie. There are $O(W)$ such nodes.

Faster algorithms to determine optimal 2- and 3-VSTs also are developed in Reference 18.

49.2.5 Binary Search Trees

Sahni and Kim [19] propose the use of a collection of red-black trees (see Chapter 11) to determine $LMP(d)$. The CRBT comprises a front-end data structure that is called the *binary interval tree* (BIT) and a back-end data structure called a *collection of prefix trees* (CPT). For any destination address d , define the *matching basic interval* to be a basic interval with the property that $r_i \leq d \leq r_{i+1}$ (note that some ds have two matching basic intervals).

The BIT is a binary search tree that is used to search for a matching basic interval for d . The BIT comprises internal and external nodes and there is one internal node for each r_i . Since the BIT has q internal nodes, it has $q + 1$ external nodes. The first and last of these, in inorder, have no significance. The remaining $q - 1$ external nodes, in inorder, represent the $q - 1$ basic intervals of the given prefix set. Figure 49.6a gives a possible (we say possible because, any red-black binary search tree organization for the internal nodes will suffice) BIT for our five-prefix example of Figure 49.2a. Internal nodes are shown as rectangles while circles denote external nodes. Every external node has three pointers: *startPointer*, *finishPointer*, and *basicIntervalPointer*. For an external node that represents the basic interval $[r_i, r_{i+1}]$, *startPointer* (*finishPointer*) points to the header node of the prefix tree (in the back-end structure) for the prefix (if any) whose range start and finish points are r_i (r_{i+1}). Note that only prefixes whose length is W can have this property. *basicIntervalPointer* points to a prefix node in a prefix tree of the back-end structure. In Figure 49.6a, the labels in the external (circular) nodes identify the represented basic interval. The external node with $r1$ in it, for example, has a *basicIntervalPointer* to the rectangular node labeled $r1$ in the prefix tree of Figure 49.6b.

For each prefix and basic interval, x , define $next(x)$ to be the smallest range prefix (i.e., the longest prefix) whose range includes the range of x . For the example of Figure 49.2a, the $next()$ values for the basic intervals $r1$ through $r7$ are, respectively, $P1, P2, P1, P3, P4, P1$, and $P1$. Notice that the next value for the range $[r_i, r_{i+1}]$ is the same as the “ $>$ ” value for r_i in Figure 49.2b, $1 \leq i < q$. The $next()$ values for the nontrivial prefixes $P1$ through $P4$ of Figure 49.2a are, respectively, “-”, $P1, P1$, and $P3$.

The back-end structure, which is a collection of prefix trees (CPT), has one prefix tree for each of the prefixes in the router table. Each prefix tree is a red-black tree. The prefix tree for prefix P comprises a header node plus one node, called a *prefix node*, for every nontrivial prefix or basic interval x such that $next(x) = P$. The header node identifies the prefix P for which this is the prefix tree. The prefix trees for each of the five prefixes of Figure 49.2a are shown in Figure 49.6b–f. Notice that prefix trees do

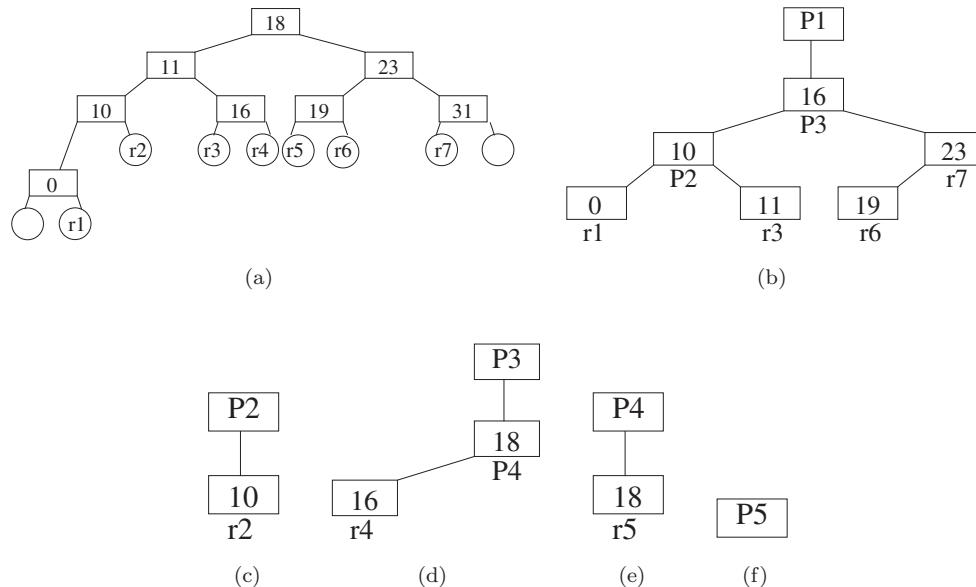

FIGURE 49.6 CBST for Figure 49.2a. (a) base interval tree (b) prefix tree for $P1$ (c) prefix tree for $P2$ (d) prefix tree for $P3$ (e) prefix tree for $P4$ (f) prefix tree for $P5$.

not have external nodes and that the prefix nodes of a prefix tree store the start point of the range or prefix represented by that prefix node. In the figures, the start points of the basic intervals and prefixes are shown inside the prefix nodes while the basic interval or prefix name is shown outside the node.

The search for $LMP(d)$ begins with a search of the BIT for the matching basic interval for d . Suppose that external node Q of the BIT represents this matching basic interval. When the destination address equals the left (right) end-point of the matching basic interval and $startPointer$ ($finishPointer$) is not null, $LMP(d)$ is pointed to by $startPointer$ ($finishPointer$). Otherwise, the back-end CPT is searched for $LMP(d)$. The search of the back-end structure begins at the node $Q.basicIntervalPointer$. By following parent pointers from $Q.basicIntervalPointer$, we reach the header node of the prefix tree that corresponds to $LMP(d)$.

When a CRBT is used, $LMP(d)$ may be found in $O(\log n)$ time. Inserts and deletes also take $O(\log n)$ time when a CRBT is used. In Reference 20, Sahni and Kim propose an alternative BIT structure (ABIT) that has internal nodes only. Although the ABIT structure increases the memory requirements of the router table, the time to search, insert, and delete is reduced by a constant factor [20]. Suri et al. [21] have proposed a B-tree data structure for dynamic router tables. Using their structure, we may find the longest matching prefix in $O(\log n)$ time. However, inserts/deletes take $O(W \log n)$ time. The number of cache misses is $O(\log n)$ for each operation. When W bits fit in $O(1)$ words (as is the case for IPv4 and IPv6 prefixes) logical operations on W -bit vectors can be done in $O(1)$ time each. In this case, the scheme of [21] takes $O(\log W * \log n)$ time for an insert and $O(W + \log n) = O(W)$ time for a delete. An alternative B-tree router-table design has been proposed by Lu and Sahni [22]. Although the asymptotic complexity of each of the router-table operations is the same using either B-tree router-table design, the design of Lu and Sahni [22] has fewer cache misses for inserts and deletes; the number of cache misses when searching for $lmp(d)$ is the same using either design. Consequently, inserts and deletes are faster when the design of Lu and Sahni [22] is used.

Several researchers ([20,23–25], for example), have investigated router table data structures that account for bias in access patterns. Gupta, Prabhakar, and Boyd [25], for example, propose the use of ranges. They assume that access frequencies for the ranges are known, and they construct a bounded-height binary search tree of ranges. This binary search tree accounts for the known range access frequencies to obtain near-optimal IP lookup. Although the scheme of [25] performs IP lookup in near-optimal time, changes in the access frequencies, or the insertion or removal of a prefix require us to reconstruct the data structure, a task that takes $O(n \log n)$ time.

Ergun et al. [24] use ranges to develop a biased skip list structure that performs longest prefix-matching in $O(\log n)$ expected time. Their scheme is designed to give good expected performance for bursty^{*} access patterns.^{*}The biased skip list scheme of Ergun et al. [24] permits inserts and deletes in $O(\log n)$ time only in the severely restricted and impractical situation when all prefixes in the router table are of the same length. For the more general, and practical, case when the router table comprises prefixes of different length, their scheme takes $O(n)$ expected time for each insert and delete. Sahni and Kim [20] extend the biased skip lists of Ergun et al. [24] to obtain a biased skip lists structure in which longest prefix-matching as well as inserts and deletes take $O(\log n)$ expected time. They also propose a splay tree scheme (see Chapter 13) for bursty access patterns. In this scheme, longest prefix-matching, insert and delete have an $O(\log n)$ amortized complexity.

49.2.6 Priority Search Trees

A priority-search tree (PST) [28] (see Chapter 19) is a data structure that is used to represent a set of tuples of the form $(key1, key2, data)$, where $key1 \geq 0$, $key2 \geq 0$, and no two tuples have the same $key1$ value. The data structure is simultaneously a min-tree on $key2$ (i.e., the $key2$ value in each node of the tree is \leq the $key2$ value in each descendant node) and a search tree on $key1$. There are two common PST representations [28]:

1. In a **radix priority-search tree** (RPST), the underlying tree is a binary radix tree on $key1$.
2. In a **red-black priority-search tree** (RBPST), the underlying tree is a red-black tree.

McCreight [28] has suggested a PST representation of a collection of ranges with distinct finish points. This representation uses the following mapping of a range r into a PST tuple:

$$(key1, key2, data) = (finish(r), start(r), data) \quad (49.9)$$

where $data$ is any information (e.g., next hop) associated with the range. Each range r is, therefore mapped to a point $map1(r) = (x, y) = (key1, key2) = (finish(r), start(r))$ in 2-dimensional space.

Let $ranges(d)$ be the set of ranges that match d . McCreight [28] has observed that when the mapping of Equation 49.12 is used to obtain a point set $P = map1(R)$ from a range set R , then $ranges(d)$ is given by the points that lie in the rectangle (including

^{*} In a *bursty* access pattern the number of different destination addresses in any subsequence of q packets is $< q$. That is, if the destination of the current packet is d , there is a high probability that d is also the destination for one or more of the next few packets. The fact that Internet packets tend to be bursty has been noted in References 26 and 27, for example.

TABLE 49.1 Time Complexity of Data Structures for Longest Matching-Prefix

BSLPT	$O(\log n)$ expected	$O(\log n)$ expected
CST	$O(\log n)$ amortized	$O(\log n)$ amortized
PST	$O(\log n)$	$O(\log n)$

points on the boundary) defined by $x_{left} = d$, $x_{right} = \infty$, $y_{top} = d$, and $y_{bottom} = 0$. These points are obtained using the method $\text{enumerateRectangle}(x_{left}, x_{right}, y_{top}) = \text{enumerateRectangle}(d, \infty, d)$ of a PST (y_{bottom} is implicit and is always 0).

When an RPST is used to represent the point set P , the complexity of

$$\text{enumerateRectangle}(x_{left}, x_{right}, y_{top})$$

is $O(\log \max X + s)$, where $\max X$ is the largest x value in P and s is the number of points in the query rectangle. When the point set is represented as an RBPST, this complexity becomes $O(\log n + s)$, where $n = |P|$. A point (x, y) (and hence a range $[y, x]$) may be inserted into or deleted from an RPST (RBPST) in $O(\log \max X)$ ($O(\log n)$) time [28].

Let R be a set of prefix ranges. For simplicity, assume that R includes the range that corresponds to the prefix $*$. With this assumption, $LMP(d)$ is defined for every d . One may verify that $LMP(d)$ is the prefix whose range is

$$[\maxStart(ranges(d)), \minFinish(ranges(d))].$$

Lu and Sahni [29] show that R must contain such range. To find this range easily, we first transform $P = \text{map1}(R)$ into a point set $\text{transform1}(P)$ so that no two points of $\text{transform1}(P)$ have the same x -value. Then, we represent $\text{transform1}(P)$ as a PST. For every $(x, y) \in P$, define $\text{transform1}(x, y) = (x', y') = (2^W x - y + 2^W - 1, y)$. Then, $\text{transform1}(P) = \{\text{transform1}(x, y) | (x, y) \in P\}$.

We see that $0 \leq x' < 2^{2W}$ for every $(x', y') \in \text{transform1}(P)$ and that no two points in $\text{transform1}(P)$ have the same x' -value. Let $PST1(P)$ be the PST for $\text{transform1}(P)$. The operation

$$\text{enumerateRectangle}(2^W d - d + 2^W - 1, \infty, d)$$

performed on $PST1$ yields $ranges(d)$. To find $LMP(d)$, we employ the

$$\minXinRectangle(x_{left}, x_{right}, y_{top})$$

operation, which determines the point in the defined rectangle that has the least x -value. It is easy to see that

$$\minXinRectangle(2^W d - d + 2^W - 1, \infty, d)$$

performed on $PST1$ yields $LMP(d)$.

To insert the prefix whose range is $[u, v]$, we insert $\text{transform1}(\text{map1}([u, v]))$ into $PST1$. In case this prefix is already in $PST1$, we simply update the next-hop information for this prefix. To delete the prefix whose range is $[u, v]$, we delete $\text{transform1}(\text{map1}([u, v]))$ from $PST1$. When deleting a prefix, we must take care not to delete the prefix $*$. Requests to delete this prefix should simply result in setting the next-hop associated with this prefix to \emptyset .

Since, \minXinRectangle , insert, and delete each take $O(W)$ ($O(\log n)$) time when $PST1$ is an RPST (RBPST), $PST1$ provides a router-table representation in which longest-prefix matching, prefix insertion, and prefix deletion can be done in $O(W)$ time each when an RPST is used and in $O(\log n)$ time each when an RBPST is used.

Tables 49.1 and 49.2 summarize the performance characteristics of various data structures for the longest matching-prefix problem.

TABLE 49.2 Memory Complexity of Data Structures for Longest Matching-Prefix

Data Structure	Memory Usage

CST	$O(n)$
PST	$O(n)$

49.3 Highest-Priority Matching

The trie data structure may be used to represent a dynamic prefix-router-table in which the highest-priority tie-breaker is in use. Using such a structure, each of the dynamic router-table operations may be performed in $O(W)$ time. Lu and Sahni [30] have developed the binary tree on binary tree (BOB) data structure for highest-priority dynamic router-tables. Using BOB, a lookup takes $O(\log^2 n)$ time and cache misses; a new rule may be inserted and an old one deleted in $O(\log n)$ time and cache misses. Although BOB handles filters that are non-intersecting ranges, specialized versions of BOB have been proposed for prefix filters. Using the data structure PBOB (prefix BOB), a lookup, rule insertion and deletion each take $O(W)$ time and cache misses. The data structure LMPBOB (longest matching-prefix BOB) is proposed in Reference 30 for dynamic prefix-router-tables that use the longest matching-prefix rule. Using LMPBOB, the longest matching-prefix may be found in $O(W)$ time and $O(\log n)$ cache misses; rule insertion and deletion each take $O(\log n)$ time and cache misses. On practical rule tables, BOB and PBOB perform each of the three dynamic-table operations in $O(\log n)$ time and with $O(\log n)$ cache misses. Other data structures for maximum-priority matching are developed in References 31 and 32.

49.3.1 The Data Structure BOB

The data structure binary tree on binary tree (BOB) comprises a single balanced binary search tree at the top level. This top-level balanced binary search tree is called the point search tree (PTST). For an n -rule NHRT, the PTST has at most $2n$ nodes (we call this the PTST **size constraint**). With each node z of the PTST, we associate a point, $\text{point}(z)$. The PTST is a standard red-black binary search tree (actually, any binary search tree structure that supports efficient search, insert, and delete may be used) on the $\text{point}(z)$ values of its node set [1]. That is, for every node z of the PTST, nodes in the left subtree of z have smaller point values than $\text{point}(z)$, and nodes in the right subtree of z have larger point values than $\text{point}(z)$.

Let R be the set of nonintersecting ranges. Each range of R is stored in exactly one of the nodes of the PTST. More specifically, the root of the PTST stores all ranges $r \in R$ such that $\text{start}(r) \leq \text{point}(\text{root}) \leq \text{finish}(r)$; all ranges $r \in R$ such that $\text{finish}(r) < \text{point}(\text{root})$ are stored in the left subtree of the root; all ranges $r \in R$ such that $\text{point}(\text{root}) < \text{start}(r)$ (i.e., the remaining ranges of R) are stored in the right subtree of the root. The ranges allocated to the left and right subtrees of the root are allocated to nodes in these subtrees using the just stated **range allocation rule** recursively.

For the range allocation rule to successfully allocate all $r \in R$ to exactly one node of the PTST, the PTST must have at least one node z for which $\text{start}(r) \leq \text{point}(z) \leq \text{finish}(r)$. Figure 49.7 gives an example set of nonintersecting ranges and a possible PTST for this set of ranges (we say possible, because we haven't specified how to select the $\text{point}(z)$ values and even with specified $\text{point}(z)$ values, the corresponding red-black tree isn't unique). The number inside each node is $\text{point}(z)$, and outside each node, we give $\text{ranges}(z)$.

Let $\text{ranges}(z)$ be the subset of ranges of R allocated to node z of the PTST.* Since the PTST may have as many as $2n$ nodes and since each range of R is in exactly one of the sets $\text{ranges}(z)$, some of the $\text{ranges}(z)$ sets may be empty.

The ranges in $\text{ranges}(z)$ may be ordered using the $<$ relation for non-intersecting ranges.[†] Using this $<$ relation, we put the ranges of $\text{ranges}(z)$ into a red-black tree (any balanced binary search tree structure that supports efficient search, insert,

* We have overloaded the function ranges . When u is a node, $\text{ranges}(u)$ refers to the ranges stored in node u of a PTST; when u is a destination address, $\text{ranges}(u)$ refers to the ranges that match u .

[†] Let r and s be two ranges. $r < s \iff \text{start}(r) < \text{start}(s) \vee (\text{start}(r) = \text{start}(s) \wedge \text{finish}(r) > \text{finish}(s))$.

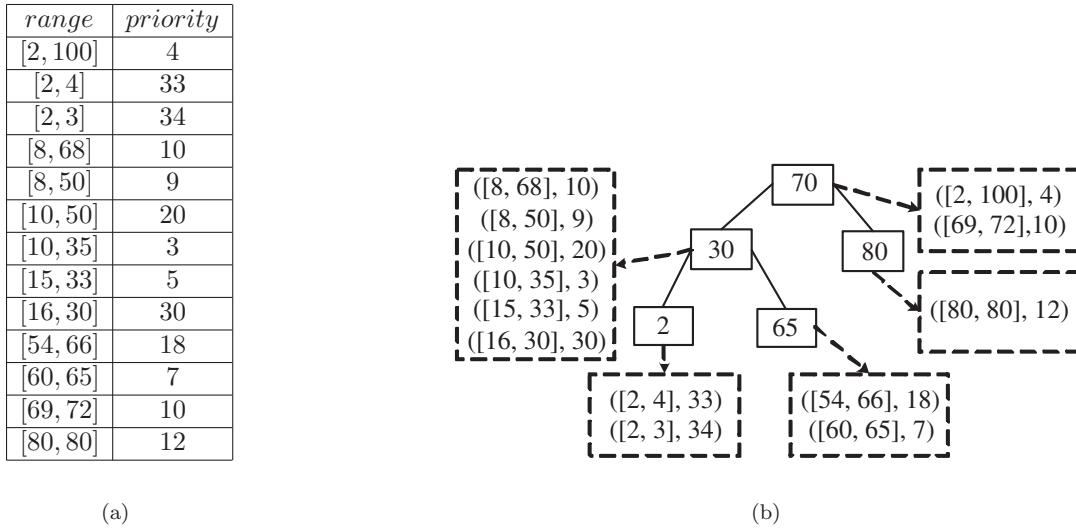

FIGURE 49.7 (a) A nonintersecting range set and (b) A possible PTST.

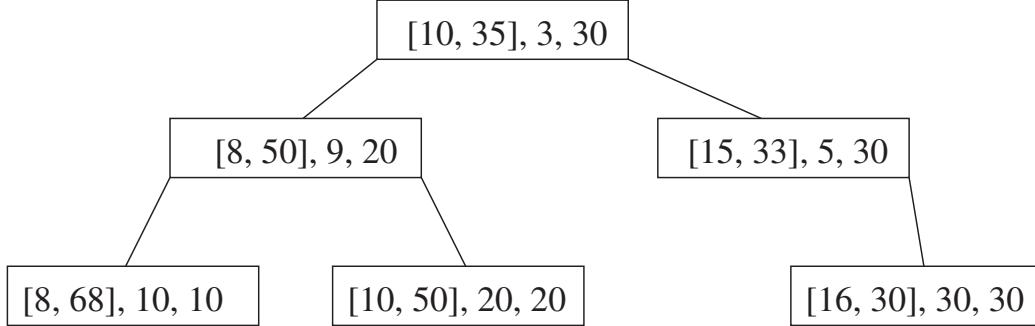

FIGURE 49.8 An example RST for $\text{ranges}(30)$ of Figure 49.7b. Each node shows $(\text{range}(x), p(x), mp(x))$.

delete, join, and split may be used) called the range search-tree or $RST(z)$. Each node x of $RST(z)$ stores exactly one range of $\text{ranges}(z)$. We refer to this range as $\text{range}(x)$. Every node y in the left (right) subtree of node x of $RST(z)$ has $\text{range}(y) < \text{range}(x)$ ($\text{range}(y) > \text{range}(x)$). In addition, each node x stores the quantity $mp(x)$, which is the maximum of the priorities of the ranges associated with the nodes in the subtree rooted at x . $mp(x)$ may be defined recursively as below.

$$mp(x) = \begin{cases} p(x) & \text{if } x \text{ is leaf} \\ \max \{mp(\text{leftChild}(x)), mp(\text{rightChild}(x)), p(x)\} & \text{otherwise} \end{cases}$$

where $p(x) = \text{priority}(\text{range}(x))$. Figure 49.8 gives a possible RST structure for $\text{ranges}(30)$ of Figure 49.7b.

Lemma 49.1

(Lu and Sahni [30]) Let z be a node in a PTST and let x be a node in $RST(z)$. Let $st(x) = \text{start}(\text{range}(x))$ and $fn(x) = \text{finish}(\text{range}(x))$.

1. For every node y in the right subtree of x , $st(y) \geq st(x)$ and $fn(y) \leq fn(x)$.
2. For every node y in the left subtree of x , $st(y) \leq st(x)$ and $fn(y) \geq fn(x)$.

Both BOB and BOT (the binary tree on trie structure of Gupta and McKeown [32]) use a range allocation rule identical to that used in an interval tree [33] (See Chapter 19). While BOT may be used with any set of ranges, BOB applies only to a set of non-intersecting ranges. However, BOB reduces the search complexity of BOT from $O(W \log n)$ to $O(\log^2 n)$ and reduces the update complexity from $O(W)$ to $O(\log n)$.

49.3.2 Search for the Highest-Priority Matching Range

The highest-priority range that matches the destination address d may be found by following a path from the root of the PTST toward a leaf of the PTST. Figure 49.9 gives the algorithm. For simplicity, this algorithm finds $hp = priority(hpr(d))$ rather than $hpr(d)$. The algorithm is easily modified to return $hpr(d)$ instead.

We begin by initializing $hp = -1$ and z is set to the root of the PTST. This initialization assumes that all priorities are ≥ 0 . The variable z is used to follow a path from the root toward a leaf. When $d > point(z)$, d may be matched only by ranges in $RST(z)$ and those in the right subtree of z . The method $RST(z) \rightarrow hpRight(d, hp)$ (Figure 49.10) updates hp to reflect any matching ranges in $RST(z)$. This method makes use of the fact that $d > point(z)$. Consider a node x of $RST(z)$. If $d > fn(x)$, then d is to the right (i.e., $d > finish(range(x))$) of $range(x)$ and also to the right of all ranges in the right subtree of x . Hence, we may proceed to examine the ranges in the left subtree of x . When $d \leq fn(x)$, $range(x)$ as well as all ranges in the left subtree of x match d . Additional matching ranges may be present in the right subtree of x . $hpLeft(d, hp)$ is the analogous method for the case when $d < point(z)$.

Complexity The complexity of the invocation $RST(z) \rightarrow hpRight(d, hp)$ is readily seen to be $O(height(RST(z))) = O(\log n)$. Consequently, the complexity of $hp(d)$ is $O(\log^2 n)$. To determine $hpr(d)$ we need only add code to the methods $hp(d)$, $hpRight(d, hp)$, and $hpLeft(d, hp)$ so as to keep track of the range whose priority is the current value of hp . So, $hpr(d)$ may be found in $O(\log^2 n)$ time also.

The details of the insert and delete operation as well of the BOB variants PBOB and LMPBOB may be found in Reference 30.

```
Algorithm hp(d) {
    // return the priority of hpr(d)
    // easily extended to return hpr(d)
    hp = -1; // assuming 0 is the smallest priority value
    z = root; // root of PTST
    while (z != null) {
        if (d > point(z)) {
            RST(z)→hpRight(d, hp);
            z = rightChild(z);
        }
        else if (d < point(z)) {
            RST(z)→hpLeft(d, hp);
            z = leftChild(z);
        }
        else // d == point(z)
            return max{hp, mp(RST(z)→root)};
    }
    return hp;
}
```

FIGURE 49.9 Algorithm to find $priority(hpr(d))$.

```
Algorithm hpRight(d, hp) {
    // update hp to account for any ranges in RST(z) that match d
    // d > point(z)
    x = root; // root of RST(z)
    while (x != null)
        if (d > fn(x))
            x = leftChild(x);
        else {
            hp = max{hp, p(x), mp(leftChild(x))};
            x = rightChild(x);
        }
}
```

FIGURE 49.10 Algorithm $hpRight(d, hp)$.

49.4 Most-Specific-Range Matching

Let $msr(d)$ be the most-specific range that matches the destination address d . For static tables, we may simply represent the n ranges by the up to $2n - 1$ basic intervals they induce. For each basic interval, we determine the most-specific range that matches all points in the interval. These up to $2n - 1$ basic intervals may then be represented as up to $4n - 2$ prefixes [31] with the property that $msr(d)$ is uniquely determined by $LMP(d)$. Now, we may use any of the earlier discussed data structures for static tables in which the filters are prefixes. In this section, therefore, we discuss only those data structures that are suitable for dynamic tables.

49.4.1 Nonintersecting Ranges

Let R be a set of nonintersecting ranges. For simplicity, assume that R includes the range z that matches all destination addresses ($z = [0, 2^{32} - 1]$ in the case of IPv4). With this assumption, $msr(d)$ is defined for every d . Similar to the case of prefixes, for nonintersecting ranges, $msr(d)$ is the range $[maxStart(ranges(d)), minFinish(ranges(d))]$ (Lu and Sahni [29] show that R must contain such a range). We may use

$$PST1(transform1(map1(R)))$$

to find $msr(d)$ using the same method described in Section 49.2.6 to find $LMP(d)$.

Insertion of a range r is to be permitted only if r does not intersect any of the ranges of R . Once we have verified this, we can insert r into $PST1$ as described in Section 49.2.6. Range intersection may be verified by noting that there are two cases for range intersection. When inserting $r = [u, v]$, we need to determine if $\exists s = [x, y] \in R [u < x \leq v < y \vee x < u \leq y < v]$. We see that $\exists s \in R [x < u \leq y < v]$ iff $map1(R)$ has at least one point in the rectangle defined by $x_{left} = u$, $x_{right} = v - 1$, and $y_{top} = u - 1$ (recall that $y_{bottom} = 0$ by default). Hence, $\exists s \in R [x < u \leq y < v]$ iff $minXinRectangle(2^W u - (u - 1) + 2^W - 1, 2^W(v - 1) + 2^W - 1, u - 1)$ exists in $PST1$.

To verify $\exists s \in R [u < x \leq v < y]$, map the ranges of R into 2-dimensional points using the mapping, $map2(r) = (start(r), 2^W - 1 - finish(r))$. Call the resulting set of mapped points $map2(R)$. We see that $\exists s \in R [u < x \leq v < y]$ iff $map2(R)$ has at least one point in the rectangle defined by $x_{left} = u + 1$, $x_{right} = v$, and $y_{top} = (2^W - 1) - v - 1$. To verify this, we maintain a second PST, $PST2$ of points in $transform2(map2(R))$, where $transform2(x, y) = (2^W x + y, y)$. Hence, $\exists s \in R [u < x \leq v < y]$ iff $minXinRectangle(2^W(u + 1), 2^Wv + (2^W - 1) - v - 1, (2^W - 1) - v - 1)$ exists.

To delete a range r , we must delete r from both $PST1$ and $PST2$. Deletion of a range from a PST is similar to deletion of a prefix as discussed in Section 49.2.6.

The complexity of the operations to find $msr(d)$, insert a range, and delete a range are the same as that for these operations for the case when R is a set of ranges that correspond to prefixes.

49.4.2 Conflict-Free Ranges

The range set R has a **conflict** iff there exists a destination address d for which $ranges(d) \neq \emptyset \wedge msr(d) = \emptyset$. R is **conflict free** iff it has no conflict. Notice that sets of prefix ranges and sets of nonintersecting ranges are conflict free. The two-PST data structure of Section 49.4.1 may be extended to the general case when R is an arbitrary conflict-free range set. Once again, we assume that R includes the range z that matches all destination addresses. $PST1$ and $PST2$ are defined for the range set R as in Sections 49.2.6 and 49.4.1.

Lu and Sahni [29] have shown that when R is conflict free, $msr(d)$ is the range

$$[maxStart(ranges(d)), minFinish(ranges(d))]$$

Hence, $msr(d)$ may be obtained by performing the operation

$$minXinRectangle(2^W d - d + 2^W - 1, \infty, d)$$

on $PST1$. Insertion and deletion are complicated by the need to verify that the addition or deletion of a range to/from a conflict-free range set leaves behind a conflict-free range set. To perform this check efficiently, Lu and Sahni [29] augment $PST1$ and $PST2$ with a representation for the chains in the normalized range-set, $norm(R)$, that corresponds to R . This requires the use of several red-black trees. The reader is referred to [29] for a description of this augmentation.

The overall complexity of the augmented data structure of [29] is $O(\log n)$ for each operation when $RPSTs$ are used for $PST1$ and $PST2$. When $RPSTs$ are used, the search complexity is $O(W)$ and the insert and delete complexity is $O(W + \log n) = O(W)$.

50.1 Introduction

[Chapter 49](#) discussed algorithms for 1-d packet classification. In this chapter we consider multi-dimensional classification in detail. First we discuss the motivation and then the algorithms for multi-dimensional classification. As we will see, packet classification on multiple fields is in general a difficult problem. Hence, researchers have proposed a variety of algorithms which, broadly speaking, can be categorized as “basic search algorithms”, geometric algorithms, heuristic algorithms, or hardware-specific search algorithms. In this chapter, we will describe algorithms that are representative of each category, and discuss which type of algorithm might be suitable for different applications.

Until recently, Internet routers provided only “best-effort” service, servicing packets in a first-come-first-served manner. Routers are now called upon to provide different qualities of service to different applications which means routers need new mechanisms such as admission control, resource reservation, per-flow queueing, and fair scheduling. All of these mechanisms require the router to distinguish packets belonging to different flows.

Flows are specified by *rules* applied to incoming packets. We call a collection of rules a *classifier*. Each rule specifies a flow that a packet may belong to based on some criteria applied to the packet header, as shown in [Figure 50.1](#). To illustrate the variety of classifiers, consider some examples of how packet classification can be used by an ISP to provide different services. [Figure 50.2](#) shows *ISP*₁ connected to three different sites: enterprise networks *E*₁ and *E*₂ and a Network Access Point[‡] (NAP), which is in turn connected to *ISP*₂ and *ISP*₃. *ISP*₁ provides a number of different services to its customers, as shown in [Table 50.1](#).

[Table 50.2](#) shows the flows that an incoming packet must be classified into by the router at interface X. Note that the flows specified may or may not be mutually exclusive. For example, the first and second flows in [Table 50.2](#) overlap. This is common in practice, and when no explicit priorities are specified, we follow the convention that rules closer to the top of the list take priority (referred to as the “*First matching rule in table*” tie-breaker rule in [Chapter 49](#)).

50.1.1 Problem Statement

Each rule of a classifier has *d* components. $R[i]$ is the *i*th component of rule *R*, and is a regular expression on the *i*th field of the packet header. A packet *P* is said to match rule *R*, if $\forall i$, the *i*th field of the header of *P* satisfies the regular expression $R[i]$. In practice, a rule component is not a general regular expression but is often limited by syntax to a simple address/mask or

‡ A network access point is a network site which acts as an exchange point for Internet traffic. ISPs connect to the NAP to exchange traffic with other ISPs.

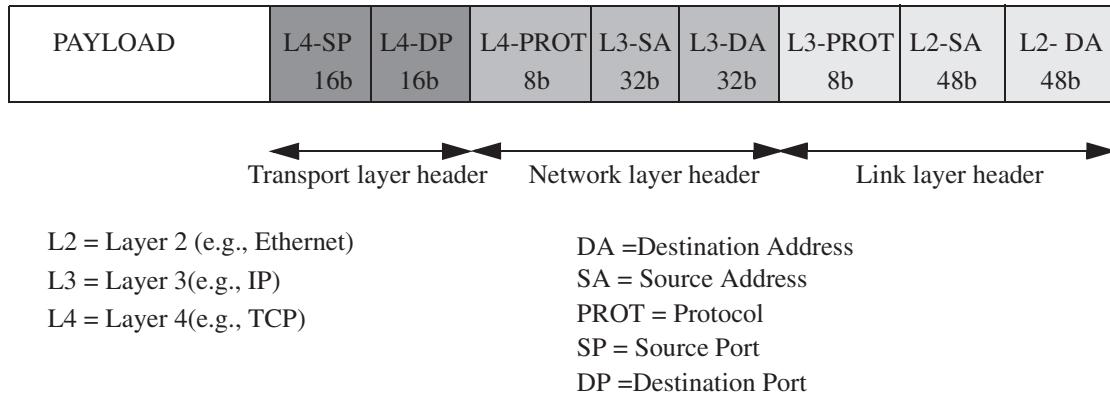

FIGURE 50.1 This figure shows some of the header fields (and their widths) that might be used for classifying the packet. Although not shown in this figure, higher layer (e.g., application-level) headers may also be used.

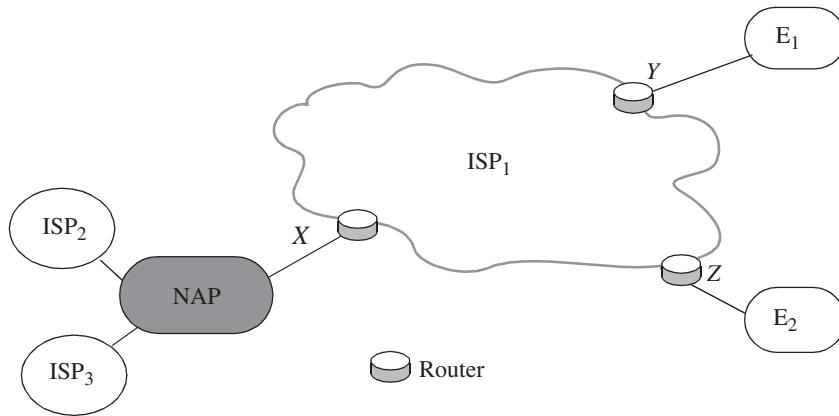

FIGURE 50.2 Example network of an ISP (ISP_1) connected to two enterprise networks (E_1 and E_2) and to two other ISP networks across a network access point (NAP).

TABLE 50.1 Examples of Services Enabled by Packet Classification

Service	Example
Packet Filtering	Deny all traffic from ISP_3 (on interface X) destined to E_2 .
Policy Routing	Send all voice-over-IP traffic arriving from E_1 (on interface Y) and destined to E_2 via a separate ATM network.
Accounting & Billing	Treat all video traffic to E_1 (via interface Y) as highest priority and perform accounting for the traffic sent this way.
Traffic Rate Limiting	Ensure that ISP_2 does not inject more than 10 Mbps of email traffic and 50 Mbps of total traffic on interface X.
Traffic Shaping	Ensure that no more than 50 Mbps of web traffic is injected into ISP_2 on interface X.

operator/number(s) specification. In an address/mask specification, a 0 (respectively 1) at bit position x in the mask denotes that the corresponding bit in the address is a don't care (respectively significant) bit. Examples of operator/number(s) specifications are *eq* 1232 and *range* 34–9339. Note that a prefix can be specified as an address/mask pair where the mask is contiguous — i.e., all bits with value 1 appear to the left of bits with value 0 in the mask. It can also be specified as a range of width equal to 2^t where $t = 32 - \text{prefixlength}$. Most commonly occurring specifications can be represented by ranges. An example real-life classifier in four dimensions is shown in Table 50.3. By convention, the first rule R1 is of highest priority and rule R7 is of lowest priority. Some example classification results are shown in Table 50.4

Longest prefix matching for routing lookups is a special-case of one-dimensional packet classification. All packets destined to the set of addresses described by a common prefix may be considered to be part of the same flow. The address of the next hop where the packet should be forwarded to is the associated action. The length of the prefix defines the priority of the rule.

50.2 Performance Metrics for Classification Algorithms

1. *Search speed*—Faster links require faster classification. For example, links running at 10Gbps can bring 31.25 million packets per second (assuming minimum sized 40 byte TCP/IP packets).
2. *Low storage requirements*—Small storage requirements enable the use of fast memory technologies like SRAM (Static Random Access Memory). SRAM can be used as an on-chip cache by a software algorithm and as on-chip SRAM for a hardware algorithm.
3. *Ability to handle large real-life classifiers*.
4. *Fast updates*—As the classifier changes, the data structure needs to be updated. We can categorize data structures into those which can add or delete entries incrementally, and those which need to be reconstructed from scratch each time the classifier changes. When the data structure is reconstructed from scratch, we call it “pre-processing”. The update rate differs among different applications: a very low update rate may be sufficient in firewalls where entries are added manually or infrequently, whereas a router with per-flow queues may require very frequent updates.
5. *Scalability in the number of header fields used for classification*.
6. *Flexibility in specification*—A classification algorithm should support general rules, including prefixes, operators (range, less than, greater than, equal to, etc.) and wildcards. In some applications, non-contiguous masks may be required.

50.3 Classification Algorithms

50.3.1 Background

For the next few sections, we will use the example classifier in [Table 50.5](#) repeatedly. The classifier has six rules in two fields labeled F1 and F2; each specification is a prefix of maximum length 3 bits. We will refer to the classifier as $C = \{R_j\}$ and each rule R_j as a 2-tuple: $\langle R_{j1}, R_{j2} \rangle$.

TABLE 50.5 Example 2-Dimensional Classifier

Rule	F1	F2
R_1	00*	00*
R_2	0*	01*
R_3	1*	0*
R_4	00*	0*
R_5	0*	1*
R_6	*	1*

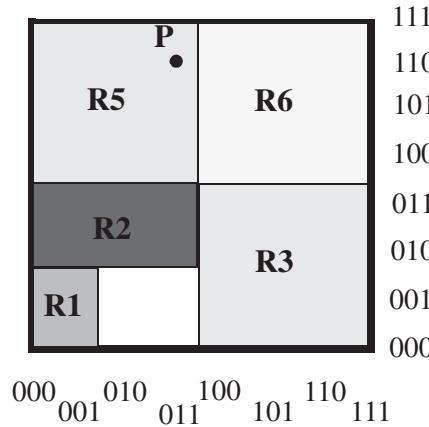

FIGURE 50.3 Geometric representation of the classifier in [Table 50.5](#). A packet represents a point, for instance $P(011, 110)$ in two-dimensional space. Note that R_4 is hidden by R_1 and R_2 .

50.3.1.1 Bounds from Computational Geometry

There is a simple geometric interpretation of packet classification. While a prefix represents a contiguous interval on the number line, a two-dimensional rule represents a rectangle in two-dimensional Euclidean space, and a rule in d dimensions represents a d -dimensional hyper-rectangle. A classifier is therefore a collection of prioritized hyper-rectangles, and a packet header represents a point in d dimensions. For example, [Figure 50.3](#) shows the classifier in [Table 50.5](#) geometrically in which high priority rules overlay lower priority rules. Classifying a packet is equivalent to finding the highest priority rectangle that contains the point representing the packet. For example, point $P(011, 110)$ in [Figure 3](#) would be classified by rule R_5 .

There are several standard geometry problems such as *ray shooting*, *point location* and *rectangle enclosure* that resemble packet classification. Point location involves finding the enclosing region of a point, given a set of non-overlapping regions. The best bounds for point location in N rectangular regions and $d > 3$ dimensions are $O(\log N)$ time with $O(N^d)$ space;^{*} or $O((\log N)^{d-1})$ time with $O(N)$ space [1,2]. In packet classification, hyper-rectangles can overlap, making classification at least as hard as point location. Hence, a solution is either impractically large (with 100 rules and 4 fields, N^d space is about 100MBytes) or too slow ($(\log N)^{d-1}$ is about 350 memory accesses).

We can conclude that: (1) Multi-field classification is considerably more complex than one-dimensional longest prefix matching, and (2) Complexity may require that practical solutions use heuristics.

50.3.1.2 Range Lookups

Packet classification is made yet more complex by the need to match on ranges as well as prefixes. The cases of looking up static arbitrary ranges, and dynamic *conflict-free* ranges in one dimension have been discussed in [Chapter 49](#). One simple way to handle dynamic arbitrary (overlapping) ranges is to convert each W -bit range to a set of $2W - 2$ prefixes (see [Table 50.6](#)) and then use any of the longest prefix matching algorithms detailed in [Chapter 49](#), thus resulting in $O(NW)$ prefixes for a set consisting of N ranges.

^{*} The time bound for $d \leq 3$ is $O(\log \log N)$ [1] but has large constant factors.

TABLE 50.6 Example 4-Bit Ranges and Their Constituent Prefixes

Range	Constituent Prefixes
[4, 7]	01**
[3, 8]	0011,01**,1000
[1, 14]	0001,001*,01**,10**,110*,1110

TABLE 50.7 Categories (not Non-overlapping) of Classification Algorithms

Category	Algorithms
Basic data structures	Linear search, caching, hierarchical tries, set-pruning tries
Geometry-based	Grid-of-tries, AQT, FIS
Heuristic	RFC, hierarchical cuttings, tuple-space search
Hardware	Ternary CAM, bitmap-intersection (and variants)

50.3.2 Taxonomy of Classification Algorithms

The classification algorithms we will describe here can be categorized into the four classes shown in [Table 50.7](#).

We now proceed to describe representative algorithms from each class.

50.3.3 Basic Data Structures

50.3.3.1 Linear Search

The simplest data structure is a linked-list of rules stored in order of decreasing priority. A packet is compared with each rule sequentially until a rule is found that matches all relevant fields. While simple and storage-efficient, this algorithm clearly has poor scaling properties; the time to classify a packet grows linearly with the number of rules.

50.3.3.2 Hierarchical Tries

A d -dimensional hierarchical radix trie is a simple extension of the one dimensional radix trie data structure, and is constructed recursively as follows. If d is greater than 1, we first construct a 1-dimensional trie, called the $F1$ -trie, on the set of prefixes $\{R_{j1}\}$, belonging to dimension $F1$ of all rules in the classifier, $C = \{R_j\} = \{< R_{j1}, R_{j2}, \dots, R_{jd} >\}$. For each prefix, p , in the $F1$ -trie, we recursively construct a $(d - 1)$ -dimensional hierarchical trie, T_p , on those rules which specify exactly p in dimension $F1$, i.e., on the set of rules $\{R_j : R_{j1} = p\}$. Prefix p is linked to the trie T_p using a next-trie pointer. The storage complexity of the data structure for an N -rule classifier is $O(NdW)$. The data structure for the classifier in [Table 50.5](#) is shown in [Figure 50.4](#). Hierarchical tries are sometimes called “multi-level tries,” “backtracking-search tries,” or “trie-of-tries”.

Classification of an incoming packet (v_1, v_2, \dots, v_d) proceeds as follows. The query algorithm first traverses the $F1$ -trie based on the bits in v_1 . At each $F1$ -trie node encountered, the algorithm follows the next-trie pointer (if present) and traverses the $(d - 1)$ -dimensional trie. The query time complexity for d -dimensions is therefore $O(W^d)$. Incremental updates can be carried out similarly in $O(d^2 W)$ time since each component of the updated rule is stored in exactly one location at maximum depth $O(dW)$.

50.3.3.3 Set-Pruning Tries

A set-pruning trie data structure [3] is similar, but with reduced query time obtained by replicating rules to eliminate recursive traversals. The data structure for the classifier in [Table 50.5](#) is shown in [Figure 50.5](#). The query algorithm for an incoming packet (v_1, v_2, \dots, v_d) need only traverse the $F1$ -trie to find the longest matching prefix of v_1 , follow its next-trie pointer (if present), traverse the $F2$ -trie to find the longest matching prefix of v_1 , and so on for all dimensions. The rules are replicated to ensure that every matching rule will be encountered in the path. The query time is reduced to $O(dW)$ at the expense of increased storage of $O(N^d dW)$ since a rule may need to be replicated $O(N^d)$ times. Update complexity is $O(N^d)$, and hence, this data structure works only for relatively static classifiers.

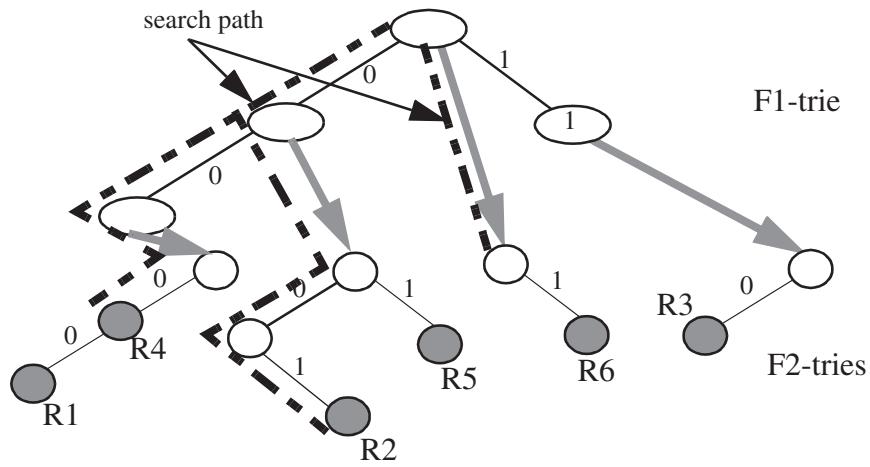

FIGURE 50.4 A hierarchical trie data structure. The gray pointers are the “next-trie” pointers. The path traversed by the query algorithm on an incoming packet (000, 010) is shown.

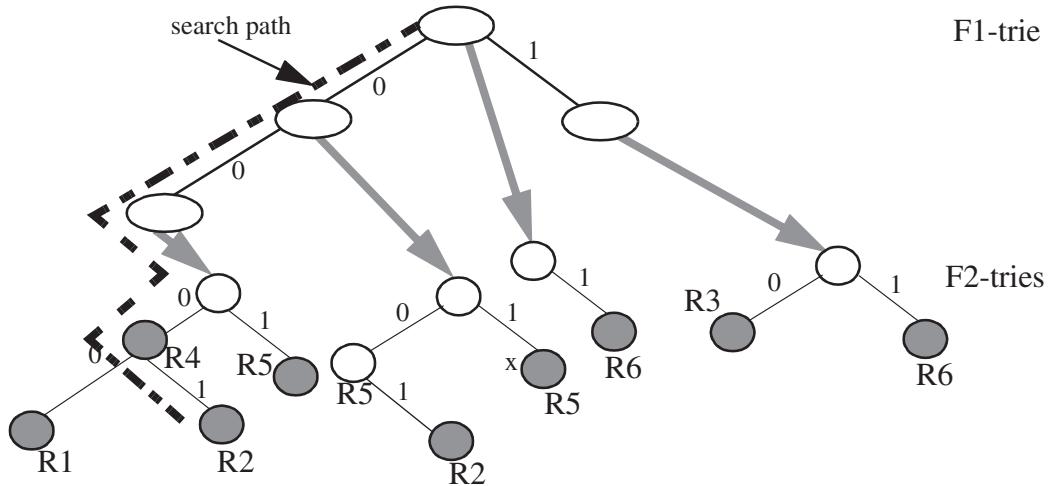

FIGURE 50.5 A set-pruning trie data structure. The gray pointers are the “next-trie” pointers. The path traversed by the query algorithm on an incoming packet (000, 010) is shown.

50.3.4 Geometric Algorithms

50.3.4.1 Grid-of-Tries

The grid-of-tries data structure, proposed by Srinivasan et al. [4] for 2-dimensional classification, reduces storage space by allocating a rule to only one trie node as in a hierarchical trie, and yet achieves $O(W)$ query time by pre-computing and storing a *switch pointer* in some trie nodes. A switch pointer is labeled with “0” or “1” and guides the search process. The conditions which must simultaneously be satisfied for a switch pointer labeled b ($b = '0'$ or “1”) to exist from a node w in the trie T_w to a node x of another trie T_x are (see Figure 50.6):

1. T_x and T_w are distinct tries built on the prefix components of dimension $F2$. T_x and T_w are pointed to by two distinct nodes, say r and s respectively of the same trie, T , built on prefix components of dimension $F1$.
2. The bit-string that denotes the path from the root node to node w in trie T_w concatenated with the bit b is identical to the bit-string that denotes the path from the root node to node x in the trie T_x .
3. Node w does not have a child pointer labeled b , and
4. Node s in trie T is the closest ancestor of node r that satisfies the above conditions.

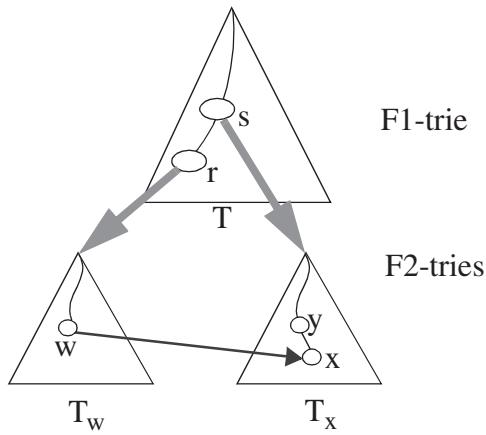

FIGURE 50.6 The conditions under which a switch pointer exists from node w to node x .

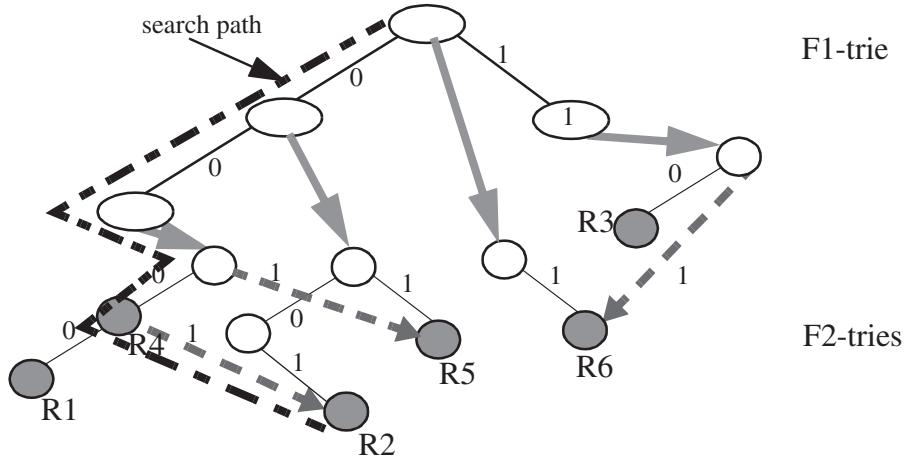

FIGURE 50.7 The grid-of-tries data structure. The switch pointers are shown dashed. The path traversed by the query algorithm on an incoming packet (000, 010) is shown.

If the query algorithm traverses paths $U1(s, \text{root}(T_x), y, x)$ and $U2(r, \text{root}(T_w), w)$ in a hierarchical trie, it need only traverse the path $(s, r, \text{root}(T_w), w, x)$ on a grid-of-tries. This is because paths $U1$ and $U2$ are identical (by condition 2 above) till $U1$ terminates at node w because it has no child branch (by condition 3 above). The switch pointer eliminates the need for backtracking in a hierarchical trie without the storage overhead of a set-pruning trie. Each bit of the packet header is examined at most once, so the time complexity reduces to $O(W)$, while storage complexity $O(NW)$ is the same as a 2-dimensional hierarchical trie. However, the presence of switch pointers makes incremental updates difficult, so the authors recommend rebuilding the data structure (in time $O(NW)$) for each update. An example of the grid-of-tries data structure is shown in Figure 50.7.

Reference 4 reports 2MBytes of storage for a 20,000 two-dimensional classifier with destination and source IP prefixes in a maximum of 9 memory accesses.

Grid-of-tries works well for two dimensional classification, and can be used for the last two dimensions of a multi-dimensional hierarchical trie, decreasing the classification time complexity by a factor of W to $O(NW^{d-1})$. As with hierarchical and set-pruning tries, grid-of-tries handles range specifications by splitting into prefixes.

50.3.4.2 Cross-Producting

Cross-producting [4] is suitable for an arbitrary number of dimensions. Packets are classified by composing the results of separate 1-dimensional range lookups for each dimension as explained below.

Constructing the data structure involves computing a set of ranges (basic intervals), G_k , of size $s_k = |G_k|$, projected by rule specifications in each dimension k , $1 \leq k \leq d$. Let r_k^j , $1 \leq j \leq s_k$, denote the j^{th} range in G_k . r_k^j may be encoded simply as j in the k^{th}

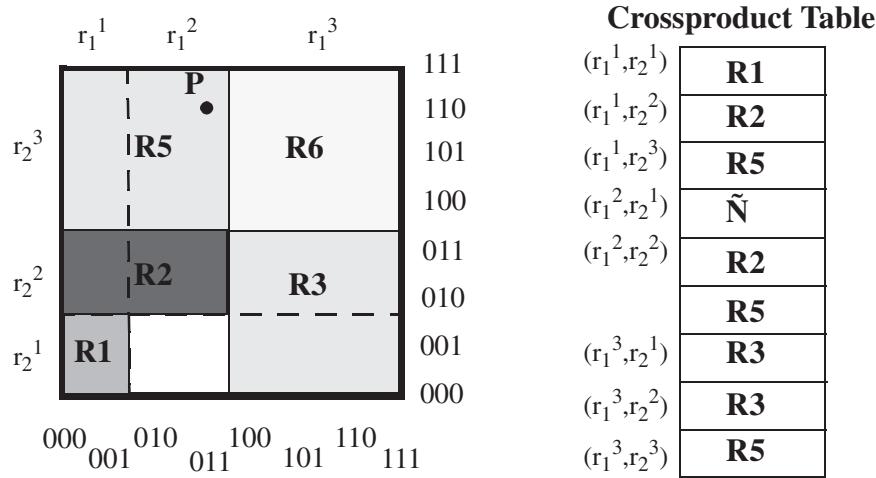

FIGURE 50.8 The table produced by the crossproducing algorithm and its geometric representation.

dimension. A cross-product table C_T of size $\prod_{k=1}^{d-d} s_k$ is constructed, and the best matching rule for each entry $(r_1^{i_1}, r_2^{i_2}, \dots, r_d^{i_d})$, $1 \leq i_k \leq s_k$, $1 \leq k \leq d$ is pre-computed and stored. Classifying a packet (v_1, v_2, \dots, v_d) involves a range lookup in each dimension k to identify the range $r_k^{i_k}$ containing point v_k . The tuple $< r_1^{i_1}, r_2^{i_2}, \dots, r_d^{i_d} >$ (or, if using the above encoding for r_k^j , the tuple $< i_1, i_2, \dots, i_d >$) is then found in the cross-product table C_T which contains the pre-computed best matching rule. Figure 50.8 shows an example.

Given that N prefixes lead to at most $2N - 2$ ranges, $s_k \leq 2N$ and C_T is of size $O(N^d)$. The lookup time is $O(dt_{RL})$ where t_{RL} is the time complexity of finding a range in one dimension. Because of its high worst case storage complexity, cross-producing is suitable only for very small classifiers. Reference [4] proposes using an on-demand cross-producing scheme together with caching for classifiers bigger than 50 rules in five dimensions. Updates require reconstruction of the cross-product table, and so cross-producing is suitable for relatively static classifiers.

50.3.4.3 A 2-Dimensional Classification Scheme [5]

Lakshman and Stiliadis [5] propose a 2-dimensional classification algorithm where one dimension, say $F1$, is restricted to have prefix specifications while the second dimension, $F2$, is allowed to have arbitrary range specifications. The data structure first builds a trie on the prefixes of dimension $F1$, and then associates a set G_w of non-overlapping ranges to each trie node, w , that represents prefix p . These ranges are created by (possibly overlapping) projections on dimension $F2$ of those rules, S_w , that specify exactly p in dimension $F1$. A range lookup data structure (e.g., an array or a binary search tree) is then constructed on G_w and associated with trie node w . An example is shown in Figure 50.9.

Searching for point $P(v_1, v_2)$ involves a range lookup in data structure G_w for each trie node, w , encountered. The search in G_w returns the range containing v_2 , and hence the best matching rule. The highest priority rule is selected from the rules $\{R_w\}$ for all trie nodes encountered during the traversal.

The storage complexity is $O(NW)$ because each rule is stored only once in the data structure. Queries take $O(W \log N)$ time because an $O(\log N)$ range lookup is performed for every node encountered in the $F1$ -trie. This can be reduced to $O(W + \log N)$ using fractional cascading [6], but that makes incremental updates impractical.

50.3.4.4 Area-Based Quadtree

The Area-based Quadtree (AQT) was proposed by Buddhikot et al. [7] for two-dimensional classification. AQT allows incremental updates whose complexity can be traded off with query time by a tunable parameter. Each node of a quadtree [6] represents a two dimensional space that is decomposed into four equal sized quadrants, each of which is represented by a child node. The initial two dimensional space is recursively decomposed into four equal-sized quadrants till each quadrant has at most one rule in it (Figure 50.10 shows an example of the decomposition). Rules are allocated to each node as follows. A rule is said to cross a quadrant if it completely spans at least one dimension of the quadrant. For instance, rule R6 spans the quadrant represented by the root node in Figure 50.10, while R5 does not. If we divide the 2-dimensional space into four quadrants, rule R5 crosses the north-west quadrant while rule R3 crosses the south-west quadrant. We call the set of rules crossing the quadrant represented by a node in dimension k , the k -crossing filter set (k -CFS) of that node.

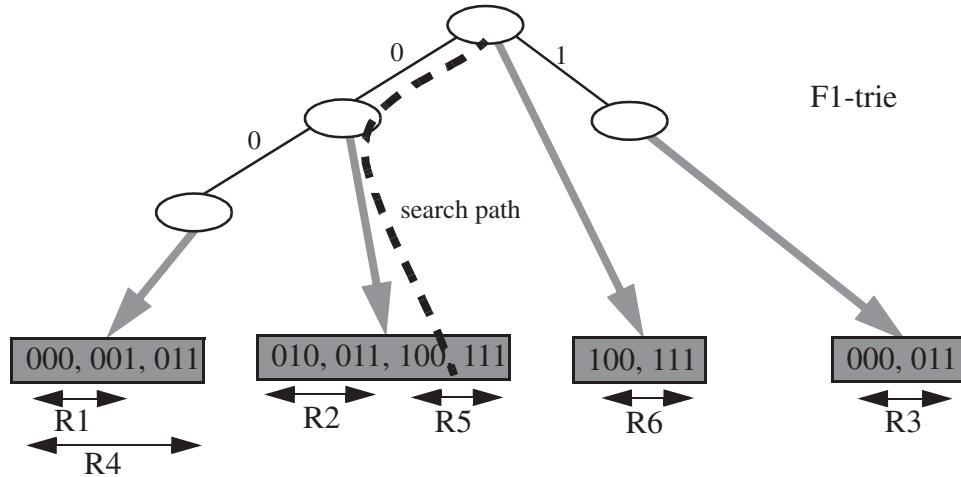

FIGURE 50.9 The data structure of [5] for the example classifier of Table 50.5. The search path for example packet P(011, 110) resulting in R5 is also shown.

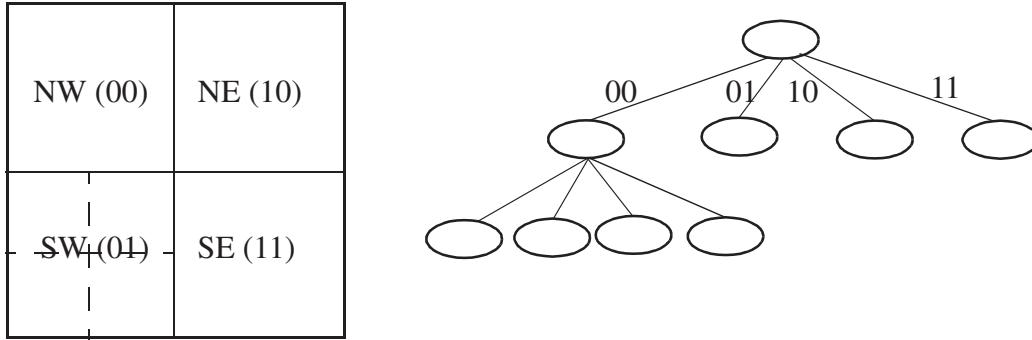

FIGURE 50.10 A quadtree constructed by decomposition of two-dimensional space. Each decomposition results in four quadrants.

Two instances of the same data structure are associated with each quadtree node—each stores the rules in k -CFS ($k = 1, 2$). Since rules in crossing filter sets span at least one dimension, only the range specified in the other dimension need be stored. Queries proceed two bits at a time by transposing one bit from each dimension, with two 1-dimensional lookups being performed (one for each dimension on k -CFS) at each node. Figure 50.11 shows an example.

Reference 7 proposes an efficient update algorithm that, for N two-dimensional rules, has $O(NW)$ space complexity, $O(\alpha W)$ search time and $O(\alpha \sqrt[4]{N})$ update time, where α is a tunable integer parameter.

50.3.4.5 Fat Inverted Segment Tree (FIS-tree)

Feldman and Muthukrishnan [8] propose the Fat Inverted Segment tree (FIS-tree) for two dimensional classification as a modification of a segment tree. A segment tree [6] stores a set S of possibly overlapping line segments to answer queries such as finding the highest priority line segment containing a given point. A segment tree is a balanced binary search tree containing the end points of the line segments in S . Each node, w , represents a range G_w , the leaves represent the original line segments in S , and parent nodes represent the union of the ranges represented by their children. A line segment is allocated to a node w if it contains G_w but not $G_{parent(w)}$. The highest priority line segment allocated to a node is pre-computed and stored at the node. A query traverses the segment tree from the root, calculating the highest priority of all the pre-computed segments encountered. Figure 50.12 shows an example segment tree.

An FIS-tree is a segment tree with two modifications: (1) The segment tree is compressed (made “fat” by increasing the degree to more than two) in order to decrease its depth and occupies a given number of levels l , and (2) Up-pointers from child to parent nodes are used. The data structure for 2-dimensions consists of an FIS-tree on dimension $F1$ and a range lookup data associated with each node. An instance of the range lookup data structure associated with node w of the FIS-tree stores the ranges formed by the $F2$ -projections of those classifier rules whose $F1$ -projections were allocated to w .

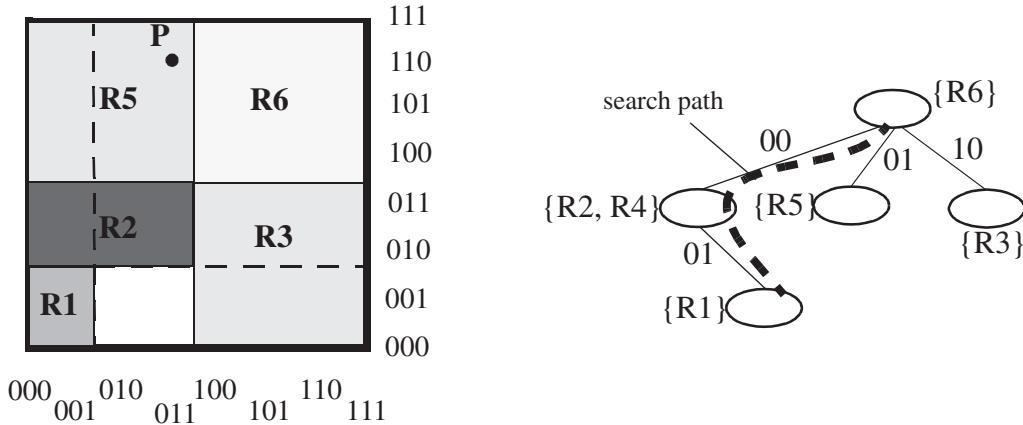

FIGURE 50.11 An AQT data structure. The path traversed by the query algorithm on an incoming packet (000, 010) yields R1 as the best matching rule.

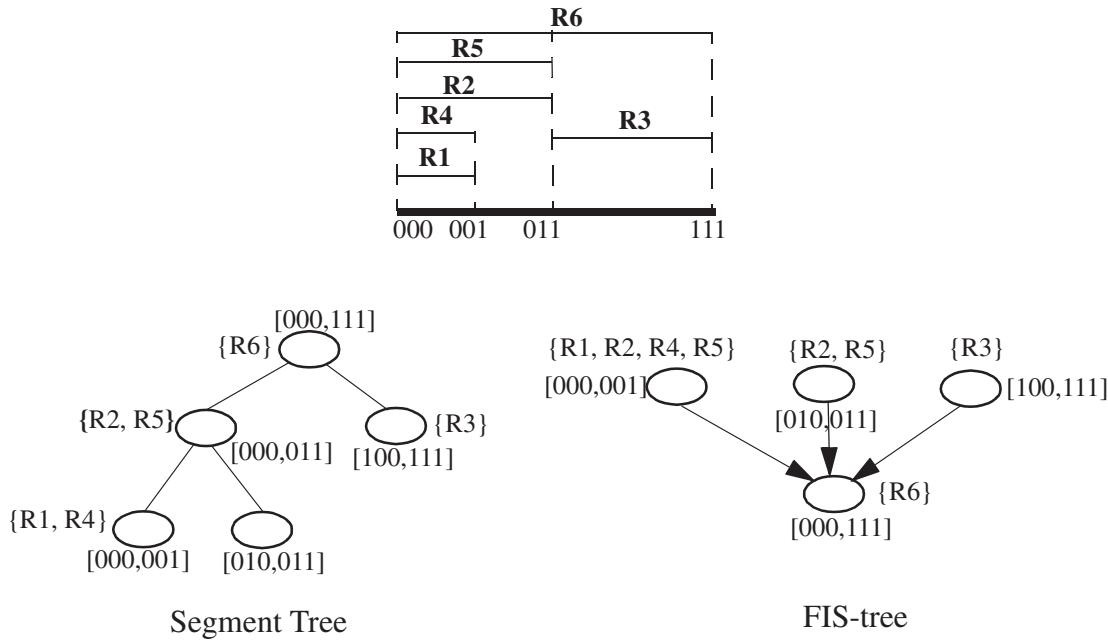

FIGURE 50.12 The segment tree and the 2-level FIS-tree for the classifier of Table 50.5.

A query for point $P(v_1, v_2)$ first solves the range lookup problem on dimension $F1$. This returns a leaf node of the FIS-tree representing the range containing the point v_1 . The query algorithm then follows the up-pointers from this leaf node towards the root node, carrying out 1-dimensional range lookups at each node. The highest priority rule containing the given point is calculated at the end of the traversal.

Queries on an l -level FIS-tree have complexity $O((l+1)t_{RL})$ with storage complexity $O(ln^{1+1/l})$, where t_{RL} is the time for a 1-dimensional range lookup. Storage space can be traded off with search time by varying l . Modifications to the FIS-tree are necessary to support incremental updates—even then, it is easier to support inserts than deletes [8]. The static FIS-tree can be extended to multiple dimensions by building hierarchical FIS-trees, but the bounds are similar to other methods studied earlier [8].

Measurements on real-life 2-dimensional classifiers are reported in Reference 8 using the static FIS-tree data structure. Queries took 15 or fewer memory operations with a two level tree, 4–60 K rules and 5 MBytes of storage. Large classifiers with one million 2-dimensional rules required 3 levels, 18 memory accesses per query and 100MBytes of storage.

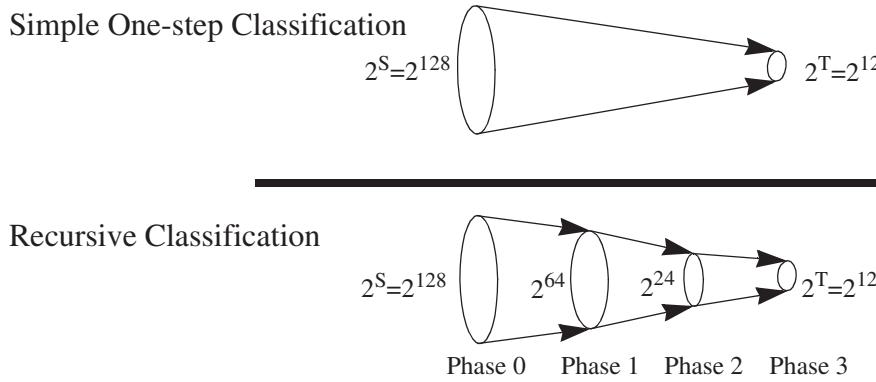

FIGURE 50.13 Showing the basic idea of Recursive Flow Classification. The reduction is carried out in multiple phases, with a reduction in phase I being carried out recursively on the image of the phase $I - 1$. The example shows the mapping of 2^S bits to 2^T bits in three phases.

50.3.4.6 Dynamic Multi-Level Tree Algorithms

Two algorithms, called *Heap-on-Trie* (*HoT*) and *Binarysearchtree-on-Trie* (*BoT*) are introduced in Reference 9 that build a heap and binary search tree respectively on the last dimension, and multi-level tries on all the remaining $d - 1$ dimensions. If $W = O(\log N)$: *HoT* has query complexity $O(\log^d N)$, storage complexity $O(N \log^d N)$, and update complexity $O(\log^{d+1} N)$; and *BoT* has query complexity $O(\log^{d+1} N)$, storage complexity $O(N \log^d N)$, and update complexity $O(\log^d N)$. If $W \neq O(\log N)$, each of the above complexity formulae need to be modified to replace a factor $O(\log^{d-1} N)$ with $O(W^{d-1})$.

50.3.5 Heuristics

As we saw in Section 50.3.1.1, the packet classification problem is expensive to solve in the worst-case—*theoretical bounds state that solutions to multi-field classification either require storage that is geometric, or a number of memory accesses that is poly-logarithmic, in the number of classification rules*. We can expect that classifiers in real networks have considerable structure and redundancy that might be exploited by a heuristic. That is the motivation behind the algorithms described in this section.

50.3.5.1 Recursive Flow Classification (RFC)

RFC [10] is a heuristic for packet classification on multiple fields. Classifying a packet involves mapping S bits in the packet header to a T bit action identifier, where $T = \log N$, $T \ll S$. A simple, but impractical method could pre-compute the action for each of the 2^S different packet headers, yielding the action in one step. RFC attempts to perform the same mapping over several phases, as shown in Figure 50.13; at each stage the algorithm maps one set of values to a smaller set. In each phase a set of memories return a value shorter (i.e., expressed in fewer bits) than the index of the memory access. The algorithm, illustrated in Figure 50.14, operates as follows:

1. In the first phase, d fields of the packet header are split up into multiple chunks that are used to index into multiple memories in parallel. The contents of each memory are chosen so that the result of the lookup is narrower than the index.
2. In subsequent phases, memories are indexed using the results from earlier phases.
3. In the final phase, the memory yields the action.

The algorithm requires construction of the contents of each memory detailed in Reference 10. This paper reports that with real-life four-dimensional classifiers of up to 1700 rules, RFC appears practical for 10Gbps line rates in hardware and 2.5Gbps rates in software. However, the storage space and pre-processing time grow rapidly for classifiers larger than 6000 rules. An optimization described in Reference 10 reduces the storage requirement of a 15,000 four-field classifier to below 4MBytes.

50.3.5.2 Hierarchical Intelligent Cuttings (HiCuts)

HiCuts [11] partitions the multi-dimensional search space guided by heuristics that exploit the structure of the classifier. Each query leads to a leaf node in the HiCuts tree, which stores a small number of rules that can be searched sequentially to find the best match. The characteristics of the decision tree (its depth, degree of each node, and the local search decision to be made at each node) are chosen while pre-processing the classifier based on its characteristics (see Reference 11 for the heuristics used).

Each node, v , of the tree represents a portion of the geometric search space. The root node represents the complete d -dimensional space, which is partitioned into smaller geometric sub-spaces, represented by its child nodes, by cutting across

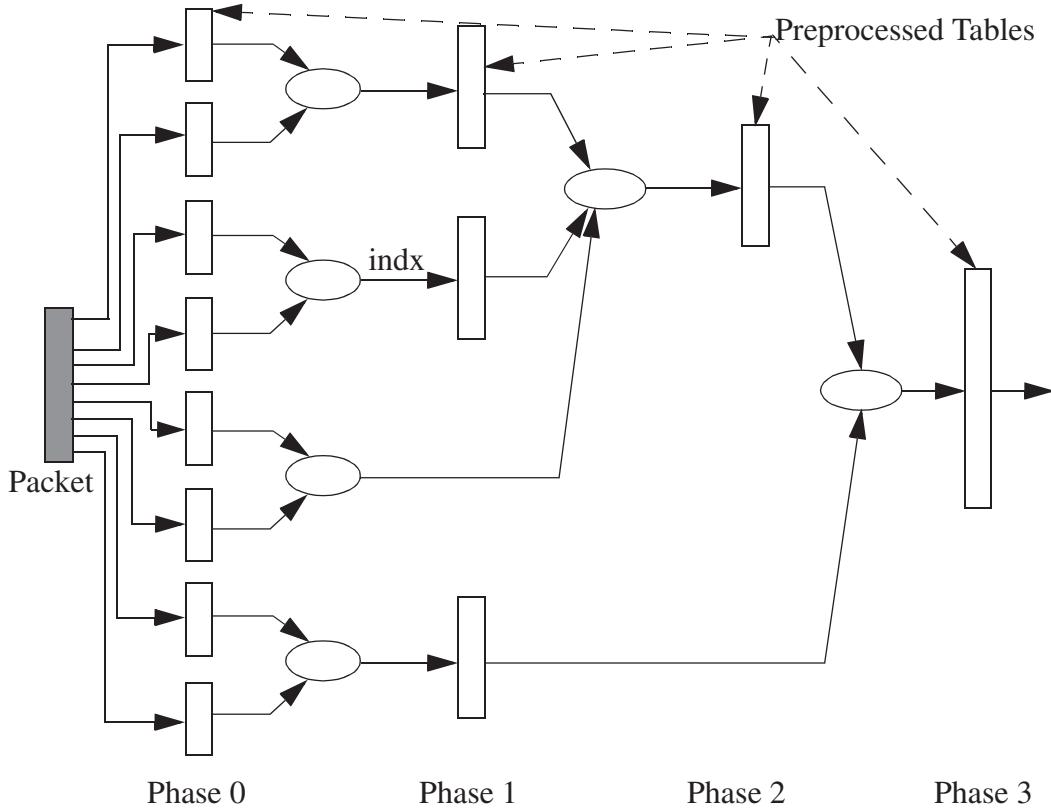

FIGURE 50.14 Packet flow in RFC.

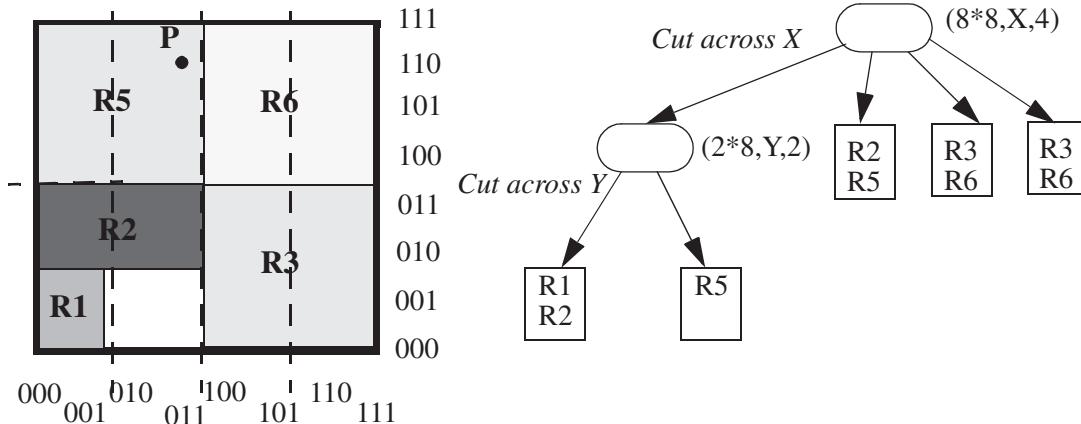

FIGURE 50.15 A possible HiCuts tree for the example classifier in Table 50.5. Each ellipse in the tree denotes an internal node v with a tuple $\langle \text{size of 2-dimensional space represented, dimension to cut across, number of children} \rangle$. Each square is a leaf node which contains the actual classifier rules.

one of the d dimensions. Each sub-space is recursively partitioned until no sub-space has more than B rules, where B is a tunable parameter of the pre-processing algorithm. An example is shown in Figure 50.15 for two dimensions with $B = 2$.

Parameters of the HiCuts algorithm can be tuned to trade-off query time against storage requirements. On 40 real-life four-dimensional classifiers with up to 1,700 rules, HiCuts requires less than 1 MByte of storage with a worst case query time of 20 memory accesses, and supports fast updates.

Rule	Specification	Tuple	Tuple	Hash Table Entries
R1	(00*,00*)	(2,2)	(0,1)	{R6}
R2	(0**,01*)	(1,2)	(1,1)	{R3,R5}
R3	(1**,0**)	(1,1)	(1,2)	{R2}
R4	(00*,0**)	(2,1)	(2,1)	{R4}
R5	(0**,1**)	(1,1)	(2,2)	{R1}
R6	(***,1**)	(0,1)		

FIGURE 50.16 The tuples and associated hash tables in the tuple space search scheme for the example classifier of Table 50.5.

50.3.5.3 Tuple Space Search

The basic tuple space search algorithm [12] decomposes a classification query into a number of exact match queries. The algorithm first maps each d -dimensional rule into a d -tuple whose i^{th} component stores the length of the prefix specified in the i^{th} dimension of the rule (the scheme supports only prefix specifications). Hence, the set of rules mapped to the same tuple are of a fixed and known length, and can be stored in a hash table. Queries perform exact match operations on each of the hash tables corresponding to all possible tuples in the classifier. An example is shown in Figure 50.16.

Query time is M hashed memory accesses, where M is the number of tuples in the classifier. Storage complexity is $O(N)$ since each rule is stored in exactly one hash table. Incremental updates are supported and require just one hashed memory access to the hashed table associated with the tuple of the modified rule. In summary, the tuple space search algorithm performs well for multiple dimensions in the average case if the number of tuples is small. However, the use of hashing makes the time complexity of searches and updates non-deterministic. The number of tuples could be very large, up to $O(W^d)$, in the worst case. Furthermore, since the scheme supports only prefixes, the storage complexity increases by a factor of $O(W^d)$ for generic rules as each range could be split into W prefixes in the manner explained in Section 50.3.1. Of course, the algorithm becomes attractive for real-life classifiers that have a small number of tuples.

50.3.6 Hardware-Based Algorithms

50.3.6.1 Ternary CAMs

A TCAM stores each W -bit field as a $(val, mask)$ pair; where val and $mask$ are each W -bit numbers. A $mask$ of “0” wildcards the corresponding bit position. For example, if $W = 5$, a prefix 10^* will be stored as the pair $(10000, 11000)$. An element matches a given input key by checking if those bits of val for which the $mask$ bit is “1”, match those in the key.

A TCAM is used as shown in Figure 50.17. The TCAM memory array stores rules in decreasing order of priorities, and compares an input key against every element in the array in parallel. The N -bit bit-vector, $matched$, indicates which rules match and so the N -bit priority encoder indicates the address of the highest priority match. The address is used to index into a RAM to find the action associated with this prefix. TCAMs are being increasingly deployed because of their simplicity of use and speed (as they are able to do classification in hardware at the rate of the hardware clock).

Several companies today ship 9Mb TCAMs capable of single and multi-field classification in as little as 10 ns. Both faster and denser TCAMs can be expected in the near future. There are, however, some disadvantages to TCAMs:

1. A TCAM is less dense than a RAM, storing fewer bits in the same chip area. One bit in an SRAM typically requires 4–6 transistors, while one bit in a TCAM requires 11–15 transistors [13]. A 9Mb TCAM running at 100 MHz costs about \$200 today, while the same amount of SRAM costs less than \$10. Furthermore, range specifications need to be split into multiple masks, reducing the number of entries by up to $(2W - 2)^d$ in the worst case. If only two 16-bit dimensions specify ranges, this is a multiplicative factor of 900. Newer TCAMs, based on DRAM technology, have been proposed and promise higher densities.
2. TCAMs dissipate more power than RAM solutions because an address is compared against every TCAM element in parallel. At the time of writing, a 9Mb TCAM chip running at 100 MHz dissipates about 10–15 watts (the exact number varies with manufacturer). In contrast, a similar amount of SRAM running at the same speed dissipates 1W.
3. A TCAM is more unreliable while being in operational use in a router in the field than a RAM, because a *soft-error* (error caused by alpha particles and package impurities that can flip a bit of memory from 0 to 1, or vice-versa) could go undetected for a long amount of time. In a SRAM, only one location is accessed at any time, thus enabling easy on-the-fly error detection and correction. In a TCAM, wrong results could be given out during the time that the error is undetected – which is particularly problematic in such applications as filtering or security.

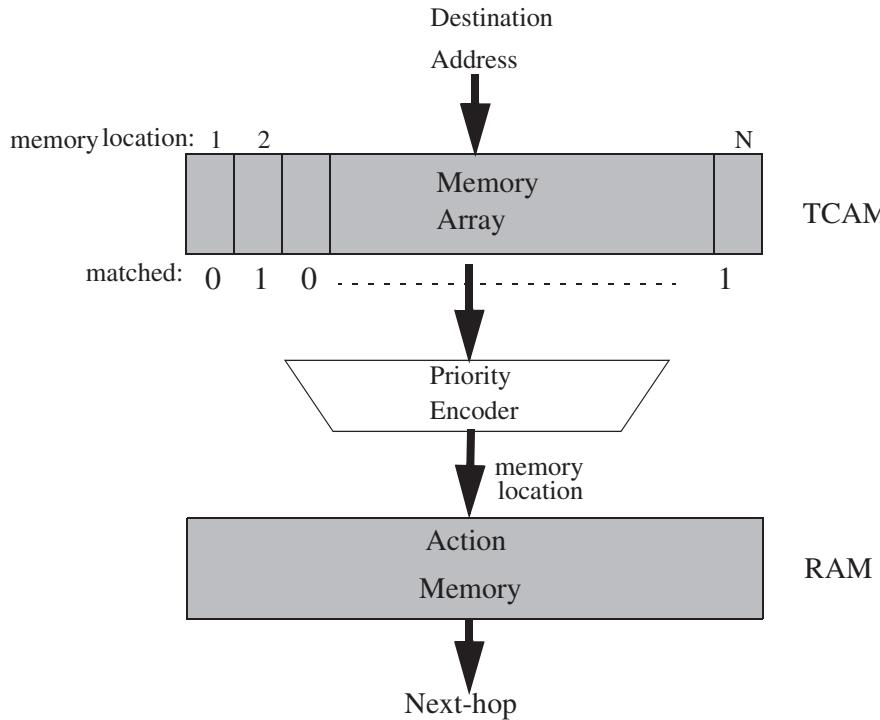

FIGURE 50.17 The classification operation using a ternary CAM. The packet header in this example is assumed to comprise only the destination address.

However, the above disadvantages of a TCAM need to be weighed against its enormous simplicity of use in a hardware platform. Besides, it is the only known “algorithm” that is capable of doing classification at high speeds without explosion in either storage space or time.

Due to their high cost and power dissipation, TCAMs will probably remain unsuitable in the near future for (1) Large classifiers (512K-1M rules) used for microflow recognition at the edge of the network, (2) Large classifiers (256-512 K rules) used at edge routers that manage thousands of subscribers (with a few rules per subscriber). Of course, software-based routers need to look somewhere else.

50.3.6.2 Bitmap-Intersection

The bitmap-intersection classification scheme, proposed in Reference 5, is based on the observation that the set of rules, S , that match a packet is the intersection of d sets, S_i , where S_i is the set of rules that match the packet in the i^{th} dimension alone. While cross-producing pre-computes S and stores the best matching rule in S , this scheme computes S and the best matching rule during each classification operation.

In order to compute intersection of sets in hardware, each set is encoded as an N -bit bitmap where each bit corresponds to a rule. The set of matching rules is the set of rules whose corresponding bits are ‘‘1’’ in the bitmap. A query is similar to cross-producing: First, a range lookup is performed in each of the d dimensions. Each lookup returns a bitmap representing the matching rules (pre-computed for each range) in that dimension. The d sets are intersected (a simple bit-wise AND operation) to give the set of matching rules, from which the best matching rule is found. See Figure 50.18 for an example.

Since each bitmap is N bits wide, and there are $O(N)$ ranges in each of d dimensions, the storage space consumed is $O(dN^2)$. Query time is $O(dt_{RL} + dN/w)$ where t_{RL} is the time to do one range lookup and w is the memory width. Time complexity can be reduced by a factor of d by looking up each dimension independently in parallel. Incremental updates are not supported.

Reference [5] reports that the scheme can support up to 512 rules with a 33 MHz field-programmable gate array and five 1Mbit SRAMs, classifying 1Mpps. The scheme works well for a small number of rules in multiple dimensions, but suffers from a quadratic increase in storage space and linear increase in classification time with the size of the classifier. A variation is described in Reference 5 that decreases storage at the expense of increased query time. This work has been extended significantly by [14] by aggregating bitmaps wherever possible and thus decreasing the time spent in reading the bitmaps. Though the bitmap-intersection scheme is primarily meant for hardware, it is easy to see how it can be used in software, where the aggregated bitmap technique of [14] could be especially useful.

Dimension 1			Dimension 2		
r_1^1	{R1,R2,R4,R5,R6}	110111	r_2^1	{R1,R3,R4}	101100

51.1 Introduction

Current search engines process thousands of queries per second over a collection of billions of web pages with a sub-second average response time. There are two reasons for this astonishing performance: Massive parallelism and a simple yet efficient data structure, called *inverted index*.

In this chapter we will describe inverted indices. The parallelism deployed by search engines is quite straightforward: Given a collection of documents and a user query the goal of information retrieval is to find all documents that are relevant to a user query and return them in decreasing order of relevance. Since on the Web there are often thousands of matches for a given user query, Web search engines usually return just the top 10 results and retrieve more results only upon request. This can be easily parallelized over m machines: Distribute the documents equally over $m - 1$ machines, find the best up to 10 documents for each machine and return them to the machine without documents, which then merges the lists to determine the overall top 10.

Since the users are only presented with the top 10 results they are usually annoyed if these results contain duplicates or near-duplicates. Thus, it is crucial for a search engine to detect near-duplicate web pages. In Section 51.4 we will describe a technique for doing so based on fingerprints, which we will introduce in Section 51.3.

51.2 Inverted Indices

Given a user query consisting of terms t_1, \dots, t_n , a search engine has to find all documents relevant to the query. Usually Web search engines make the following simplifying assumption: A document is relevant only if it contains *all* query terms. To find all these documents the search engine uses the *inverted (file) index data structure*. It consists of two parts:

- A data structure containing every word t that appears in at least one document together with a pointer p_t for each word and potentially a count f_t of the number of documents containing the word; and
- An *inverted list* for every term t that consists of all the documents containing t and is pointed to by p_t .

One popular implementation is to store the sorted list of words in a search tree whose leaves are connected by a linked list. This imposes an order on the words. The inverted lists are implemented as one large (virtual) array such that t 's inverted list consists of all documents between the position in the array pointed to by p_t and by $p_{t'}$, where t' is the term following t in the sorted list. In the web scenario this array does not fit onto a single machine and thus needs to be distributed over multiple machines, either in RAM or on disk.

^{*} This chapter has been reprinted from first edition of this Handbook, without any content updates.

Another implementation would be to store the list of words in any search tree or hash function together with the pointers p_t . A special terminator document id (like 0) is appended to the inverted lists and they can be stored either in one large array or in multiple arrays.

To determine all documents containing the query terms t_1, \dots, t_n (called a *Boolean AND*) the intersection of their inverted lists can be computed by traversing their lists in parallel. If one of the query terms is negated (*Boolean NOT*), i.e. the user does not want this term to be contained in the query, the negation of the corresponding list is used. To speed up the computation in the case that a very frequent term is combined with a very infrequent term the documents in the inverted list are stored in sorted order and a one-level or two-level search tree is stored for each inverted list. The one-level search tree consists of every $1/f$ -th entry entry in the inverted list together with a pointer to the location of this entry in the inverted list, where f is a constant like 100. At query time entries in the inverted list of the frequent term can be skipped quickly to get to the next document that contains the infrequent term. The space requirement is only $1/f$ of the space requirement of the space requirement of the inverted lists.

51.2.1 Index Compression

Of course, data compression is crucial when indexing billions of documents. For that it is usually assumed that the documents are numbered consecutively from 1 to N and that the documents are stored in the inverted list by increasing document id. A simple but powerful technique is called *delta-encoding*: Instead of storing the actual document ids in the inverted list, the document id of the first document is stored together with the difference between the i -th and the $i + 1$ -st document containing the term. When traversing the inverted list the first document id is summed up with delta-values seen so far to get the document id of the current document. Note that delta-encoding does not interfere with the one-level or two-level search tree stored on top of the inverted list. The advantage of delta-encoding is that it turns large integer (document ids) into mostly small integers (the delta values), depending of course on the value of f_t . A variable length encoding scheme, like Golomb codes, of the delta values then leads to considerable space saving. We sketch Golomb codes in the next paragraph. See Reference 1 for more details on variable compression schemes.

There is a trade-off between the space used for the index and the time penalty encountered at query time for decompressing the index. If the index is read from disk, the time to read the appropriate part of the index dominates the compression time and thus more compression can be used. If the index is in RAM, then less compression should be used, except if sophisticated compression is the only way to make the index fit in RAM.

Let n be the number of unique words in all the documents and let f be the number of words in all the documents, including repetitions. Given an integer x it takes at least $\log x$ bits to represent x in binary. However, the algorithm reading the index needs to know how many bits to read. There are these two possibilities: (1) represent x in binary by $\log N$ bits in binary with the top $\log N - \log x$ bits set to 0; or (2) represent x in unary by x 1's followed by a 0. Usually the binary representation is chosen, but the unary representation is more space efficient when $x < \log N$. Golomb codes combine both approaches as follows.

Choose $b \approx 0.69 \frac{N \cdot n}{f}$. The *Golomb code* for an integer $x \geq 1$ consists of two parts:

- A unary encoding of q followed by 0, where $q = \lfloor (x - 1)/b \rfloor$; and
- A binary encoding of the remainder $r = x - qb - 1$. If b is a power of 2, this requires $\log b$ bits.

Note that $\frac{N \cdot n}{f}$ is the average distance between entries in the inverted index, that is, the average value after the delta-encoding. The value of b was chosen to be roughly 69% of the average. Every entry of value b or less requires 1 bit for the unary part and $\log b$ bits for the binary part. This is a considerable space saving over the binary representation since $\log b + 1 < \log N$. As long as $(x - 1)/b < \log N - \log b - 1$, there is a space saving over implementing using the binary encoding. So only entries that are roughly $\log N$ times larger than the average require more space than the average.

If the frequency f_t of a term t is known, then the inverted list of t can be compressed even better using $b_t \approx 0.69 \frac{N}{f_t}$ instead of b . This implies that for frequent terms, b_t is smaller than b and thus fewer bits are used for small integers, which occur frequently in the delta-encoding of frequent terms.

51.2.2 Index Granularity

Another crucial issue is the level of granularity used in the inverted index. So far, we only discussed storing document ids. However to handle some query operators, like quotes, that require the query term to be next to each other in the document, the exact position of the document is needed. There are two possible ways to handle this:

1. One way is to consider all documents to be concatenated into one large document and then store the positions in this large document instead of the document ids. Additionally one special inverted list is constructed that stores the position of the first word of each document. At query time an implicit Boolean AND operation is performed with this special inverted list to determine to which document a given position belongs. Note that the above compression techniques continue to work.

This approach is very space efficient but incurs a run-time overhead at query time for traversing the special inverted list and performing the Boolean AND operation.

2. Another solution is to store (document id, position)-pairs in the inverted list and to delta-encode the document ids and also the position within the same document. This approach uses more space, but does not incur the run-time overhead.

Another data structure that a search engine could use are suffix trees (see [Chapter 30](#)). They require more space and are more complicated, but allow more powerful operations, like searching for syllables or letters.

51.3 Fingerprints

Fingerprints are short strings that represent larger strings and have the following properties:

- If the fingerprints of two strings are different then the strings are guaranteed to be different.
- If the fingerprints of two strings are identical then there is only a small probability that the strings are different.

If two different strings have the same fingerprint, it is called a *collision*. Thus, fingerprints are a type of hash functions where the hash table is populated only very sparsely in exchange for a very low collision probability.

Fingerprints are very useful. For example, search engines can use them to quickly check whether a URL that is contained on a web page is already stored in the index. We will describe how they are useful for finding near-duplicate documents in the next section. One fingerprinting scheme is due to Rabin [\[2\]](#) and is equivalent to cyclic redundancy checks. We follow here the presentation by Broder [\[3\]](#). Let s be a binary string and let $s' = 1s$, i.e. s' equals s prefixed with a 1. The string $s' = (s_1, s_2, \dots, s_m)$ induces a polynomial $S(t)$ over Z_2 as follows:

$$S(t) = s_1 t^{m-1} + s_2 t^{m-2} + \dots + s_m.$$

Let $P(t)$ be an irreducible polynomial of degree k over Z_2 . The fingerprint of s is defined to be the polynomial

$$f(s) = S(t) \bmod P(t)$$

over Z_2 , which can be simply represented as a string of its coefficients. As shown in Reference [3](#) the probability that two distinct strings of length m from a set of n strings have the same fingerprint is less than $nm^2/2^k$. Thus, given n and m the probability of collision can be reduced to the required value simply by increasing k , that is, the length of a fingerprint.

Rabin's fingerprints have the property that given two overlapping strings $s = (s_1, s_2, \dots, s_m)$ and $t = (t_1, t_2, \dots, t_m)$ such that $t_{i+1} = s_i$ for all $1 \leq i < m$ then the fingerprint of t can be computed from the fingerprint of s very efficiently: If

$$f(s) = r_1 t^{k-1} + r_2 t^{k-2} + \dots + r_k,$$

then

$$f(t) = r_2 t^{k-1} + r_3 t^{k-2} + \dots + r_k t + t_m + (r_1 t^k) \bmod P(t).$$

Note that $Q(t) = t^k \bmod P(t)$ is equivalent to $P(t)$ with the leading coefficient removed, which means it can be computed easily. Thus

$$f(t) = r_2 t^{k-1} + r_3 t^{k-2} + \dots + r_k t + t_m + r_1 Q(t).$$

Hence $f(t)$ can be computed from $f(s)$ as follows: Assume $f(s)$ is stored in a shift register and $Q(t)$ is stored in another register. Shift left with t_m as input and if $r_1 = 1$ perform a bit-wise EX-OR operation with $Q(t)$. See [\[3\]](#) for a software implementation for a typical 32-bit word computer.

Other ways of computing fingerprints are cryptographic checksums like Sha-1 or MD5.

51.4 Finding Near-Duplicate Documents

Users of search engines strongly dislike getting near-duplicate results on the same results page. Of course it depends on the user what s/he considers to be near-duplicate. However, most users would agree that pages with the same content except for different ads or a different layout or a different header or footer are near-duplicates. By "near-duplicate" we mean these kinds of "syntactic" duplicates – semantic duplication is even harder detect.

Unfortunately, there are a variety of circumstances that create near-duplicate pages. The main reasons are (1) local copies of public-domain pages (for example the PERL-manual or the preamble of the US constitution) or various databases and (2) multiple visits of the same page by the crawler (the part of the search engine that retrieves web pages to store in the index)

without detection of the replication. The latter can happen because there were small changes to the URL and the content of the page. Usually, crawlers fingerprint the URL as well as the content of the page and thus can easily detect exact duplicates.

There are various approaches to detect near-duplicate pages. One approach that works very well in the Web setting was given by Broder [4] and was validated on the Web [5]. The basic idea is to associate a set of fingerprints with each document such that the similarity of two pages is proportional to the size of the intersection of their respective sets.

We describe first how to compute the fingerprints and show then how they can be used to efficiently detect near-duplicates. The set of fingerprints for a document is computed using the *shingling* technique introduced by Brin et al. [6]. Let a *token* be either a letter, a word, a line, or a sentence in a document. Each document consists of a sequence of tokens. We call a contiguous sequence of q tokens a *q -shingle* of the document. We want to compute fingerprints for all q -shingles in a document. Using Rabin's fingerprints this can be done efficiently if we start from the first shingle and then use a sliding window approach to compute the fingerprint of the shingle currently in the window.

Let S_D be the set of fingerprints generated for document D . The idea is simply to define the similarity or *resemblance* $r(A, B)$ of document A and B as

$$r(A, B) = \frac{|S_A \cap S_B|}{|S_A \cup S_B|}.$$

Experiments have indicated that a resemblance value close to 1 captures well the information notion of “syntactic” near-duplication that we discussed above.

Storing the whole set S_D would take a lot of space. It suffices, however, to keep a fixed number of fingerprints from S_D for each document D . This subset is called a *sketch*. As we will show below the sketches can be computed in time linear in the size of D and will be stored for each document. The resemblance of two documents can be approximated by using the sketches instead of the full sets of fingerprints. Thus, the time is only linear in the size of the sketches.

Sketches are determined as follows: Recall that each fingerprints requires k bits. Thus, $S_D \subseteq \{1, \dots, n\}$, where $n = 2^k$. Let π be a permutation chosen uniformly at random from the set of all permutations of $[n]$. Let $X = \min(\min\{\pi(S_A)\}, \min\{\pi(S_B)\})$.

The crucial observation is that if $\min\{\pi(S_A)\} = \min\{\pi(S_B)\}$, then $X = \min\{\pi(S_A)\}$ must belong to $\pi(S_A) \cap \pi(S_B)$. If $\min\{\pi(S_A)\} \neq \min\{\pi(S_B)\}$, then X belongs to either $\pi(S_A) - \pi(S_B)$ or to $\pi(S_B) - \pi(S_A)$, and, thus, X does not belong to $\pi(S_A) \cap \pi(S_B)$. It follows that $\min\{\pi(S_A)\} = \min\{\pi(S_B)\}$ if and only if X belongs to $\pi(S_A) \cap \pi(S_B)$. Since π was chosen uniformly at random the probability of the latter is

$$\frac{|S_A \cap S_B|}{|S_A \cup S_B|} = r(A, B).$$

It follows that

$$\Pr(\min\{\pi(S_A)\} = \min\{\pi(S_B)\}) = r(A, B).$$

We choose p independent random permutations. For each document the sketch consists of the permuted fingerprint values $\min\{\pi_1(S_D)\}, \min\{\pi_2(S_D)\}, \dots, \min\{\pi_p(S_D)\}$. The resemblance of two documents is then estimated by the intersection of their sketches, whose expected value is proportional to the resemblance.

In practice, π cannot be chosen uniformly at random which led to the study of min-wise independent permutations [7].

To detect the near-duplicates in a set of documents we build for each shingle in a sketch the list of documents to which this shingle belongs. Using this list we generate for each shingle and each pair of document containing this shingle an (document id, document id)-pair. Finally we simply sort these pairs to determine the resemblance for each pair. The running time is proportional to the number of (document id, document id)-pairs. If each shingle only belongs to a constant number of documents, it is linear in the number of unique shingles.

In a web search engine it often suffices to remove the near-duplicates at query time. To do this the sketch is stored with each document. The search engine determines the top 50 or so results and then performs a pair-wise near-duplicate detection with some resemblance threshold, removing the near duplicate results, to determine the top 10 results.

The described near-duplicate detection algorithm assumes that the similarity between documents depends on the size of the overlap in their fingerprint sets. This corresponds to the Jaccard coefficient of similarity used in information retrieval. A more standard approach in information retrieval is to assign a weight vector of terms to each document and to define the similarity of two documents as the cosine of their (potentially normalized) term vectors. Charikar [8] gives an efficient near-duplicate detection algorithm based on this measure. He also presents a near-duplicate detection algorithms for another metric, the Earth Mover Distance.

Other similarity detection mechanisms are given in References 6 and 9–11. Many near-duplicate web pages are created because a whole web host is duplicated. Thus, a large percentage of the near-duplicate web pages can be detected if near-duplicate web hosts can be found. Techniques for this problem are presented in References 12 and 13.

51.5 Conclusions

In this chapter we presented the dominant data structure for web search engines, the inverted index. We also described fingerprints, which are useful at multiple places in a search engine, and document sketches for near-duplicate detection. Other useful data structures for web information retrieval are adjacency lists: All web search engines claim to perform some type of analysis of the hyperlink structure. For this, they need to store the list of incoming links for each document, a use of the classic adjacency list representation.

Web search engines also sometimes analyze the log of the user queries issued at the search engine. With hundreds of millions of queries per day these logs are huge and can only be processed with one-pass data stream algorithms.

52.1 Introduction

The World Wide Web (the Web) was started as an experimental network in 1991. Its growth since then can only be termed explosive. It has several billion pages today and is growing exponentially with time. This growth is totally distributed. There is no central authority to control the growth. The hyperlinks endow the Web with some structure in the sense that viewing the individual web pages as nodes and the hyperlinks as directed edges between them, the Web can be looked upon as a directed graph. What stands out is that this directed graph is not only dynamic—it is rapidly growing and changing—it has been much too large for some time to even have a complete snapshot. Experimental understanding of its structure is based on large but partial web crawls. What properties are being investigated is itself driven by the requirements of the increasingly sophisticated nature of the applications being developed as well as analogies and insights from fields like bibliometrics involving study of citations in academic literature [1].

Let us briefly consider topic search, discussed in detail in Chapter 51, which involves searching for pages on the Web which correspond closely to a given search topic. The seminal work in this area is Kleinberg's HITS algorithm [2] that assumes that for any topic on the Web there are pages which could be considered to be "authoritative" on that topic, and pages which are "hubs" in the sense that they contain links to relevant pages on that topic. Given a collection of pages and links between them, selected by some sampling method as pertaining to the given topic, HITS algorithm ranks the pages by weights which are representative of the quality of the pages as hubs or authorities. These weights are nothing but principal eigen values, and are, in some sense, a "measure" of the "densemess" of the interconnections between the pages. This model of dense interconnection between hubs and authorities of a given topic gave rise to the notion of "cyber communities" in the Web associated with different topics. Underlying this model of cyber communities was the hypothesis that a subgraph representing a Web community would contain "bipartite cores." Bipartite cores, as the name suggests, are complete bipartite graphs corresponding to the hubs and authorities around which the communities are supposed to have developed. Experimental investigations of the structure of the web graph, taking place on the graphs extracted out of the partial crawls, has confirmed much of the above and more. The structural understanding resulting from the experimental investigations has fueled both, theoretical model building which attempts to explain experimentally observed phenomena, and development of new algorithmic techniques that solve traditional problems of search and information retrieval on the web graph in novel ways. Moreover, the reality of the Web as a structure which is too large and continuously changing, makes the standard off-line and on-line models for algorithm design totally inapplicable. Over the last seven-eight years researchers have attempted to grapple with these unique issues of complexity in the study of the Web. Interestingly, contributions to this study of the Web have come not only from computer scientists, but also from physicists who have brought to Web model building techniques from statistical mechanics that have been successful in predicting macro level behavior of a variety of natural phenomenon from millions of its constituent parts. In this chapter an attempt is made to put together what to the author are the main strands of this rapidly evolving model

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

building. The rest of the chapter is organized as follows: Section 2 surveys the experimental observations and reflects what are the major trends in the findings. Section 3 contains the basic theoretical framework developed to explain the experimental findings. Section 4 contains examples of web algorithmics. Section 5 is crystal gazing and reflects what to the author are the grand challenges.

52.2 Experimental Observations

Recent literature contains reports of a number of experiments conducted to investigate topological properties satisfied by the web graph [3–5]. These experiments were conducted over a period of time, and using Web samples of varying sizes. Albert, Jeong and Barabasi [3] used nd.edu subset of the Web. Kumar et al. [5] used a cleaned up version of a 1997 web crawl carried out by Alexa Inc. Broder et al. [4] based their measurements on an Altavista crawl having about 200 million pages and 1.5 billion hyperlinks. The most fundamental observation that emerges from these experiments conducted at different times, focusing on different subparts of the Web, is that the degree distribution of nodes in the web graph follows a power law. The degree distribution is said to satisfy power law if the fraction of nodes of degree x is proportional to $x^{-\alpha}$ for $\alpha > 0$. Power law distribution is observed for both the indegrees and the outdegrees of the web graph. Broder et al. report that for indegrees the power coefficient —indexexperimental observations!indegree distribution $\alpha \approx 2.1$, and for outdegrees $\alpha \approx 2.72$. There is a very close match in literature in the value of α for indegree distribution. For outdegree distribution the value of α reported varies from 2.4 to 2.72 [3].

Broder et al. [4] also analysed the crawl for connectedness. Viewing the web graph as an undirected graph, it was observed that 91% of the nodes were connected to each other and formed a giant connected component. Interestingly, it was found that the distribution of the number of connected components by their sizes also satisfied power law ($\alpha \approx 2.5$). Power law distribution in the sizes of the components was observed even when the graph was viewed as directed. However, the size of the largest strongly connected component (giant SCC) was only 28% of the total web crawl. The giant SCC was reachable from about 22% of the nodes (the set IN). About similar percentage of nodes were reachable from the giant SCC (the set OUT). A significant portion of the rest of the nodes constituted, in Broder et al.'s terminology, "tendrils", nodes reachable from IN or from which the set OUT is reachable. All the experiments done so far point to fractal like self similar nature of the Web in the sense that structure described above is likely to be exhibited in any non-trivial crawl carried out at any time.

Kumar et al. [5] also carried out experiments to measure the number of bipartite cores in the Web. In a cleaned up version of the web graph consisting of 24 million nodes, they reported discovering around 135,000 bipartite cliques $K_{i,j}$ with $i \geq 3$ and $j = 3$. The number of $K_{i,j}$'s with $i, j = 3$ was approximately 90,000, and the numbers dropped exponentially with increase in j . Finding such cliques in the web graph is an algorithmically challenging problem which we will further discuss in the section on Web algorithmics.

Measurements have also been made of the "diameter" of the Web [3,4]. If the Web has the structure as asserted in Reference 4, then the probability of a path existing between any two random vertices is approximately 24%, and the average shortest path length is 16. Albert et al. [3] measured the average shortest path length on a directed graph generated having in and outdegree distribution satisfying the power law coefficients of 2.1 and 2.45 respectively. In a directed graph with 8×10^8 vertices the average shortest path length was determined to be approximately 19, and was a linear function of the logarithm of the number of vertices. The Web, therefore, is considered to exhibit the "small worlds" phenomenon [6].

52.3 Theoretical Growth Models

This fractal like structure of an evolving graph, whose growth processes are so organised that the degree distribution of its vertices satisfy power law, which has a large number of bipartite cliques as subgraphs, and exhibits the small world phenomenon has generated a lot of interest among computer scientists recently. Part of the reason is that the web graph does not belong to the much studied $G_{n,p}$ model which consists of all graphs with n vertices having p as the probability that there is an edge between any two vertices [7]. Graphs in $G_{n,p}$ are essentially sparse and are unlikely to have many bipartite cliques as subgraphs. Moreover, for large n the degree distribution function is Poisson. There is consensus that the primary reason for the web graph to be different from a traditional random graph is that edges in the Web exhibit *preferential attachment*. Hyperlinks from a new web page are more likely to be directed to popular well established website/webpage just as a new manuscript is more likely to cite papers that are already well cited. It is interesting to note that preferential attachment has been used to model evolving phenomena in fields ranging from economics [8], biology [9], to languages [10]. Simon [11] used preferential attachment to explain power law distributions already observed in phenomena like distribution of incomes, distribution of species among genera, distribution of word frequencies in documents etc. A modern exposition of Simon's argument in the framework of its applicability to web graphs is provided by Mitzenmacher [12], and is the basis of Barabasi et al.'s "mean field theory" based model [13], as well as the "rate equation" approach of Krapivsky and Redner [14]. All three use continuous differential equations to model the dynamics

of the evolving web graph. This approach is attractive because of its simplicity and the ease with which it enables one to focus on understanding the issues involved, particularly those relating to power law distributions associated with the Web.

Let us consider the following growth model (we will call this the basic model) which forms the kernel of most of the reported models in literature. At each time step a new node is added to the web graph. This node gets one edge incident at it from one of the existing nodes in the graph, and has one edge pointing out of it. Let us assume that the tail (the node from which the edge emanates) of the edge which is incident at the node just added is chosen uniformly at random from the existing nodes. The head (the node at which the edge is incident) of the edge which emanates from the node just added is chosen with probability proportional to the indegree of the head in keeping with the preferential attachment paradigm that new web pages tend to attach themselves to popular web pages. We assume, to keep matters simple, that whole process starts with a single node with one edge emanating which is incident at the node itself.

Let $I_k(t)$ and $O_k(t)$ denote the number of nodes in the evolved web graph with indegree and outdegree equal to k respectively after t timesteps. $I_k(t)$ and $O_k(t)$ are random variables for all $k, t \geq 1$. We will assume for the purposes of what follows that their expected values are concentrated around their means, and we will use $I_k(t)$ and $O_k(t)$ to denote the expected value also. Note that, at time t , one node and two directed edges are added to the graph. The expected increase in the value of $I_k(t)$ is controlled by two processes. One is the expected increase in the value of $I_{k-1}(t)$, and the other is the expected decrease in the value of $I_k(t)$. The expected increase is $(k-1)I_{k-1}(t)/t$. This is because of our assumption that the probability is proportional to the indegree of the head of the node at which the edge emanating from the node just added is incident and t is the total number of nodes in the graph. Reasoning in the same way we get that the expected decrease is $kI_k(t)/t$. Since this change has taken place over one unit of time we can write

$$\frac{\Delta(I_k(t))}{\Delta(t)} = \frac{(k-1)I_{k-1}(t) - kI_k(t)}{t}$$

or, in the continuous domain

$$\frac{dI_k(t)}{dt} = \frac{(k-1)I_{k-1}(t) - kI_k(t)}{t}. \quad (52.1)$$

We can solve Equation 52.1 for different values of k starting with 1. For $k=1$ we note that the growth process at each time instance introduces a node of indegree 1. Therefore, Equation 52.1 takes the form

$$\frac{dI_1(t)}{dt} = 1 - \frac{I_1(t)}{t}$$

whose solution has the form $I_1(t) = i_1 t$. Substituting this in the above equation we get $i_1 = 1/2$. Working in the same way we can show that $I_2(t) = t/6$. It is not too difficult to see that $I_k(t)$ are a linear function of t . Therefore, substituting $I_k(t) = i_k t$ in Equation 52.1 we get the recurrence equation

$$i_k = \frac{k-1}{k+1} i_{k-1}$$

whose solution is

$$i_k = \frac{1}{k(k+1)}. \quad (52.2)$$

What interpretation do we put to the solution $I_k(t) = i_k t$? It essentially means that in the steady state (i.e., $t \rightarrow \infty$) the number of nodes in the graph with indegree k is proportional to i_k . Equation 52.2 implies $I_k \sim k^{-2}$, i.e. indegree distribution satisfies power law with $\alpha = 2$.

Let us now develop an estimate for O_k . The counterpart of Equation 52.1 in this case is

$$\frac{dO_k(t)}{dt} = \frac{O_{k-1}(t) - O_k(t)}{t}. \quad (52.3)$$

Assuming that in the steady state $O_k(t) = o_k t$, we can show that $o_1 = 1/2$, and for $k > 1$

$$o_k = \frac{o_{k-1}}{2}.$$

This implies $O_k \sim 2^{-k}$. That the outdegree distribution is exponential and not power law should not come as a surprise if we recall that the process that affected outdegree was uniform random and had no component of preferential attachment associated with it.

It would be instructive to note that very simple changes in the growth model affect the degree distribution functions substantially. Consider the following variation on the growth model analysed above. The edge emanating out of the node added does not just attach itself to another node on the basis of its indegree. With probability β the edge points to a node chosen uniformly at

random, and with probability $1 - \beta$ the edge is directed to a node chosen proportionally to its indegree. The Equation 52.1 now takes the form

$$\frac{dI_k(t)}{dt} = \frac{(\beta I_{k-1}(t) + (1 - \beta)(k-1)I_{k-1}(t)) - (\beta I_k(t) + (1 - \beta)kI_k(t))}{t}.$$

Note that the first term of the first part of the r.h.s. corresponds to increase due to the uniform process and the second term increase due to the preferential attachment process. The recurrence equation now takes the form [12]

$$i_k(1 + \beta + k(1 - \beta)) = i_{k-1}(\beta + (k-1)(1 - \beta))$$

or,

$$\begin{aligned} \frac{i_k}{i_{k-1}} &= 1 - \frac{2 - \beta}{1 + \beta + k(1 - \beta)} \\ &\sim 1 - \left(\frac{2 - \beta}{1 - \beta} \right) \left(\frac{1}{k} \right) \end{aligned}$$

for large k . It can be verified by substitution that

$$i_k \sim k^{-\frac{2-\beta}{1-\beta}} \quad (52.4)$$

satisfies the above recurrence. It should be noted that in this case the power law coefficient can be any number larger than 2 depending upon the value of β .

How do we get power law distribution in the outdegree of the nodes of the graph? Simplest modification to the basic model to ensure that would be to choose the tail of the edge incident at the added node to be chosen with probability proportional to the outdegree of the nodes. Aiello et al. [15], and Cooper and Frieze [16] have both given analysis of the version of the basic model in which, at any time epoch, apart from edges incident and emanating out of the added node being chosen randomly and according to the out and in degree distributions of the existing nodes, edges are added between existing nodes of the graph. Both in and out degree distributions show power law behaviour. From Web modeling perspective this is not particularly satisfying because there is no natural analogue of preferential attachment to explain the process that controls the number of hyperlinks in a web page. Never-the-less all models that enable power law distribution in outdegree of nodes in literature resort to it in one form or the other. We will now summarize the other significant variations of the basic model that have been reported in literature.

Kumar et al. [17] categorise evolutionary web graph models according to the rate of growth enabled by them. *Linear growth* models allow one node to be added at one time epoch along with a fixed number of edges to the nodes already in the graph. *Exponential growth* models allow the graph to grow by a fixed fraction of the current size at each time epoch. The models discussed above are linear growth models. Kumar et al. in Reference 17 introduce the notion of *copying* in which the head of the edge emanating out of the added node is chosen to be the head of an edge emanating out of a “designated” node (chosen randomly). The intuition for copying is derived from the insight that links out of a new page are more likely to be directed to pages that deal with the “topic” associated with the page. The designated node represents the choice of the topic and the links out of it are very likely links to “other” pages relating to the topic. Copying from the designated node is done with probability $1 - \beta$. With probability β the head is chosen uniformly at random. The exponential growth model that they have analyzed does not involve the copying rule for distribution of the new edges to be added. The tail of a new edge is chosen to be among the new nodes with some probability factor. If the tail is to be among the old nodes, then the old node is chosen with probability proportional to its out degree. The analysis, as in References 15,16, is carried out totally within the discrete domain using martingale theory to establish that the expected values are sharply clustered. For the linear growth model the power law coefficient is the same as in Equation 52.4. The copying model is particularly interesting because estimates of the distribution of bipartite cliques in graphs generated using copying match those found experimentally.

Another approach that has been used to model evolutionary graphs is the so called *Master Equation Approach* introduced by Dorogovtsev et al. [18] which focuses on the probability that at time t a node introduced at time i , has degree k . If we denote this quantity by $p(k, i, t)$, then the equation controlling this quantity for indegree in the basic model becomes

$$p(k, i, t+1) = \frac{k-1}{t+1} p(k-1, i, t) + \left(1 - \frac{k}{t+1}\right) p(k, i, t). \quad (52.5)$$

First term on the r.h.s. corresponds to the probability with which the node increases its indegree. The second term is the complementary probability with which the node remains in its former state. The over all degree distribution of nodes of indegree k

in the graph is

$$P(k, t) = \frac{1}{t+1} \sum_{i=0}^{i=t} p(k, i, t).$$

Using this definition over Equation 52.5 we get

$$(t+1)P(k, t+1) = (k-1)P(k-1, t) + (t-k)P(k, t).$$

For extremely large networks the stationary form of this equation, i.e. at $t \rightarrow \infty$ is

$$P(k) = \frac{k-1}{k+1} P(k-1). \quad (52.6)$$

Notice that the solution to Equation 52.6 with appropriate initial conditions is of the form $P(k) \sim k^{-2}$ which is the same as that obtained by working in the continuous domain.

Rigorous analysis of the stochastic processes done so far in References 15–17 has so far taken into account growth, that is, birth, process only. The combinatorics of a web graph model that involves death processes also has still to be worked out. It must be pointed out that using less rigorous techniques a series of results dealing with issues like non-linear preferential attachment and growth rates, growth rates that change with time (aging and decay), and death processes in the form of edge removals have appeared in literature. This work is primarily being done by physicists. Albert and Barabasi [19], and Dorogovtsev and Mendes [20] are two comprehensive surveys written for physicists which the computer scientists would do well to go through. However, with all this work we are still far away from having a comprehensive model that takes into account all that we understand of the Web. All models view web growth as a global process. But we know that a web page to propagate Esperanto in India is more likely to have hyperlinks to and from pages of Esperanto enthusiasts in rest of the world. From modeling perspective every new node added during the growth process may be associated with the topic of the node chosen, let us say by preferential attachment, to which the added node first points to. This immediately reduces the set of nodes from which links can point to it. In effect the probability for links to be added between two nodes which are associated with some topics will be a function of how related the topics are. That there is some underlying structure to the web graph that is defined by the topics associated with the nodes in the graph has been in the modeling horizon for some time. Search engines that use web directories organised hierarchically as graphs and trees of topics have been designed [21]. Experiments to discover the topic related underlying structures have been carried out [22–24]. A model that takes into account the implicit topic based structure and models web growth as a number of simultaneously taking place local processes [25] is as step in this direction. All that is known about the Web and the models that have been developed so far are pointers to the realisation that development mathematically tractable models that model the phenomena faithfully is a challenging problem which will excite the imagination and the creative energies of researchers for some time.

52.4 Properties of Web Graphs and Web Algorithmics

The properties of web graphs that have been studied analytically are average shortest path lengths between two vertices, size of giant components and their distributions. All these properties have been studied extensively for $G_{n,p}$ class of random graphs. Seminal work in this area for graphs whose degrees were given was done by Malloy and Reed [26] who came up with a precise condition under which phase transition would take place and giant components as large as the graph itself would start to show up. In what follows we will discuss these issues using generating functions as done by Newman, Strogatz, and Watts [27] primarily because of the simplicity with which these reasonably complex issues can be handled in an integrated framework.

52.4.1 Generating Function Framework

Following [27] we define for a large undirected graph with N nodes the generating function

$$G_0(x) = \sum_{k=0}^{k=\infty} p_k x^k, \quad (52.7)$$

where p_k is the probability that a randomly chosen vertex has degree k . We assume that the probability distribution is correctly normalised, that is, $G_0(1) = 1$. $G_0(x)$ can also represent graphs where we know the exact number n_k of vertices of degree k by defining

$$G_0(x) = \frac{\sum_{k=0}^{k=\infty} n_k x^k}{\sum_{k=0}^{k=\infty} n_k}.$$

The denominator is required to ensure that the generating function is properly normalised. Consider the function $[G_0(x)]^2$. Note that coefficient of the power of x^n in $[G_0(x)]^2$ is given by $\sum_{i+j=n} p_i p_j$ which is nothing but the probability of choosing two vertices such that the sum of their degrees is n . The product of two or more generating functions representing different degree distributions can be interpreted in the same way to represent probability distributions reflecting independent choices from the two or more distributions involved.

Consider the problem of estimating the average degree of a vertex chosen at random. The average degree is given by $\sum_k kp_k$ which is also equal to $G'_0(1)$. Interestingly the average degree of a vertex chosen at random and the average degree of a vertex pointed to by a random edge are different. A random edge will point to a vertex with probability proportional to the degree of the vertex which is of the order of kp_k . The appropriately normalised distribution is given by the generating function

$$\frac{\sum_k kp_k x^k}{\sum_k kp_k} = x \frac{G'_0(x)}{G'_0(1)}. \quad (52.8)$$

The generating function given above in Equation 52.8 will have to be divided by x if we wanted to consider the distribution of degree of immediate neighbors excluding the edges by which one reached them. We will denote that generating function by $G_1(x)$. The neighbors of these immediate neighbors are the *second* neighbors of the original node. The probability that any of the second neighbors connect to any of the immediate neighbors or one another is no more than order of N^{-1} and hence can be neglected when N is large. Under this assumption the distribution of the second neighbors of the originally randomly chosen node is

$$\sum_k p_k [G_1(x)]^k = G_0(G_1(x)).$$

The average number of second neighbors, therefore, is

$$z_2 = \left[\frac{d}{dx} G_0(G_1(x)) \right]_{x=1} = G'_0(1)G'_1(1), \quad (52.9)$$

using the fact that $G_1(1) = 1$.

52.4.2 Average Path Length

We can extend this reasoning to estimate the distributions for the m th neighbors of a randomly chosen node. The generating function for the distribution for the m th neighbor, denoted by $G^m(x)$, is given by

$$G^m(x) = \begin{cases} G_0(x) & m = 1 \\ G^{(m-1)}(G_1(x)) & m \geq 2. \end{cases}$$

Let z_m denote the average number of m th nearest neighbors. We have

$$z_m = \left. \frac{dG^m(x)}{dx} \right|_{x=1} = G'_1(1)G^{(m-1)'}(1) = [G'_1(1)]^{m-1} z_1 = \left[\frac{z_2}{z_1} \right]^{m-1} z_1. \quad (52.10)$$

Let l be the smallest integer such that

$$1 + \sum_{i=1}^{i=l} z_i \geq N.$$

The average shortest path length between two random vertices can be estimated to be of the order l . Using Equation 52.10 we get

$$l \sim \frac{\log[(N-1)(z_2 - z_1) + z_1^2] - \log z_1^2}{\log(z_2/z_1)}.$$

When $N \gg z_1$ and $z_2 \gg z_1$ the above simplifies to

$$l \sim \frac{\log(N/z_1)}{\log(z_2/z_1)} + 1.$$

There do exist more rigorous proofs of this result for special classes of random graphs. The most interesting observation made in Reference 27 is that only estimates of nearest and second nearest neighbors are necessary for calculation of average shortest path length, and that making these purely local measurements one can get a fairly good measure of the average shortest distance which is a global property. One, of course, is assuming that the graph is connected or one is limiting the calculation to the giant connected component.

52.4.3 Emergence of Giant Components

Consider the process of choosing a random edge and determining the component(s) of which one of its end nodes is a part. If there are no other edges incident at that node then that node is a component by itself. Otherwise the end node could be connected to one component, or two components and so on. Therefore, the probability of a component attached to the end of a random edge is the sum of the probability of the end node by itself, the end node connected to one other component, or two other components and so on. If $H_1(x)$ is the generating function for the distribution of the sizes of the components which are attached to one of the ends of the edge, then $H_1(x)$ satisfies the recursive equation

$$H_1(x) = xG_1(H_1(x)). \quad (52.11)$$

Note that each such component is associated with the end of an edge. Therefore, the component associated with a random vertex is a collection of such components associated with the ends of the edges leaving the vertex, and so, $H_0(x)$ the generating function associated with size of the whole component is given by

$$H_0(x) = xG_0(H_1(x)). \quad (52.12)$$

We can use Equations 52.11 and 52.12 to compute the average component size which, in an analogous manner to computing the average degree of a node, is nothing but

$$H_0'(1) = 1 + G_0'(1)H_1'(1). \quad (52.13)$$

Similarly using Equation (52.11) we get

$$H_1'(1) = 1 + G_1'(1)H_1'(1),$$

which gives the average component size as

$$1 + \frac{G_0'(1)}{1 - G_1'(1)}. \quad (52.14)$$

The giant component first appears when $G_1'(1) = 1$. This condition is equivalent to

$$G_0'(1) = G_0''(1). \quad (52.15)$$

Using Equation 52.7 the condition implied by Equation 52.15 can also written as

$$\sum_k k(k-2)p_k = 0. \quad (52.16)$$

This condition is the same as that obtained by Molloy and Reed in References 26. The sum on the l.h.s. of Equation 52.16 increases monotonically as edges are added to the graph. Therefore, the giant component comes into existence when the sum on the l.h.s. of Equation 52.16 becomes positive. Newman et al. state in Reference 27 that once there is a giant component in the graph, then $H_0(x)$ generates the probability distribution of the sizes of the components excluding the giant component. Molloy and Reed have shown in References 28 that the giant component almost surely has $cN + o(N)$ nodes. It should be remembered that the results in References 26–28 are all for graphs with specified degree sequences. As such they are applicable to graphs with power law degree distributions. However, web graphs are directed and a model that explains adequately the structure consistent with all that is known experimentally is still to be developed.

52.4.4 Search on Web Graphs

Perhaps the most important algorithmic problem on the Web is mining of data. We will, however, have not much to say about it partly because it has been addressed in Chapter 51, but also because we want to focus on issues that become specially relevant in an evolving web graph. Consider the problem of finding a path between two nodes in a graph. On the Web this forms the core of the peer to peer (P2P) search problem defined in the context of locating a particular file on the Web when there is no information available in a global directory about the node on which the file resides. The basic operation available is to pass messages to neighbors in a totally decentralised manner. Normally a distributed message passing flooding technique on an arbitrary random network would be suspect because of the very large number of messages that may be so generated. Under the assumption that a node knows about the identities of its neighbors and perhaps neighbors' neighbors, Adamic et al. [29] claim, experimentally through simulations, that in power law graphs with N nodes the average search time is of the order of $N^{0.79}$ (graphs are undirected and power law coefficients for the generated graphs is 2.1) when the search is totally random. The intuitive explanation is that even in a random search the search process tends to gravitate towards nodes of high degree. When the strategy is to choose to

move to the highest degree neighbor the exponent comes down to 0.70. Adamic et al. [29] have come up with a fairly simple analysis to explain why random as well as degree directed search algorithms need not have time complexity more than rootic in N (reported exponent is 0.1). In what follows we develop the argument along the lines done by Mehta [30] whose analysis, done assuming that the richest node is selected on the basis of looking at the neighbors and neighbors' neighbors, has resulted in a much sharper bound than the one in Reference 29. We will assume that the cut off degree, m , beyond which the probability distribution is small enough to be ignored is given by $m = N^{1/\alpha}$ [31].

Using

$$p_k = p(k) = \frac{k^{-\alpha}}{\sum k^{-\alpha}}$$

as the probability distribution function, the expected degree z of a random node is

$$z = G'_0(1) \approx \frac{\int_1^m k^{1-\alpha} dk}{\int_1^m k^{-\alpha} dk} = \frac{(\alpha - 1)(m^{2-\alpha} - 1)}{(\alpha - 2)(m^{1-\alpha} - 1)} \sim \ln m, \quad (52.17)$$

under the assumption that α tends to 2 and $m^{1-\alpha}$ is small enough to be ignored. Similarly the PDF for $G_1(x)$ is

$$p_1(k) = \frac{p_k k}{\sum p_k k} = \frac{k^{1-\alpha}}{(\sum k^{1-\alpha})} = ck^{1-\alpha}, \quad (52.18)$$

where

$$c = \frac{1}{\sum k^{1-\alpha}} = \frac{\alpha - 2}{(m^{2-\alpha} - 1)} \approx \frac{1}{\ln m} = \frac{\alpha}{\ln N}. \quad (52.19)$$

The CDF for $G_1(x)$ using (52.18) and (52.19) is

$$P(x) = \int_1^x p_1(k) dk = \frac{\ln x}{\ln m}. \quad (52.20)$$

The search proceeds by choosing at each step the highest degree node among the n neighbors of the current node. The total time taken can be estimated to be the sum of the number of nodes traversed at each step. The number of steps itself can be bounded by noting that the sum of the number of steps at each step can not exceed the size of the graph. Let $p_{max}(x, n)$ be the distribution of the degree of the richest node (largest degree node) among the n neighbors of a node. Determining the richest node is equivalent to taking the maximum of n independent random variables and in terms of the CDF $P(x)$,

$$p_{max}(x, n) = \begin{cases} 0 & x = 0 \\ (P(x) - P(x-1))^n & 0 < x \leq m \\ 0 & x > m \end{cases} \quad (52.21)$$

This can be approximated as follows

$$p_{max}(x, n) = \frac{d(P(x)^n)}{dx} = nP(x)^{n-1} \frac{dP(x)}{dx} = n(\log_m x)^{n-1} cx^{-1}. \quad (52.22)$$

We can now calculate the expected degree of the richest node among the n nodes as

$$f(n) = E[x_{max}(n)] = \sum_1^m xp_{max}(x, n) = nc \sum_1^m (\log_m x)^{n-1}. \quad (52.23)$$

Note that if the number of neighbors of every node on the average is z , then the number of second neighbors seen when one is at the current richest node is $f(z)(z-1)$. This is because one of the neighbors of every other node is the richest node. At the next step, the expected degree of the node whose current degree is $f(z)$ is given by $E(f(z)) = f(f(z))$ and the number of second neighbors seen at this stage correspondingly is $f(f(z))(z-1)$. The overlap between two successive computations of neighbors takes place only when there is an edge which makes a node a neighbor as well as the second neighbor. However, the probability of this happening is of the order of N^{-1} and can be ignored in the limit for large N . Therefore we can assume that at every stage

new nodes are scanned and the number of steps, l , is controlled by

$$(z-1) \sum_{i=0}^{i=l} f^i(z) = N. \quad (52.24)$$

Assuming for the sake of simplicity $f(f(z)) = f(z)$ (simulations indicate that value of $f^i(z)$ increases with i and then stabilises) we can set $E[n] = n$ or

$$E(n) = n = nc \sum_1^m (\log_m(x))^{n-1}, \quad (52.25)$$

or

$$(\ln m)^n = \sum_1^m (\ln x)^{n-1} \sim \int_1^m (\ln x)^{n-1} dx. \quad (52.25)$$

Substituting e^t for x we get

$$\begin{aligned} (\ln m)^n &= \int_1^{\ln m} e^t t^{n-1} dt \\ &\sim \int_1^{\ln m} t^{n-1} \left(1 + \sum_0^{\infty} \frac{t^i}{i!}\right) dt \\ &= \frac{(\ln m)^n}{n} + \left| \sum_0^{\infty} \frac{t^{n+i}}{i!(n+i)} \right|_0^{\ln m} \\ &\leq \frac{(\ln m)^n}{n} + \frac{(\ln m)^n}{n+c} e^{\ln m}, \end{aligned}$$

where c is a constant. The above implies

$$1 = \frac{1}{n} + \frac{m}{n+c},$$

which gives

$$n = O(m).$$

Substituting this in Equation 52.24 we get

$$(\ln m - 1) \sum_0^l O(m) = N,$$

or

$$l \sim \frac{N}{m \ln m} = \frac{N^{1-1/\alpha}}{\ln m}.$$

Taking α to be 2.1 the number of steps would be of the order of $N^{0.52}/\ln m$. Mehta [30] also reports results of simulations carried out on graphs generated with α equal to 2.1 using the method given in Reference 31. The simulations were carried out on the giant components. He reports the number of steps to be growing proportional to $N^{0.34}$. The simulation results are very preliminary as the giant components were not very large (largest was of the order of 20 thousand nodes).

52.4.5 Crawling and Trawling

Crawling can be looked upon as a process where an agent moves along the nodes and edges of a randomly evolving graph. Off-line versions of the Web which are the basis of much of what is known experimentally about the Web have been obtained essentially through this process. Cooper and Frieze [32] have attempted to study the expected performance of a crawl process where the agent makes a fixed number of moves between the two successive time steps involving addition of nodes and edges to the graph. The results are fairly pessimistic. Expected proportion of unvisited nodes is of order of 0.57 of the graph size when the edges are added uniformly at random. The situation is even worse when the edges are distributed in proportion to the degree of nodes. The proportion of the unvisited vertices increases to 0.59.

Trawling, on the other hand, involves analyzing the web graph obtained through a crawl for subgraphs which satisfy some particular structure. Since the web graph representation may run into Tera bytes of data, the traditional random access model for computing the algorithmic complexity loses relevance. Even the standard external memory models may not apply as data may

be on tapes and may not fit totally on the disks available. In these environments it may even be of interest to develop algorithms where the figure of merit may be the number of passes made over the graph represented on tape (S. Rajagopalan. Private Communication). In any case the issue in trawling is to design algorithms that efficiently stream data between secondary and main memory.

Kumar et al. discuss in Reference 5 the design of trawling algorithms to determine bipartite cores in web graphs. We will focus only on the core issue here which is that the size of the web graph is huge in comparison to the cores that are to be detected. This requires pruning of the web graph before algorithms for core detection are run. If (i, j) cores (i represents outdegree and j indegree) have to be detected then all nodes with outdegree less than i and indegree less than j have to be pruned out. This can be done with repeated sorting of the web graph by in and out degrees and keeping track of only those nodes that satisfy the pruning criteria. If an index is kept in memory of all the pruned in vertices then repeated sorting may also be avoided.

The other pruning strategy discussed in Reference 5 is the so called *inclusion exclusion* pruning in which the focus at every step is to either discover an (i, j) core or exclude a node from further contention. Consider a node x with outdegree equal to i (these will be termed fans) and let $\Gamma(x)$ be the set of nodes that are potentially those with which x could form an (i, j) core (called centers). An (i, j) core will be formed if and only if there are $i - 1$ other nodes all pointing to each node in $\Gamma(x)$. While this condition is easy to check if there are two indices in memory, the whole process can be done in two passes. In the first identify all the fans with outdegree i . Output for each such fan the set of i centers adjacent to it. In the second pass use an index on the destination id to generate the set of fans pointing to each of the i centers and compute the intersection of these sets. Kumar et al. [5] mention that this process can be batched with index only being maintained of the centers that result out of the fan pruning process. If we maintain the set of fans corresponding to the centers that have been indexed, then using the dual condition that x is a part of the core if and only if the intersection of the sets $\Gamma^{-1}(x)$ has size at least j . If this process results in identification of a core then a core is outputted otherwise the node x is pruned out. Kumar et al. [5] claim that this process does not result in any not yet identified cores to be eliminated.

The area of trawling is in its infancy and techniques that will be developed will depend primarily on the structural properties being discovered. It is likely to be influenced by the underlying web model and whether any semantic information is also used in defining the structure. This semantic information may be inferred by structural analysis or may be available in some other way. Development of future web models will depend largely on our understanding of the web, and they themselves will influence the algorithmic techniques developed.

52.5 Conclusions

The modeling and analysis of web as a dynamic graph is very much in its infancy. Continuous mathematical models, which has been the focus of this write up provides good intuitive understanding at the expense of rigour. Discrete combinatorial models that do not brush the problems of proving concentration bounds under the rug are available for very simple growth models. These growth models do not incorporate death processes, or the issues relating to aging (newly created pages are more likely to be involved in link generation processes) or for that matter that in and out degree distributions on the web are not independent and may depend upon the underlying community structure. The process of crawling which can visit only those vertices that have at least one edge pointing to it gives a very limited understanding of degree distributions. There are reasons to believe that a significantly large number of pages on the web have only out hyperlinks. All this calls for extensive experimental investigations and development of mathematical models that are tractable and help both in development of new analytical as well as algorithmic techniques.

The author would like to acknowledge Amit Agarwal who provided a willing sounding board and whose insights have significantly influenced the author's approach on these issues.

53.1 Introduction

VLSI (Very Large Scale Integration) is a technology that has enabled the manufacture of large circuits in silicon. It is not uncommon to have circuits containing millions of transistors, and this quantity continues to increase very rapidly. Designing a VLSI circuit is itself a very complex task and has spawned the area of VLSI design automation. The purpose of VLSI design automation is to develop software that is used to design VLSI circuits. The VLSI design process is sufficiently complex that it consists of the four steps shown in Figure 53.1. Architectural design is carried out by expert human engineers with some assistance from tools such as simulators. Logic design is concerned with the boolean logic required to implement a circuit. Physical design is concerned with the implementation of logic on a three dimensional physical structure: the VLSI chip. VLSI physical design consists of steps such as floorplanning, partitioning, placement, routing, circuit extraction, etc. Details about VLSI physical design automation may be found in References 1–3. Chapter 54 describes the rich area of data structures for floorplanning. In this chapter, our concern will be with the representation of a circuit in its “physical” form. In order to proceed with this endeavor, it is necessary to first understand the basics of VLSI technology.

53.2 VLSI Technology

We begin with the caveat that our presentation here only seeks to convey the basics of VLSI technology. Detailed knowledge about this area may be obtained from texts such as [4]. The transistor is the fundamental device in VLSI technology and may be viewed as a switch. It consists of a gate, a source, and a drain. The voltage on the gate controls the passage of current between the source and the drain. Thus, the gate can be used to switch the transistor “on” (current flows between the source and the drain) and “off” (no current flows). Basic logic elements such as the inverter (the NOT gate), the NAND gate, and the NOR gate are built using transistors. Transistors and logic gates can be manufactured in layers on a silicon disk called a wafer. Pure silicon is a semiconductor whose electrical resistance is between that of a conductor and an insulator. Its conductivity can be significantly improved by introducing “impurities” called dopants. N-type dopants such as phosphorus supply free electrons, while p-type dopants like boron supply holes. Dopants are diffused into the silicon wafer. This layer of the chip is called the diffusion layer and is further classified into n-type and p-type depending on the type of dopant used. The source and drain of a transistor are

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

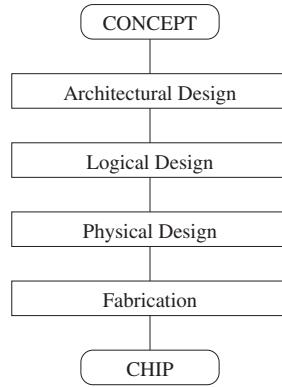

FIGURE 53.1 The VLSI design stages.

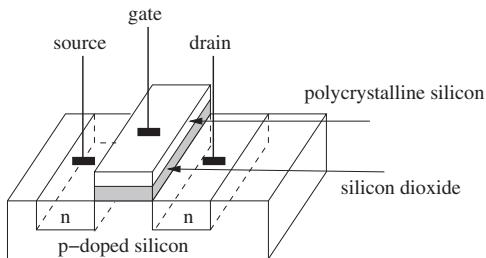

FIGURE 53.2 A transistor.

formed by separating two n-type regions with a p-type region (or vice versa). A gate is formed by sandwiching a silicon dioxide (an insulator) layer between the p-type region and a layer of polycrystalline silicon (a conductor). Figure 53.2 illustrates these concepts. Since polycrystalline silicon (poly) is a conductor, it is also used for short interconnections (wires). Up to this point, we have described the two layers (diff and poly) that are used to make all electronic devices. Although poly conducts electricity, it is not sufficient to complete all the interconnections using one layer. Modern chips usually have several layers of aluminum (“metal”), a conductor, separated from each other by insulators on top of the poly layer. These make it possible for the gates to be interconnected as specified in the design. Note that a layer of material X (e.g., poly) does not mean that there is a monolithic slab of poly over the entire chip area. The poly is only deposited where gates or wires are needed. The remaining areas are filled with insulating materials and for our purposes may be viewed as being empty. In addition to the layers as described above, it is necessary to have a mechanism for signals to pass between layers. This is achieved by contacts (to connect poly with diffusion or metal) and vias (to connect metal on different layers). Figure 53.3 shows the layout and a schematic of an nMOS inverter. We briefly describe the functioning of the inverter. If the input gate voltage is “0,” the transistor is switched off and there is no connection between the ground signal and the output. The voltage at the output is identical to that of the power source, which is a “1.” If the gate is at “1,” the transistor is switched on and there is a connection between the ground signal “0” and the output, making the output “0.”

The purpose of a layout data structure is to store and manipulate the rectangles on each layer. Some important high-level operations that a layout data structure must support are design-rule checking, layout compaction, and parasitic extraction.

Design Rule Checking (DRC): Design rules are the interface between the circuit designer and the process engineer. They specify geometric constraints on the layout so that the patterns on the processed wafer preserve the topology of the designs. An example of a design rule is that the width of a wire must be greater than a specified minimum. If this constraint is violated, it is possible that for the wire to be discontinuous because of errors in the fabrication process. Similarly, if two wires are placed too close to each other, they could touch each other. The DRC step verifies that all design rules have been met. Additional design rules for CMOS technology may be found in Reference 4, page 142.

Parasitic Extraction: Each layer of the chip has a resistance and a capacitance that are critical to the estimation of circuit performance. Inductance is usually less important on the chip, but has greater impact on the I/O components of the chip. Capacitance, resistance, and inductance are commonly referred to as “parasitics.” After a layout has been created, the parasitics must be computed in order to verify that the circuit will meet its performance goals. (Performance is usually measured by clock cycle times and power dissipation.) The parasitics are computed from the geometry of the layout. For example, the resistance of a

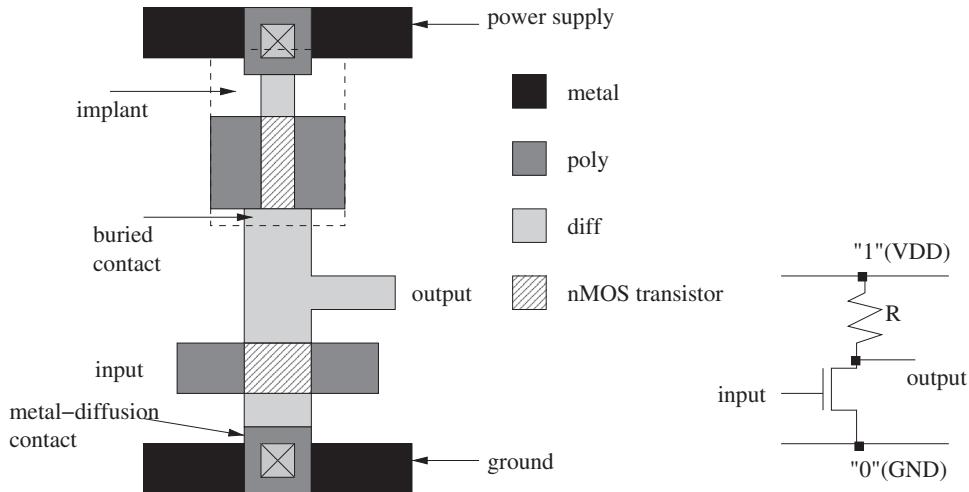

FIGURE 53.3 An inverter.

rectangular slab of metal is $\frac{\rho l}{tw}$, where ρ is the resistivity of the metal and l , w , and t are the slab's length, width, and thickness, respectively. See [4, Chapter 4] for more examples.

Compaction: The compaction step, as its name suggests, tries to make the layout as small as possible without violating any design rules. This reduces the area of the chip, which could result in more chips being manufactured from a single wafer, which significantly reduces cost per chip. Interestingly, the cost of a chip could grow as a *power of five* of its area [5] making it imperative that area be minimized! Two-dimensional compaction is NP-hard, but one-dimensional compaction can be carried out in polynomial time. Heuristics for 2D compaction often iteratively interleave one-dimensional compactations in the x - and y -directions. For more details, see [6].

53.3 Layout Data Structures: An Overview

There are two types of layout data structures that are based on differing philosophies. The first is in the context of a layout editor. Here, the idea is that a user manually designs the layout, for example, by inserting rectangles of the appropriate dimensions at the appropriate layer. This customized approach is used for library cells. The MAGIC system [7] developed at U.C. Berkeley is an example of a system that included a layout editor. MAGIC was in the public domain and was used to support classes on VLSI design in many universities. The layout editor context is especially important here because it permitted the developers of MAGIC to assume locality of reference; that is, a user is likely to perform several editing operations in the same area of the layout over a short period of time. The second philosophy is that the layout process is completely automated. This has the advantage that some user-interaction operations do not need to be supported and run time is critical. This approach is more common in industrial software, where automatic translation techniques convert electronic circuits into physical layouts. This philosophy is supported by the quad-tree and variants that were designed specifically for VLSI layout.

53.4 Corner Stitching

The corner stitching data structure was proposed by Ousterhout [8] to store non-overlapping rectilinear circuit components in MAGIC. The data structure is obtained by partitioning the layout area into horizontally maximal rectangular tiles. There are two types of tiles: solid and vacant, both of which are explicitly stored in the corner-stitching data structure. Tiles are obtained by extending horizontal lines from corners of all solid tiles until another solid tile or a boundary of the layout region is encountered. The set of solid and vacant tiles so obtained is unique for a given input. The partitioning scheme ensures that no two vacant or solid tiles share a vertical side. Each tile T is stored as a node which contains the coordinates of its bottom left corner, x_1 and y_1 , and four pointers N , E , W , and S . N (respectively, E , W , S) points to the rightmost (respectively, topmost, bottommost, leftmost) tile neighboring its north (respectively, east, west, south) boundary. The x and y coordinates of the top right corner of T are $T.E \rightarrow x_1$ and $T.N \rightarrow y_1$, respectively, and are easily obtained in $O(1)$ time. Figure 53.4 illustrates the corner stitching data structure.

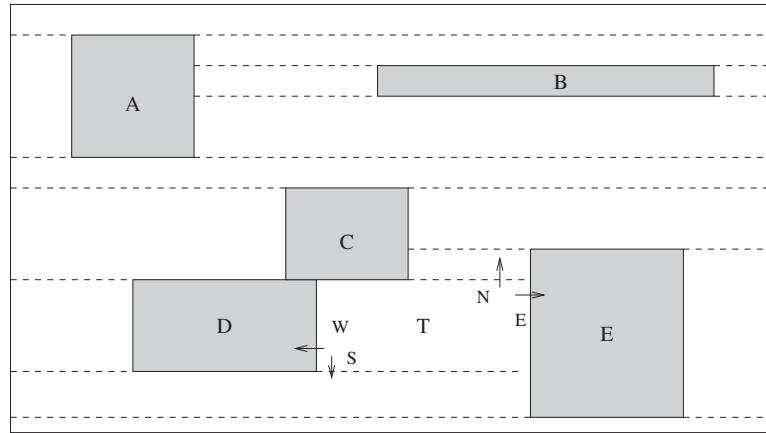

FIGURE 53.4 The corner stitching data structure. Pointers (stitches) are shown for tile T .

The corner stitching data structure supports a rich set of operations.

1. Point Finding: given a tile T and a point $p(x, y)$, search for the tile containing p by following a sequence of stitches starting at T .
2. Neighbor Finding: find all solid and vacant tiles that abut a given tile T .
3. Area Searches: determine whether any solid tiles intersect a given rectangular area R . This operation is used to determine whether a new solid tile can subsequently be inserted into area R . (Recall that tiles in a layer are not permitted to overlap.)
4. Directed Area Enumeration: enumerate all the tiles contained in a given rectangular area in a specified order. This is used during the compaction operation which may require tiles to be visited and compacted in a left-to-right order.
5. Tile Creation: insert a solid tile T into the data structure at a specified location.
6. Tile Deletion: delete a specified solid tile T from the data structure.
7. Plowing: translate a large piece of a design. Move other pieces of the design that lie in its path in the same direction.
8. Compaction: this refers to one-dimensional compaction.

We describe two operations to illustrate corner stitching:

53.4.1 Point Finding

Next, we focus on the point find operation because of its effect on the performance of corner stitching. The algorithm is presented below. Given a pointer to an arbitrary tile T in the layout, the algorithm seeks the tile in the layout containing the point P .

```
Tile Point_Find (Tile  $T$ , Point  $P$ )
1. begin
2.    $current = T;$ 
3.   while ( $P$  is not contained in  $current$ )
4.     begin
5.       while ( $P.y$  does not lie in  $current$ 's y-range)
6.         if ( $P.y$  is above  $current$ )  $current = current \rightarrow N;$ 
7.         else  $current = current \rightarrow S;$ 
8.       while ( $P.x$  does not lie in  $current$ 's x-range)
9.         if ( $P.x$  is to the right of  $current$ )  $current = current \rightarrow E;$ 
10.        else  $current = current \rightarrow W;$ 
11.     end
12.   return ( $current$ );
13. end
```

Figure 53.5 illustrates the execution of the point find operation on a pathological example. From the start tile T , the **while** loop of line 5 follows north pointers until tile A is reached. We change directions at tile A since its y -range contains P . Next, west pointers are followed until tile F is reached (whose x -range contains P). Notice that the sequence of west moves causes the algorithm to descend in the layout resulting in a vertical position that is similar to that of the start tile! As a result of this

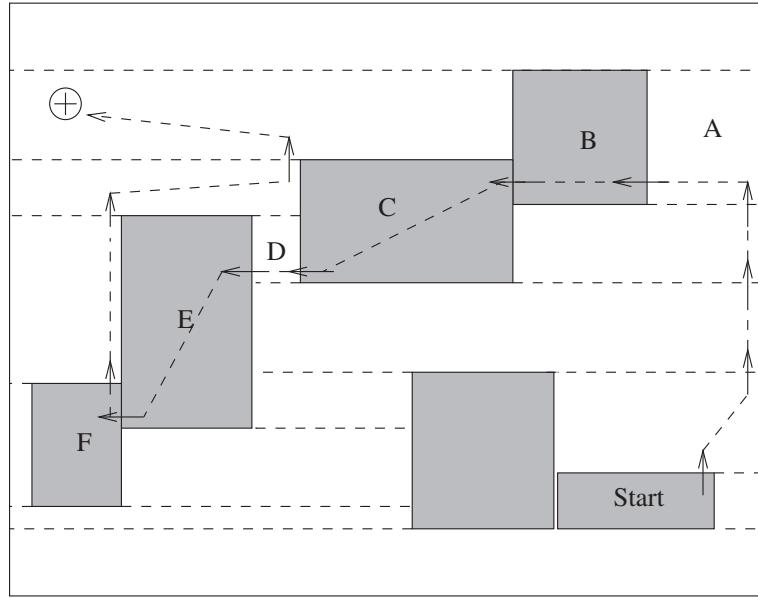

FIGURE 53.5 Illustration of point find operation and misalignment.

misalignment, the outer while loop of the algorithm must execute repeatedly until the point is found (note that the point will eventually be found since the point find algorithm is guaranteed to converge).

53.4.2 Tile Insertion

This operation creates a new solid tile and inserts it into the layout. It accomplishes this by a sequence of split and merge operations. The split operation breaks a tile into two tiles along either a vertical or a horizontal line. The merge operation combines two tiles to form a rectangular tile. Algorithm *Insert* discusses the insertion of a rectangle into the layout.

Insert(A) // (x₁, y₁) and (x₂, y₂) are the bottom left and top right corners of A.

1. **if** (!AreaSearch(A)) **return**; //area is not empty, abort.
2. Let $i = 0$; Split Q_i , the tile containing the north edge of A into two tiles along the line $y = y_2$; Let T be the upper tile and Q_i be the lower tile.
3. **while** (Q_i does not contain the south edge of A)
 - a. Split Q_i vertically into three tiles along $x = x_1$ and $x = x_2$; let the resulting tiles from left to right be L_i , Q_i , and R_i .
 - b. **if** ($i > 0$)
 - i. Merge R_{i-1} and L_{i-1} into R_i and L_i , respectively, if possible.
 - ii. Merge Q_{i-1} into Q_i ;
 - c. Let Q_{i+1} be the tile beneath Q_i .
 - d. Increment i ;
4. Split Q_i along $y = y_1$; Let Q_i be the tile above the split and B the tile below the split; Split Q_i into L_i , Q_i , and R_i using the lines $x = x_1$ and $x = x_2$;
5. Merge Q_i and Q_{i-1} to get Q_i . Q_i is the newly inserted solid tile;
6. Merge R_{i-1} , L_{i-1} with neighboring tiles; if R_i (L_i) gets merged, the merged tile is called R_i (L_i). Merge R_i and L_i with neighboring tiles;

Figure 53.6 shows the various steps involved in the insertion algorithm.

The rectangle A to be inserted is represented by thick, dashed lines in Figure 53.6a. The coordinates of the bottom left and top right corners of A are (x_1, y_1) and (x_2, y_2) , respectively. First, Step 1 of the algorithm uses *AreaSearch* to ensure that no solid tiles intersect A . Step 2 identifies tile Q_0 as the vacant tile containing A 's north edge and splits it by the horizontal line $y = y_2$ into two tiles: T above the split-line and Q_0 below the split-line. Next, in the while loop of Step 3, Q_0 is split by vertical lines at x_1 and x_2 to form L_0 , Q_0 , R_0 . Tile Q_1 is the vacant tile below Q_0 . The resulting configuration is shown in Figure 53.6b. In the next iteration, Q_1 is split to form L_1 , Q_1 , and R_1 . L_0 merges into L_1 and Q_0 merges into Q_1 . Tile Q_2 is the vacant tile below Q_1 . The resulting configuration is shown in Figure 53.6c. Next, Q_2 is split to form L_2 , Q_2 , and R_2 . R_1 is merged into R_2 and Q_1 merged into Q_2 .

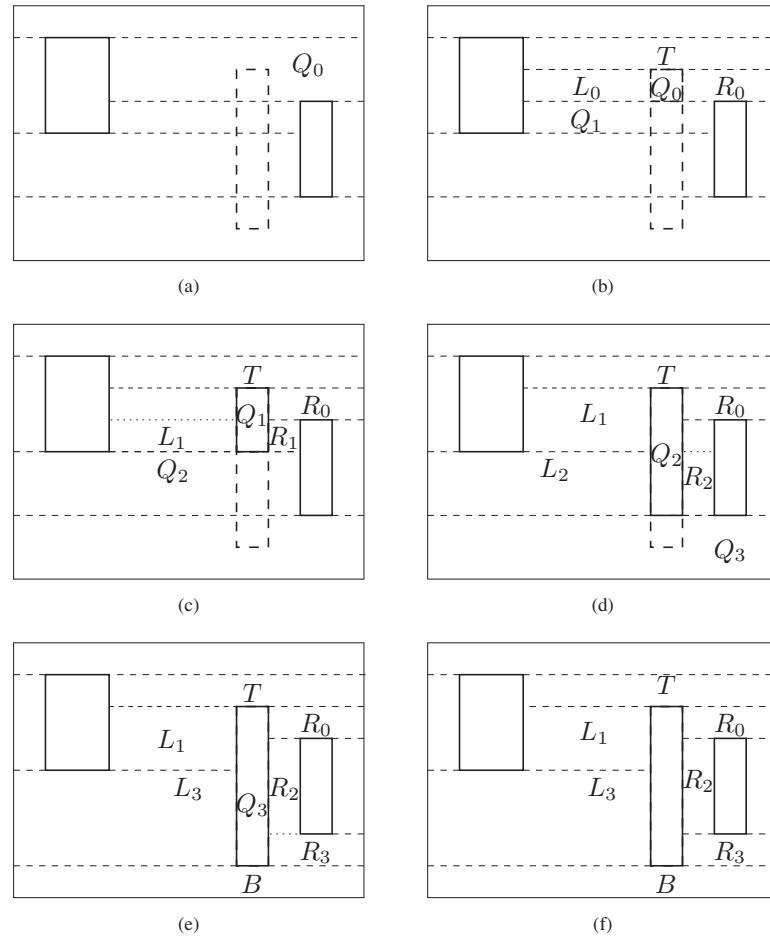

FIGURE 53.6 Illustration of insertion.

Figure 53.6d shows the configuration after Tile Q_2 is processed. The vacant tile Q_3 below Q_2 contains R 's bottom edge and the while loop of Step 3 is exited. Steps 4, 5, and 6 of the algorithm result in the configuration of Figure 53.6e. The final layout is shown in Figure 53.6f.

53.4.3 Storage Requirements of the Corner Stitching Data Structure

Unlike simpler data structures such as arrays and linked lists, it is not trivial to manually estimate the storage requirements of a corner stitched layout. For example, if n items are inserted into a linked list, then the amount of storage required is n multiplied by the number of bytes required by a single list node. Because of vacant tiles, the total number of nodes in corner stitching is considerably more than n and depends on the relative positions of the n rectangles. In References 9 and 10, a general formula for the memory requirements of the corner stitching data structure on a given layout. This formula requires knowledge about certain geometric properties of the layout called *violations* of the CV property and states that a corner stitching data structure representing a set of N solid, rectangular tiles with k violations contains $3N + 1 - k$ vacant tiles. Since each rectangular tile requires 28 bytes, the memory requirements are $28(4N + 1 - k)$ bytes.

53.5 Corner Stitching Extensions

53.5.1 Expanded Rectangles

Expanded rectangles [11] expands solid tiles in the corner stitching data structure so that each tile contains solid material and the empty space around it. No extra tiles are needed to represent empty space. Thus, there are fewer tiles than in corner stitching. However, each tile now requires 44 rather than 28 bytes because additional fields are needed to store the coordinates of the solid

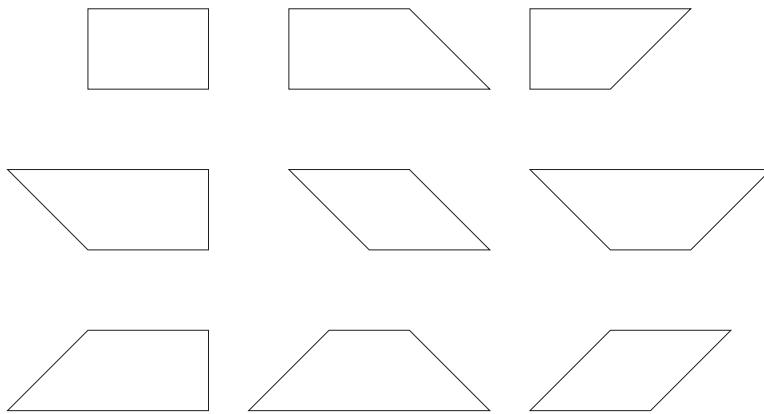

FIGURE 53.7 The different types of trapezoidal tiles.

portion of the tile. It was determined that expanded rectangles required less memory than corner stitching when the ratio of vacant to solid tiles in corner stitching was greater than 0.414. Operations on the expanded rectangles data structure are similar to those in corner stitching.

53.5.2 Trapezoidal Tiles

Marple et al. [12] developed a layout system called “Tailor” that was similar to MAGIC except that it allowed 45° layout. Thus, rectangular tiles were replaced by trapezoidal tiles. There are 9 types of trapezoidal tiles as shown in [Figure 53.7](#). An additional field that stores the type of trapezoidal tile is used. The operations on Tailor are similar to those in MAGIC and are implemented in a similar way. It is possible to extend these techniques to arbitrary angles making it possible to describe arbitrary polygonal shapes.

53.5.3 Curved Tiles

Séquin and Façanha [13] proposed two generalizations to geometries including circles and arbitrary curved shapes, which arise in microelectromechanical systems (MEMS). As with its corner stitching-based predecessors, the layout area is decomposed in a horizontally maximal fashion into tiles. Consequently, tiles have upper and lower horizontal sides. Their left and right sides are represented by parameterized cubic Bezier curves or by composite paths composed of linear, circular, and spline segments. Strategies for reducing storage by minimizing the number of tiles and curve-sharing among tiles are discussed.

53.5.4 L-Shaped Tiles

Mehta and Blust [14] extended Ousterhout’s corner stitching data structure to directly represent L- and other simple rectilinear shapes without partitioning them into rectangles. This results in a data structure that is topologically different from the other versions of corner stitching described above. A key property of this L-shaped corner stitching (LCS) data structure is that

1. All vacant tiles are either rectangles or L-shapes.
2. No two vacant tiles in the layout can be merged to form a vacant rectangle or L-shaped tile.

[Figure 53.8](#) shows three possible configurations for the same set of solid tiles.

There are four L-shape types ([Figure 53.9](#)), one for each orientation of the L-shape. The L-shapes are numbered according to the quadrant represented by the two lines meeting at the single concave corner of the L-shape. [Figure 53.10](#) describes the contents of L-shapes and rectangles in LCS and rectangles in the original rectangular corner stitching (RCS) data structure. The actual memory requirements of a node in bytes (last column of the table) are obtained by assuming that pointers and coordinates, each, require 4 bytes of storage, and by placing all the remaining bits into a single 4-byte word. Note that the space required by any L-shape is less than the space required by two rectangles in RCS and that the space required by a rectangle in LCS is equal to the space required by a rectangle in RCS. The following theorem has been proved in Reference 9:

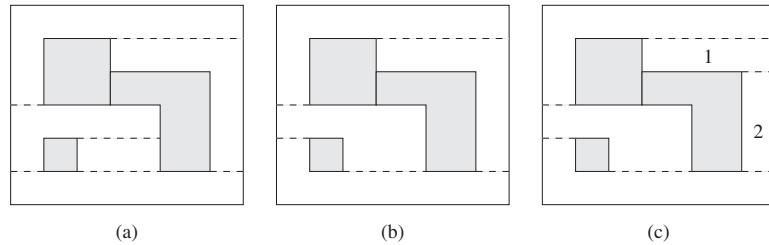

FIGURE 53.8 Layouts represented by the L-shaped corner stitching data structure: Layout (c) is invalid because the vacant tiles 1 and 2 can be merged to form an L-shaped tile. Layouts (b) and (c) are both valid, illustrating that unlike RCS, the LCS data structure does not give a unique partition for a given set of solid tiles.

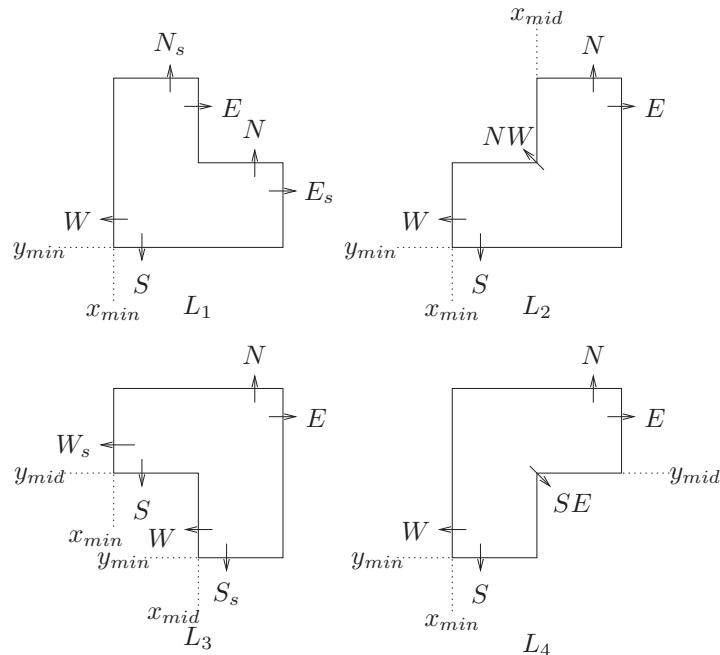

FIGURE 53.9 L-shapes and their pointers.

Theorem 53.1

The LCS data structure never requires more memory than the RCS data structure for the same set of solid rectangular tiles.

Proof. Since all solid tiles are rectangles, and since a rectangle occupies 28 bytes in both LCS and RCS, the total memory required to store solid tiles is the same in each data structure. From the definitions of RCS and LCS, there is a one-to-one correspondence between the set S_1 of vacant rectangles in RCS and the set S_2 consisting of (i) vacant rectangles in LCS and (ii) rectangles obtained by using a horizontal line to split each vacant L-shape in LCS; where each pair of related rectangles (one from S_1 , the other from S_2) have identical dimensions and positions in the layout. Vacant rectangles in LCS require the same memory as the corresponding vacant rectangles in RCS. However, a vacant L-shape requires less memory than the two corresponding rectangles in RCS. Therefore, if there is at least one vacant L-shape, LCS requires less memory than RCS. ■

Theorem 53.2

The *LCS* data structure requires 8.03%–26.7% less memory than the *RCS* data structure for a set of solid, rectangular tiles that satisfies the **CV** property.

Tile type	Number of Coordinates	Number of Pointers	Number of N/E bits	solid/vacant tile bit	R/L bit	L type bits	Number of Bytes
L_1	2	6	4	1	1	2	36
L_2	3	5	3	1	1	2	36
L_3	4	6	2	1	1	2	44
L_4	3	5	3	1	1	2	36
R in LCS	2	4	2	1	1	0	28
R in RCS	2	4	0	1	0	0	28

FIGURE 53.10 Space requirements of tiles in LCS and RCS.

53.5.4.1 Rectilinear Polygons

Since, in practice, circuit components can be arbitrary rectilinear polygons, it is necessary to partition them into rectangles to enable them to be stored in the corner stitching format. MAGIC handles this by using horizontal lines to partition the polygons. This is not necessary from a theoretical standpoint, but it simplifies the implementation of the various corner stitching operations. Nahar and Sahni [15] studied this problem and presented an $O(n + k_v \log k_v)$ algorithm to decompose a polygon with n vertices and k_v vertical inversions into rectangles using horizontal cuts only. (The number of *vertical inversions* of a polygon is defined as the minimum number of changes in vertical direction during a walk around the polygon divided by 2.) The quantity k_v was observed to be small for polygons encountered in VLSI mask data. Consequently, the Nahar-Sahni algorithm outperforms an $O(n \log n)$ planesweep algorithm on VLSI mask data. We note that this problem is different from the problem of decomposing a rectilinear polygon into a minimum number of rectangles using *both* horizontal and vertical cuts, which has been studied extensively in the literature [16–19].

However, the extension is slower than the original corner stitching, and also harder to implement. Lopez and Mehta [20] presented algorithms for the problem of optimally breaking an arbitrary rectilinear polygon into L-shapes using horizontal cuts.

53.5.4.2 Parallel Corner Stitching

Mehta and Wilson [21] have studied a parallel implementation of corner stitching. Their work focuses on two batched operations (batched insert and delete). Their approach results in a significant speed-up in run times for these operations.

53.5.4.3 Comments about Corner Stitching

1. Corner stitching requires rectangles to be non-overlapping. A single layer of the chip consists of non-overlapping rectangles, but all the layers taken together will consist of overlapping rectangles. So, an instance of the corner stitching data structure can only be used for a single layer. However, corner stitching can be used to store multiple layers in the following way: consider two layers A and B. Superimpose the two layers. This can be thought of as a single layer with four types of rectangles: vacant rectangles, type A rectangles, type B rectangles, and type AB rectangles. Unfortunately, this could greatly increase the number of rectangles to be stored. It also makes it harder to perform insertion and deletion operations. Thus, in MAGIC, the layout is represented by a number of single-layer corner stitching instances and a few multiple-layer instances when the intersection between rectangles in different layers is meaningful; for example, transistors are formed by the intersection of poly and diffusion rectangles.
2. Corner stitching is difficult to implement. While the data structure itself is quite elegant, the author's experience is that its implementation requires one to consider a lot of details that are not considered in a high-level description. This is supported by the following remark attributed to John Ousterhout [13]:

Corner-stitching is pretty straightforward at a high level, but it can become much more complicated when you actually sit down to implement things, particularly if you want the implementation to run fast

3. The *Point Find* operation can be slow. For example, *Point Find* could visit all the tiles in the data structure resulting in an $O(n)$ time complexity. On the average, it requires $O(\sqrt{n})$ time. This is expensive when compared with the $O(\log n)$ complexity that may be possible by using a tree type data structure. From a practical standpoint, the slow speed may be tolerable in an interactive environment in which a user performs one operation at a time (e.g., a *Point Find* could be performed by a mouse button click). Here, a slight difference in response time might not be noticeable by the user. Furthermore, in an interactive environment, these operations might actually be fast because they take advantage of locality

of reference (i.e., the high likelihood that two successive points being searched by a user are near each other in the layout). However, in batch mode, where a number of operations are performed without user involvement, one is more likely to experience the average case complexity (unless the order of operations is chosen carefully so as to take advantage of locality of reference). The difference in time between corner stitching and a faster logarithmic technique will be significant.

4. Corner stitching requires more memory to store vacant tiles.

53.6 Quad Trees and Variants

Quad trees have been considered in [Chapters 17](#) and [20](#). These chapters demonstrate that there are different flavors of quad-trees depending on the type of the data that are to be represented. For example, there are quad trees for regions, points, rectangles, and boundaries. In this chapter, we will be concerned with quad-trees for rectangles. We also note that [Chapter 19](#) describes several data structures that can be used to store rectangles. To the best of my knowledge, the use of these structures has not been reported in the VLSI design automation literature.

The underlying principle of the quad tree is to recursively subdivide the two-dimensional layout area into four “quads” until a stopping criterion is satisfied. The resulting structure is represented by a tree with a node corresponding to each quad, with the entire layout area represented by the root. A node contains children pointers to the four nodes corresponding the quads formed by the subdivision of the node’s quad. Quads that are not further subdivided are represented by leaves in the quad tree.

Ideally, each rectangle is the sole occupant of a leaf node. In general, of course, a rectangle does not fit inside any leaf quad, but rather intersects two or more leaf quads. To state this differently, it may intersect one or more of the horizontal and vertical lines (called bisectors) used to subdivide the layout region into quads. Three strategies have been considered in the literature as to where in the quad tree these rectangles should be stored. These strategies, which have given rise to a number of quad tree variants, are listed below and are illustrated in [Figure 53.11](#).

1. **SIMALLEST:** Store a rectangle in the *smallest quad (not necessarily a leaf quad) that contains it*. Such a quad is guaranteed to exist since each rectangle must be contained in the root quad.
2. **SINGLE:** Store a rectangle in precisely *one of the leaf quads that it intersects*.
3. **MULTIPLE:** Store a rectangle in *all of the leaf quads that it intersects*.

Obviously, if there is only one rectangle in a quad, there is no need to further subdivide the quad. However, this is an impractical (and sometimes impossible) stopping criterion. Most of the quad tree variants discussed below have auxiliary stopping criteria. Some subdivide a quad until it reaches a specified size related to the typical size of a small rectangle. Others stop if the number of rectangles in a quad is less than some threshold value. [Figure 53.12](#) lists and classifies the quad tree variants.

53.6.1 Bisector List Quad Trees

Bisector List Quad Trees (BLQT) [22], which was the first quad-tree structure proposed for VLSI layouts, used the **SIMALLEST** strategy. Here, a rectangle is associated with the smallest quad (leaf or non-leaf) that contains it. Any non-leaf quad Q is subdivided into four quads by a vertical bisector and a horizontal bisector. Any rectangle associated with this quad *must* intersect one or both of the bisectors (otherwise, it is contained in one of Q ’s children, and should not be associated with Q). The set of rectangles are partitioned into two sets: V , which consists of rectangles that intersect the vertical bisector and H , which consists of rectangles that intersect the horizontal bisector. Rectangles that intersect both bisectors are arbitrarily assigned to one of V and H . These “lists” were actually implemented using binary trees. The rationale was that since most rectangles in IC layouts were small and uniformly distributed, most rectangles will be at leaf quads. A region search operation identifies all the quads that intersect a query window and checks all the rectangles in each of these quads for intersection with the query window. The BLQT (which is also called the MX-CIF quadtree) is also described in [Chapter 17](#).

53.6.2 k -d Trees

Rosenberg [23] compared BLQT with k -d trees and showed experimentally that k -d trees outperformed an implementation of BLQT. Rosenberg’s implementation of the BLQT differs from the original in that linked lists rather than binary trees were used to represent bisector lists. It is hard to evaluate the impact of this on the experimental results, which showed that point-find and region-search queries visit fewer nodes when the k -d tree is used instead of BLQT. The experiments also show that k -d trees consume about 60%–80% more space than BLQTs.

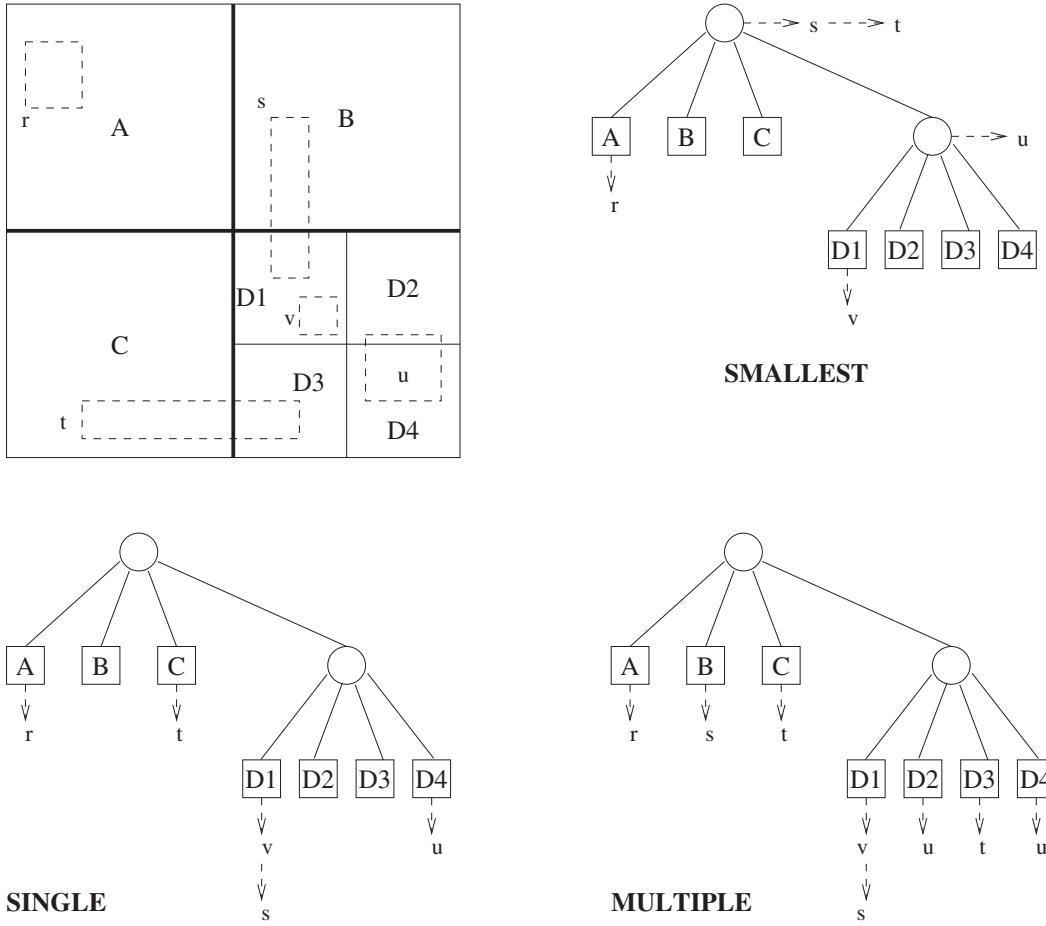

FIGURE 53.11 Quadtree variations.

Brown	MSQT	1986	MULTIPLE
Weyten et al	QLQT	1989	MULTIPLE
Pitaksanonkul et al	BQT	1989	SINGLE
Lai et al	HV	1993	SMALLEST
Lai et al	HQT	1996	MULTIPLE

FIGURE 53.12 Summary of Quad-tree variants.

53.6.3 Multiple Storage Quad Trees

In 1986, Brown proposed a variation [24] called Multiple Storage Quad Trees (MSQT). Each rectangle is stored in every leaf quad it intersects. (See the quad tree labeled “MULTIPLE” in Figure 53.11.) An obvious disadvantage of this approach is that it results in wasted space. This is partly remedied by only storing a rectangle once and having all of the leaf quads that it intersects contain a pointer to the rectangle. Another problem with this approach is that queries such as Region Search may report the same rectangle more than once. This is addressed by marking a rectangle when it is reported for the first time and by not reporting rectangles that have been previously marked. At the end of the Region Search operation, all marked rectangles need to be unmarked in preparation for the next query. Experiments on VLSI mask data were used to evaluate MSQT for different threshold values and for different Region Search queries. A large threshold value results in longer lists of pointers in the leaf quads that have to be

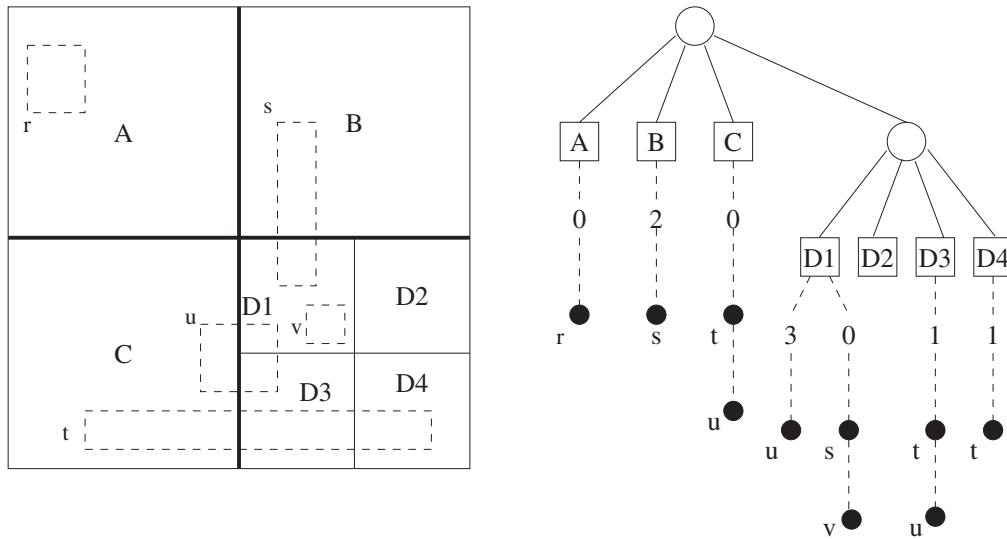

FIGURE 53.13 The leaf quads are $A, B, C, D1, D2, D3$, and $D4$. The rectangles are $r - v$. Rectangle t intersects quads $C, D3$, and $D4$ and must appear in the lists of each of the leaf nodes in the quad tree. Observe that t does not cross the lower boundaries of any of the three quads and $x=0$ in each case. However, t does cross the left boundaries of $D3$ and $D4$ and $y=1$ in these cases. Thus t goes into list 1 in $D3$ and $D4$. Since t does not cross the left boundary of C , it goes into list 0 in C . Note that the filled circles represent pointers to the rectangles rather than the rectangles themselves.

searched. On the other hand, a small threshold value results in a quad-tree with greater height and more leaf nodes as quads have to be subdivided more before they meet the stopping criterion. Consequently, a rectangle now intersects and must be pointed at by more leaf nodes. A Region Search query with a small query rectangle (window) benefits from a smaller threshold because it has to search smaller lists in a handful of leaf quads. A large window benefits from a higher threshold value because it has to search fewer quads and encounters fewer duplicates.

53.6.4 Quad List Quad Trees

In 1989, Weyten and De Pauw [25] proposed a more efficient implementation of MSQT called Quad List Quad Trees (QLQT). For Region Searches, experiments on VLSI data showed speedups ranging from 1.85 to 4.92 over MSQT, depending on the size of the window. In QLQT, four different lists (numbered 0–3) are associated with each leaf node. If a rectangle intersects the leaf quad, a pointer to it is stored in one of the four lists. The choice of the list is determined by the relative position of this rectangle with respect to the quad. The relative position is encoded by a pair of bits xy . x is 0 if the rectangle does not cross the lower boundary of the leaf quad and is 1, otherwise. Similarly, y is 0 if the rectangle does not cross the left boundary of the leaf quad and is 1, otherwise. The rectangle is stored in the list corresponding to the integer represented by this two bit string. Figure 53.13 illustrates the concept. Notice that each rectangle belongs to exactly one list 0. This corresponds to the quad that contains the bottom left corner of the rectangle. Observe, also, that the combination of the four lists in a leaf quad gives the same pointers as the single list in the same leaf in MSQT. The Region Search of MSQT can now be improved for QLQT by using the following procedure for each quad that intersects the query window: if the query window's left edge crosses the quad, only the quad's lists 0 and 1 need to be searched. If the window's bottom edge crosses the quad, the quad's lists 0 and 2 need to be searched. If the window's bottom left corner belongs to the quad, all four lists must be searched. For all other quads, only list 0 must be searched. Thus the advantages of the QLQT over MSQT are:

1. QLQT has to examine fewer list nodes than MSQT for a Region Search query.
2. Unlike MSQT, QLQT does not require marking and unmarking procedures to identify duplicates.

53.6.5 Bounded Quad Trees

Later, in 1989, Pitaksanonkul et al. proposed a variation of quad trees [26] that we refer to as Bounded Quad Trees (BQT). Here, a rectangle is only stored in the quad that contains its bottom left corner. (See the quad tree labeled “SINGLE” in Figure 53.11.) This may be viewed as a version of QLQT that only uses list 0. Experimental comparisons with k -d trees show that for small threshold values, quad trees search fewer nodes than k -d trees.

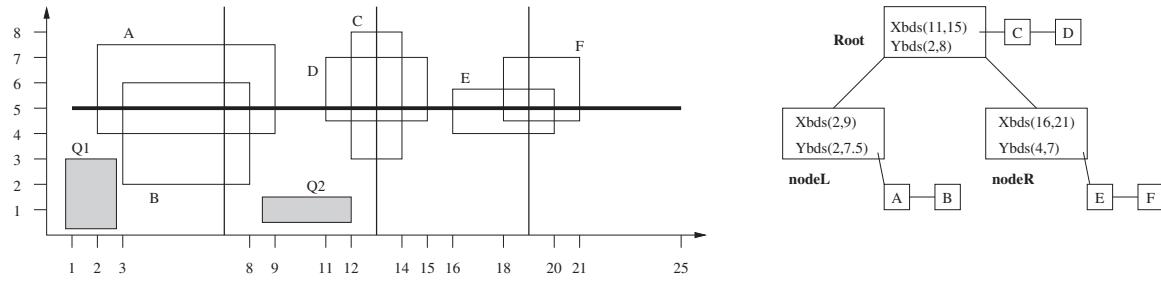

FIGURE 53.14 Bisector list implementation in HVT. All rectangles intersect the thick horizontal bisector line ($y = 5$). The first vertical cutline at $x = 13$ corresponding to the root of the tree intersects rectangles C and D. These rectangles are stored in a linked list at the root. Rectangles A and B are to the left of the vertical cutline and are stored in the left subtree. Similarly, rectangles C and D are stored in the right subtree. The X bounds associated with the root node are obtained by examining the x coordinates of rectangles C and D, while its Y bounds are obtained by examining the y coordinates of all six rectangles stored in the tree. The two shaded rectangles are query rectangles. For Q1, the search will start at **Root**, but will not search the linked list with C and D because Q1's right side is to the left of **Root**'s lower x bound. The search will then examine **nodeL**, but not **nodeR**. For Q2, the search will avoid searching the bisector list entirely because its upper side is below **Root**'s lower bound.

53.6.6 HV Trees

Next, in 1993, Lai et al. [27] presented a variation that once again uses bisector lists. It overcomes some of the inefficiencies of the original BLQT by a tighter implementation: An HV Tree consists of alternate levels of H-nodes and V-nodes. An H node splits the space assigned to it into two halves with a horizontal bisector while a V-node does the same by using a vertical bisector. A node is not split if the number of rectangles assigned to it is less than some fixed threshold.

Rectangles intersecting an H node's horizontal bisector are stored in the node's bisector list. Bisector lists are implemented using cut trees. A vertical cutline divides the horizontal bisector into two halves. All rectangles that intersect this vertical cutline are stored in the root of the cut tree. All rectangles to the left of the cutline are recursively stored in the left subtree and all rectangles to the right are recursively stored in the right subtree. So far, the data structure is identical to Kedem's binary tree implementation of the bisector list. In addition to maintaining a list of rectangles intersecting a vertical cutline at the corresponding node n , the HV tree also maintains four additional bounds which significantly improve performance of the Region Search operation. The bounds y_{upper_bound} and y_{lower_bound} are the maximum and minimum y coordinates of *any of the rectangles stored in n or in any of n 's descendants*. The bounds x_{lower_bound} and x_{upper_bound} are the minimum and maximum x coordinates of the rectangles stored in node n . Figure 53.14 illustrates these concepts. Comprehensive experimental results comparing HVT with BQT, kD, and QLQT showed that the data structures ordered from best to worst in terms of space requirements were HVT, BQT, kD, and QLQT. In terms of speed, the best data structures were HVT and QLQT followed by BQT and finally kD.

53.6.7 Hinted Quad Trees

In 1997, Lai et al. [28] described a variation of the QLQT that was specifically designed for design rule checking. Design-rule checking requires one to check rectangles in the vicinity of the query rectangle for possible violations. Previously, this was achieved by employing a traditional region query whose rectangle was the original query rectangle extended in all directions by a specified amount. Region searches start at the root of the tree and proceed down the tree as discussed previously. The hinted quadtree is based on the philosophy that it is wasteful to begin searching at the root, when, with an appropriate hint, the algorithm can start the search lower down in the tree. Two questions arise here: at which node should the search begin and how does the algorithm get to that node? The node at which the design rule check for rectangle r begins is called the *owner* of r . This is defined as the lowest node in the quad-tree that completely contains r expanded in all four directions. Since the type of r is known (e.g., whether it is n-type diffusion or metal), the amount by which r has to be expanded is also known in advance. Clearly, any rectangle that intersects the expanded r must be referenced by at least one leaf in the owner node's subtree. The owner node may be reached by following parent pointers from the rectangle. However, this could be expensive. Consequently, in HQT, each rectangle maintains a pointer to the owner virtually eliminating the cost of getting to that node. Although this is the main contribution of the HQT, there are additional implementation improvements over the underlying QLQT that are used to speed up the data structure. First, the HQT resolves the situation where the boundary of a rectangle stored in the data structure or a query rectangle coincides with that of a quad. Second, HQT sorts the four lists of rectangles stored in each leaf node with one of their x or y coordinates as keys. This reduces the search time at the leaves and consequently makes it possible to use a higher threshold than that used in QLQT.

Experimental results showed that HQT out-performs QLQT, BQT, HVT, and k -d on neighbor-search queries by at least 20%. However, its build-time and space requirements were not as good as some of the other data structures.

53.7 Concluding Remarks

Most of the research in VLSI layout data structures was carried out in the early 80s through the mid-90s. This area has not been very active since then. One reason is that there continue to be several important challenges in VLSI physical design automation that must be addressed quickly so that physical design does not become a bottleneck to the continuing advances in semiconductors predicted by Moore's Law. These challenges require physical design tools to consider "deep sub-micron effects" into account and take priority over data structure improvements. The implication of these effects is that problems in VLSI physical design are no longer purely geometric, but rather need to merge geometry with electronics. For example, in the early 1980s, one could safely use the length of a wire to estimate the delay of a signal traveling along it. This is no longer true for the majority of designs. Thus, the delay of a signal along the wire must now be estimated by factoring in its resistance and capacitance, in addition to its geometry. On the other hand, the more detailed computations of electronic quantities like capacitance, resistance, and inductance require the underlying data structures to support more complex operations. Thus, the author believes that there remain opportunities for developing better layout data structures. Another area that, to the best of our knowledge, has been neglected in the academic literature is that VLSI layout data needs to be efficiently stored in secondary storage because of its sheer size. Thus, although there is potential for academic research in this area, we believe that the design automation industry may well have addressed these issues in their proprietary software.

Unlike corner stitching, quad-trees permit rectangles to overlap. This addresses the problem that corner stitching has with handling multiple layers. On the other hand, corner stitching was designed for use in the context of an interactive layout editor, whereas quad trees are designed in the context of batched operations. We note that, to our knowledge, relatively recent data structures such as R trees have not been used for VLSI layout. It is unclear what the outcome of this comparison will be. On one hand, R-trees are considered to be faster than quad trees. On the other, the quad-trees developed in VLSI have been improved and optimized significantly as we have seen in this chapter. Also, VLSI data has generally been considered to consist of uniformly small rectangles, which may make it particularly suitable for quad trees, although this property may not be true when wires are considered.

54.1 Introduction

There are two main data models that can be used for representing floorplans: graph-based and placement based [23–29].

The graph-based approach includes constraint graphs, corner stitching, twin binary tree, and O-tree. They utilize constraint graphs or their simplified versions directly for the encoding. Constraint graphs are basic representations. The corner stitching simplifies the constraint graph by recording only the four neighboring blocks to each block. The twin binary tree then reduces the recorded information to only two neighbors of each block, and organizes the neighborhood relations in a pair of binary trees. The O-tree is a further simplification to the twin binary tree. It keeps only one tree for encoding.

The placement-based representations use the relative positions between blocks in a placement for encoding. This category includes sequence pair, bounded-sliceline grid, corner block list and slicing trees. The sequence pair and bounded-sliceline grid can be applied to general floorplan. The corner block list records only the relative position of adjacent blocks, and is available to mosaic floorplan only. The slicing trees are for slicing floorplan, which is a type of mosaic floorplan. The slicing floorplan can be constructed by hierarchical horizontal or vertical merges and thus can be captured by a binary tree structure known as the slicing tree.

The rest of this chapter is organized as follows. In Section 54.1, we give the introduction and the problem statement of floorplanning. In Section 54.2, we discuss the graph-based representations. In Section 54.3, we introduce the placement-based representations. We describe the relationship between different representations in Section 54.4. We illustrate the shape handling of rectilinear blocks in Section 54.5 and summarize the chapter in Section 54.6.

54.1.1 Statement of Floorplanning Problem

Today's complexity in circuitry design wants a hierarchical approach [1]. The entire circuit is partitioned into several sub-circuits, and the sub-circuits are further partitioned into smaller sub-circuits, until they are small enough to be handled. The relationship between the sub-circuits can be represented with a tree as shown in Figure 54.1. Here every sub-circuit is called a block, and hence

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

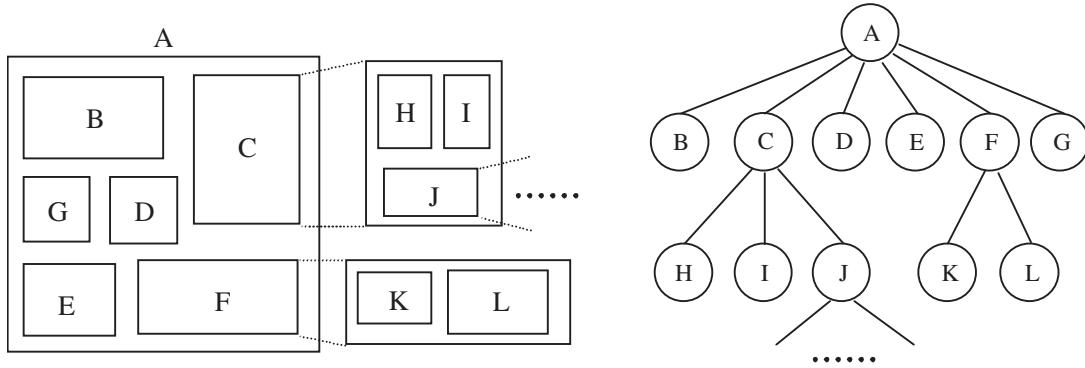

FIGURE 54.1 Hierarchical structure of blocks.

the entire circuit is called the top block. From the layout point of view, every block corresponds to a rectangle, which contains sub-blocks or directly standard cells. Among the decisions to be made is the determination of shape (aspect ratio) and the pin positions on the blocks. In the top-down hierarchical methodology, blocks are designed from the top block (the entire circuit) to the leaf blocks (small modules). The minimizations of chip area and wire length are the basic targets for any layout algorithm. In addition, there are case-dependent constraints that will influence the layouts, such as the performance, the upper or/and lower boundaries of aspect ratio, the directions of pins, etc.

Now we give the definition of floorplanning problem:

Inputs:

1. The net-lists of the sub-circuits;
2. The area estimation of blocks and, if any, the aspect ratio constraints on the blocks;
3. The target area and shape of the entire chip.

Outputs:

1. The shapes and positions of blocks;
2. The pin positions on the blocks.

The objective functions involve: the chip area, the total wire length and, if any, the performances.

54.1.2 Motivation of the Representation

Floorplan representation becomes an important issue in floorplanning for the following reasons.

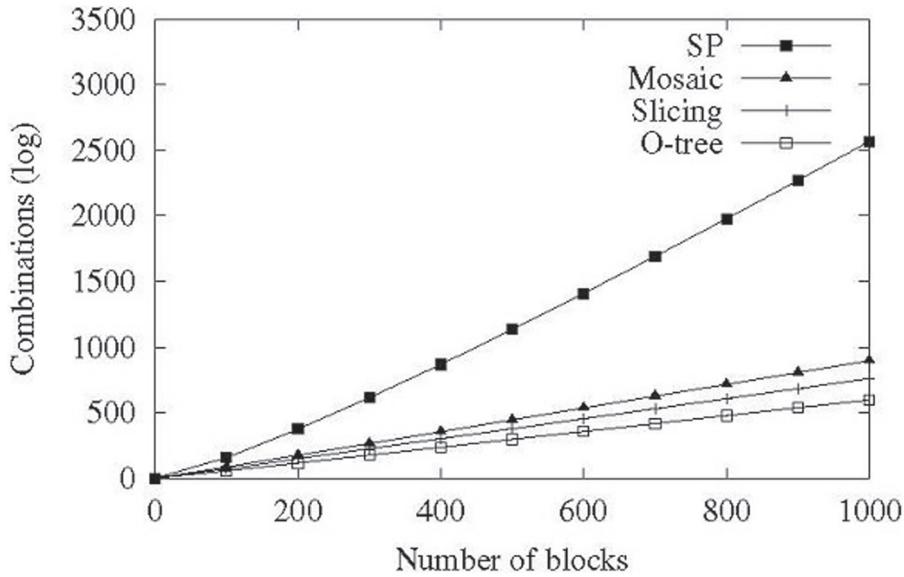

1. The blocks may have arbitrary shapes and locations, while the size of memory used to represent a two-dimensional floorplan should be $O(n)$.
2. For the general floorplanning problem, iterative improvement is the commonly used approach. The search for the best solution has proven to be NP-complete, so many heuristic optimizing algorithms, such as dynamic programming, simulated annealing, zone refinement, cluster refinement, have been adopted. The representation should also facilitate the operations called by those optimizing algorithms.
3. The storage resources requirement, the redundancy of the representation and the complexity of translating the representation into floorplan are always the concerns in floorplanning. Here redundancy refers to the situation that several different expressions actually correspond to the same physical layout. Essentially, a heuristic algorithm searches part of the solution space to find the local optimal solution, which is hopefully very close to the global optimal solution. Redundancy causes the optimizing algorithm evaluate the same floorplan repeatedly.

54.1.3 Combinations and Complexities of the Various Representations

The number of possible floorplan representations describes how large the searching space is. It also discloses the redundancy of the representation. For general floorplans with n blocks, the combinations of the various representations are listed in Table 54.1. Note that the twin binary tree representation has a one to one relation with the mosaic floorplan, and the slicing tree has a one to one relation with the slicing floorplan [2]. In other words, for these two representations, the number of combinations is equal to the number of possible floorplan configurations and there is no redundancy.

TABLE 54.1 Combinations of the Representations

Representation	Combinations
Twin binary tree	$n!^*B(n)$, where $B(n) = \binom{n+1}{1}^{-1} \binom{n+1}{2}^{-1} \sum_{k=1}^n \binom{n+1}{k-1} \binom{n+1}{k} \binom{n+1}{k+1}$
O-Tree	$O(n!2^{2n-2}/n^{1.5})$
Sequence pair	$(n!)^2$
Bounded-sliceline grid	$n! \binom{n^2}{n}$
Corner block list	$O(n!2^{3n-3}/n^{1.5})$
Slicing tree	$n!^*A(n-1)$, where $A(n)$ is the super-Catalan number with the following definition: $A(0) = A(1) = 1$ and $A(n) = (3(2n-3)A(n-1) - (n-3)A(n-2))/n$

**FIGURE 54.2** Combination of floorplans and representations.

The combination numbers of sequence pairs, mosaic floorplans, slicing floorplans, and O-trees are illustrated on a log scale in Figure 54.2. The combination numbers are normalized by $n!$, which is the number of permutations of n blocks. The slopes of the lines for mosaic floorplans, slicing floorplans, and O-tree structures are the constants 0.89, 0.76, and 0.59, respectively. On the other hand, the slope of the line for sequence pair increases with a rate of $\log n$. Table 54.2 provides the exact numbers of the combinations for the floorplans or representations with the block number ranging from 1 to 17.

The time complexities of the operations transforming a representation to a floorplan are very important, because they determine the efficiency of the floorplan optimizations. The complexities of the representations covered in this chapter are compared in Table 54.3, where n is the number of blocks in a floorplan.

For sequence-pair, the time complexity to derive a floorplan is $O(n \log \log n)$ due to a fast algorithm proposed in Reference 3. We will discuss more on this in Section 54.3.1. For bounded slicing grid, there is a trade off between the solution space and the time complexity of deriving a floorplan. To ensure that the solution space covers all the optimal solutions, we need the grid size to be at least n by n . This results in an $O(n^2)$ time complexity in deriving a floorplan [4]. For the rest of the representations, there are algorithms with $O(n)$ time complexity to convert them into constraint graphs. The time complexity to derive a floorplan is thus $O(n)$.

54.1.4 Slicing, Mosaic, LB Compact, and General Floorplans

A layout can be classified as a slicing floorplan if we can partition the chip with recursive horizontal or vertical cut lines (Figure 54.3a). In a mosaic floorplan, the chip is partitioned by horizontal and vertical segments into rectangular regions and each region corresponds to exactly one block (Figure 54.3b). For a general floorplan, we may find empty space outside rectangular block

TABLE 54.2 Exact Number of Combinations of Different Floorplan Configurations and Representations

regions ([Figure 54.3c](#)). An LB-compact floorplan is a restricted general floorplan in that all blocks are shifted to their left and bottom limits. In summary, the set of general floorplans covers the set of LB-compact floorplans, which covers the set of mosaic floorplans, and which covers the set of slicing floorplans ([Figure 54.4](#)).

For slicing and mosaic floorplans, the vertical segments define the left-right relation among the separated regions, and the horizontal segments define the above-below relation. Suppose that we shift the segments to change the sizes of the regions, we view the new floorplan to be equivalent to the original floorplan in terms of their topologies [5–7]. Therefore, we can devise representations to define the topologies of slicing and mosaic floorplans independent of the sizes of the blocks ([Figure 54.3a and b](#)).

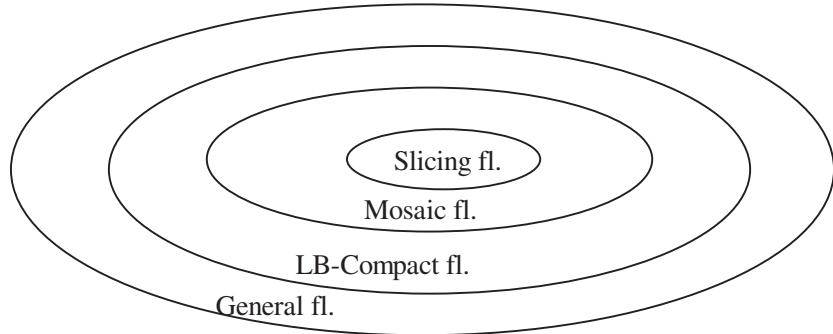

FIGURE 54.4 Set coverage of slicing floorplan, mosaic floorplans, LB-compact floorplans and general floorplans.

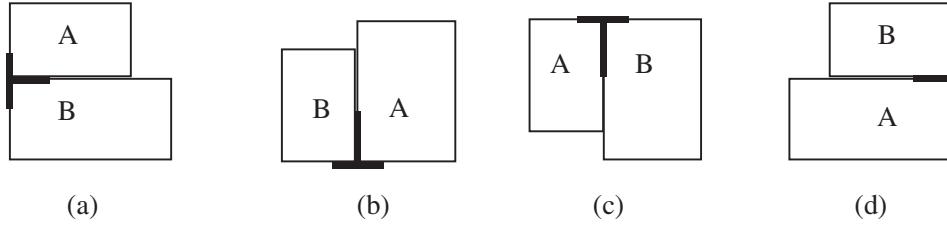

FIGURE 54.5 Four directions of T-junctions.

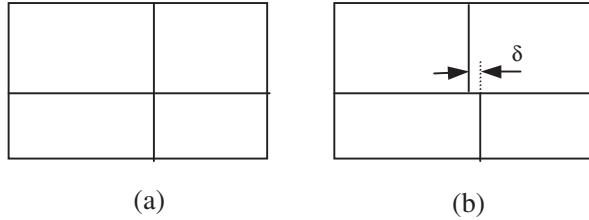

FIGURE 54.6 Degeneration.

In contrast, for a general floorplan, it is rather difficult to draw a meaningful layout (Figure 54.3c) without the knowledge of the block dimensions. One approach is to extend the mosaic floorplans to general floorplans by adding empty blocks [8]. It is shown that to convert a mosaic floorplan with n blocks into a general floorplan, the upper bound on the number of empty blocks inserted is $n - 2\sqrt{n} + 1$. [8]

In a mosaic floorplan, two adjacent blocks meet at a T-junction by sharing the non-crossing edge of the junction. There are four directions of T-junctions as is illustrated in Figure 54.5. In the case of Figure 54.5a and b, block B is termed the C-neighbor at the lower left corner of block A. In Figure 54.5c and d, block B is the C-neighbor at the upper right corner of block A. The C-neighbor is used to construct twin binary tree representation.

The degeneration of a mosaic floorplan refers to the phenomenon that two T-junctions meet together to make up a cross-junction, as illustrated in Figure 54.6a. Some representations forbid the occurrence of degeneration. One scheme to solve the problem is to break one of the intersecting lines and assume a slight shift between the two segments, as shown in Figure 54.6b. Thus the degeneration disappears.

We generate an LB compact floorplan by compacting all blocks toward left and bottom. For a placement, suppose no block can be moved left, the placement is called L-compact. Similarly, if no block can be moved down, the placement is called B-compact. A floorplan is LB-compact if it is both L-compact and B-compact (Figure 54.7).

54.2 Graph Based Representations

Graph based representations include constraint graphs, corner stitching, twin binary trees, and O-tree. They all utilize the constraint graphs or their simplified version for floorplan encoding.

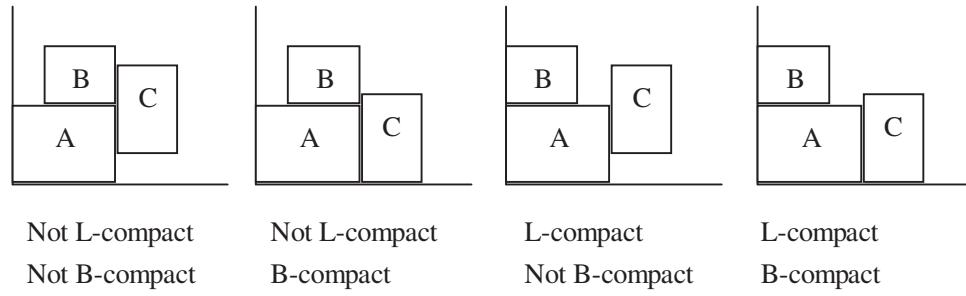

FIGURE 54.7 Examples of L-compact and B-compact.

54.2.1 Constraint Graphs

Constraint graphs are directed acyclic graphs representing the adjacency relations between the blocks in a floorplan. In this subsection, we first define the constraint graphs for general floorplans. We then show that for mosaic floorplans, the constraint graphs have nice properties of triangulation and duality.

54.2.1.1 The Generation of Constraint Graphs

Constraint graphs reflect the relative positions between blocks [9]. Constraint graphs can be applied to general floorplans, as is shown in Figure 54.8. A node in the constraint graph represents a block. A directed edge denotes the location relationship between two blocks. For example, $A \rightarrow B$ means block A is to the left of B in a horizontal constraint graph (Figure 54.8b). $A \rightarrow E$ means block A is on top of E in a vertical constraint graph (Figure 54.8c). Here we imply that if $A \rightarrow B$ and $B \rightarrow C$, then $A \rightarrow C$. Thus even though block A stands to the left of C, the edge between A and C is not necessarily shown. To mark the four sides of the chip, we add the nodes labeled with “left,” “right,” “top” and “down.” A pair of horizontal and vertical constraints graphs can represent a floorplan. Every constraint graph, whether it is a horizontal one or a vertical one, is planar and acyclic. Figure 54.9 shows an example of the constraint graphs to a mosaic floorplan. Figure 54.9a is the mosaic floorplan. Figure 54.9b and c are the corresponding horizontal and vertical constraint graphs, respectively.

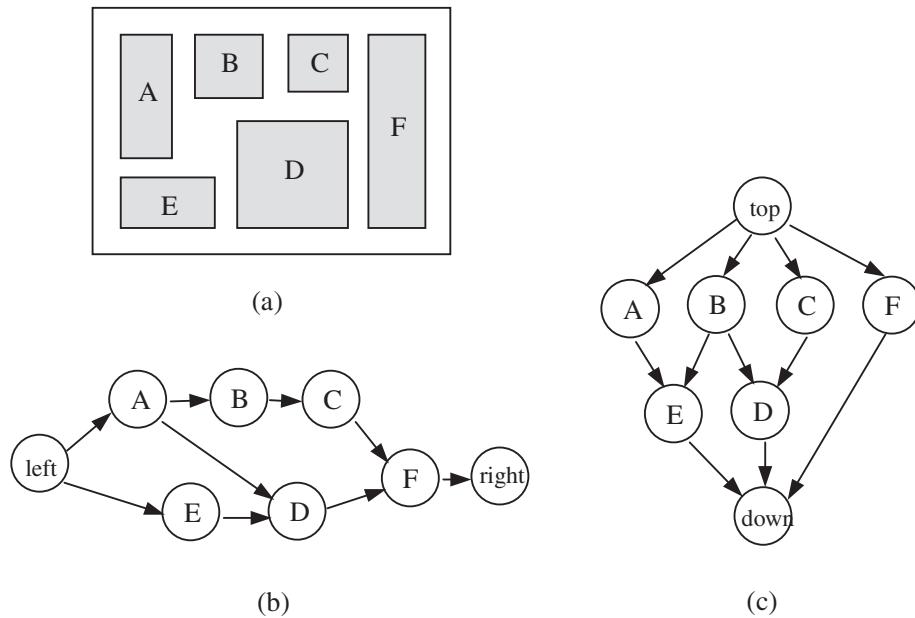

FIGURE 54.8 Constraint graphs for a general floorplan.

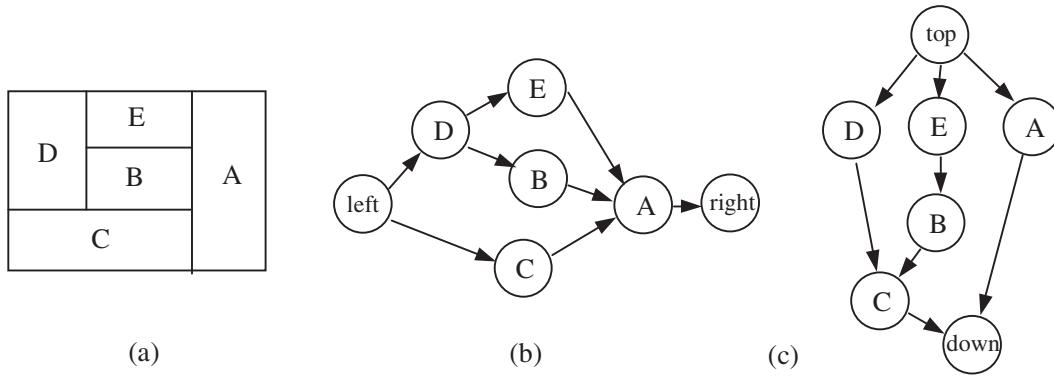

FIGURE 54.9 Constraint graphs for a mosaic floorplan.

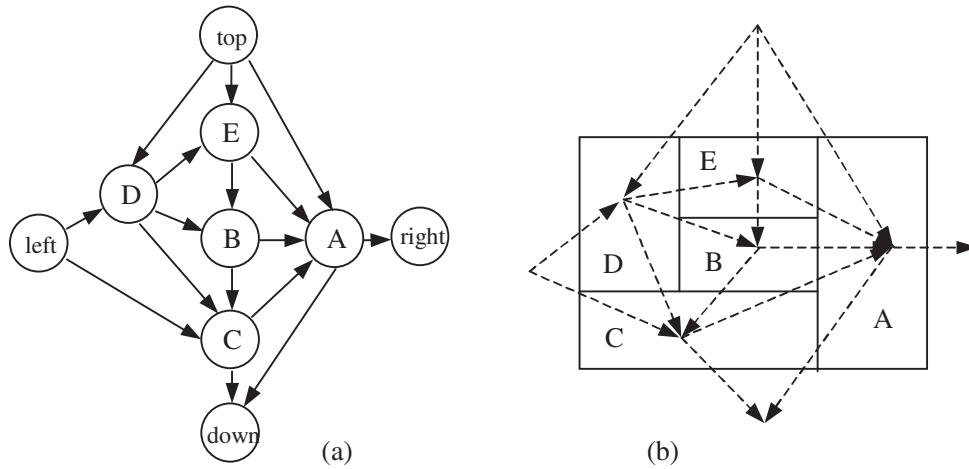

FIGURE 54.10 Triangulation.

54.2.1.2 Triangulation

For a mosaic floorplan without degeneration, if its horizontal and vertical constraint graphs are merged together, then we have the following conclusions [9]:

1. Every face is a triangle.
2. All internal nodes have a degree of at least 4.
3. All cycles, if not faces, have the length of at least 4.

Shown in Figure 54.10a is the result of merging the pair of constraint graphs in Figure 54.9. In fact, the merged constraint graph is a dual graph of its original floorplan (Figure 54.9b).

54.2.1.3 Tutte's Duality [10]

We can also build an edge-based constraint graph for a mosaic floorplan, where the nodes denote the lines separating the blocks while the edges denote the blocks. Labeling the lines with numbers (Figure 54.11a), we build a vertical constraint graph (Figure 54.11b) and a horizontal constraint graph (Figure 54.11c). Figure 54.11d demonstrates the result of merging the vertical and horizontal constraint graphs. Here, to make the merged graph clear, the edges representing horizontal constraints are drawn with dotted lines, and a letter at the intersection of a solid edge and a dotted edge denotes the two edges simultaneously. It is very interesting that, for mosaic floorplans, the vertical and horizontal constraint graphs are dual, as is called Tutte's duality.

Let's see how Tutte's duality is used to solve the sizing problem in floorplanning. We map the constraint graphs into circuit diagrams by replacing the edges in the vertical constraint graph with resistors, as illustrated in Figure 54.12.

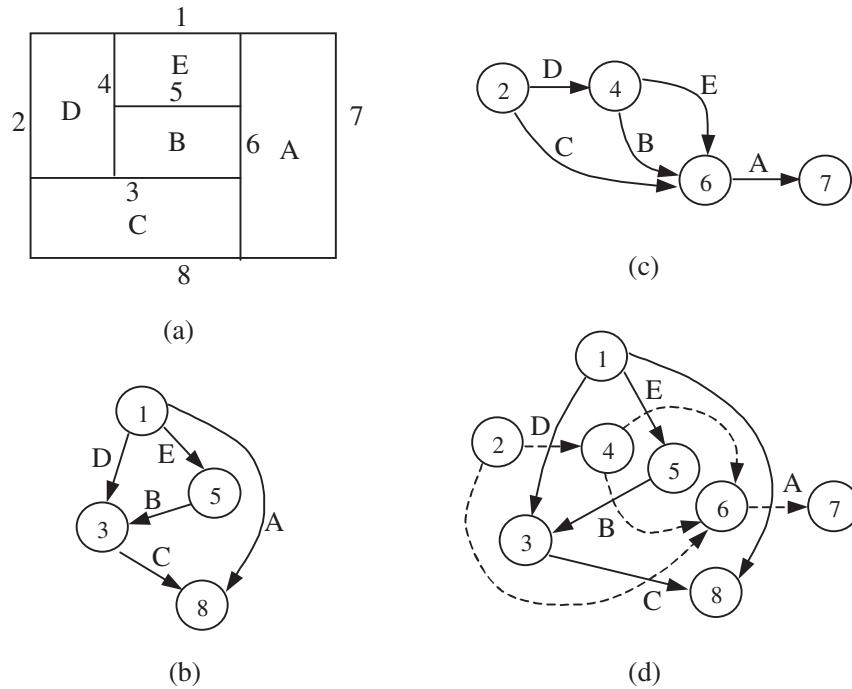

FIGURE 54.11 Line-based constraint graphs.

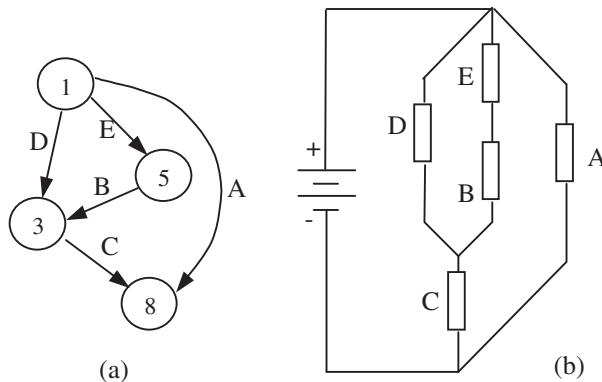

FIGURE 54.12 Mapping a constraint graph to a circuit.

The circuit is subject to Kirchoff voltage law. As a result, taking Figure 54.12 as an example, we have:

$$\begin{aligned}
 V_E + V_B &= V_D & I_E &= I_B \\
 V_D + V_C &= V_A & I_E + I_D &= I_C \\
 V_A &= V_{source} & I_C + I_A &= I_{source} \\
 R_i = \frac{V_i}{I_i}, \quad i \in \{A, B, C, D, E\}
 \end{aligned}$$

Note that, if we denote the height and the width of block i to be H_i and W_i , we have (refer to Figure 54.12a):

$$\begin{aligned}
 H_E + H_B &= H_D & W_E &= W_B \\
 H_D + H_C &= H_A & W_E + W_D &= W_C \\
 H_A &= H_{chip} & W_C + W_A &= W_{chip} \\
 AspectRatio_i = \frac{H_i}{W_i}, \quad i \in \{A, B, C, D, E\}
 \end{aligned}$$

By comparing the above two equation arrays, we can find that there is a perfect correspondence between the solutions of the circuit and the floorplan. Let us set the following assumptions: (only two of the three equations are independent)

$$\begin{aligned} R_i &= \text{AspectRatio}, \\ V_{\text{source}} &= H_{\text{chip}} \\ I_{\text{source}} &= W_{\text{chip}} \end{aligned}$$

Then we have:

$$\begin{aligned} V_i &= H_i \\ I_i &= W_i \end{aligned}$$

Thus the theories dealing with large circuits can be borrowed to solve the sizing problem in floorplanning.

Constraint graphs have the advantages of being able to cope with any types of floorplans. However, it would be rather difficult to shift to a new floorplan with just a few simple operations on the graph. The efficiency is greatly discounted for the iteratively improving algorithms. Thus in Reference 11, a transitive closure graph (TCG) was proposed to simplify the rules of the operations. The relation of each pair of blocks is prescribed in either horizontal or vertical constraint graph via transitive closure, but not in both graphs.

54.2.2 Corner Stitching

Corner stitching is used to represent the topology of a mosaic floorplan. Simplified from constraint graphs, corner stitching [12] keeps only four pointers at the two opposite corners for every block. All the operations on a constraint graph can also be fulfilled on a corner stitching representation with acceptable increases in time complexity, while the storage for corner stitching becomes easier since the number of pointers attached to every block is fixed (equals to 4). Readers are referred to Chapter 53 for detailed descriptions and analyses of corner stitching.

54.2.3 Twin Binary Tree

Twin binary tree [2] representation applies to mosaic floorplans without degeneration. The twin binary tree is constructed as follows, every block takes its C-neighbor (Figure 54.5) as its parent. In the first tree, only the C-neighbors in lower left corners (Figure 54.5a and b) are taken into account. If the related T-junction is of type (a), then the block is a left child of its parent, and if the T-junction is of type (b), then the block is a right child. The most bottom-left block in the floorplan acts as the root of the tree. Similarly, in the second tree, the C-neighbors in upper right corners (Figure 54.12c and d) are used, and the most upper-right block becomes the tree's root. Figure 54.13 gives an example of a twin binary tree.

The pointers of twin binary trees are in fact a subset of those in corner stitching. Besides, It has been proved that twin binary tree is a non-redundant representation. In other words, every pair of trees corresponds to a unique mosaic floorplan.

The twin properties of binary trees can be illustrated with Figure 54.14. Consider the trees shown in Figure 54.13, we add a left child labeled "0" to every node without left child except the most left node, and a right child labeled "1" to every node without right child except the most right node. The resultant trees are the so-called extended trees (Figure 54.14). The sequences of the in-order traverse of the two extended trees shown in Figure 54.14 are "A0B1C1F0D1E" and "A1B0C0F1D0E" respectively. If we separate them into the label parts and the bit parts, we have $\pi_1 = ABCFDE$, $\alpha_1 = 01101$, $\pi_2 = ABCFDE$ and $\alpha_2 = 10010$. It is interesting to find that $\pi_1 = \pi_2$ and $\alpha_1 = \bar{\alpha}_2$. So rather than store the two binary trees, we only keep the linear lists π and α in memory.

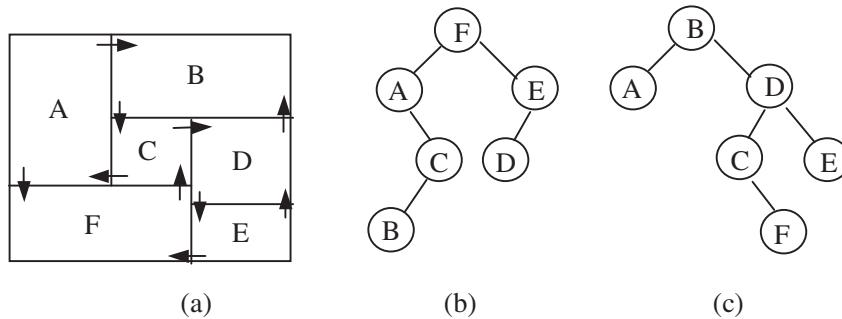

FIGURE 54.13 Twin binary tree.

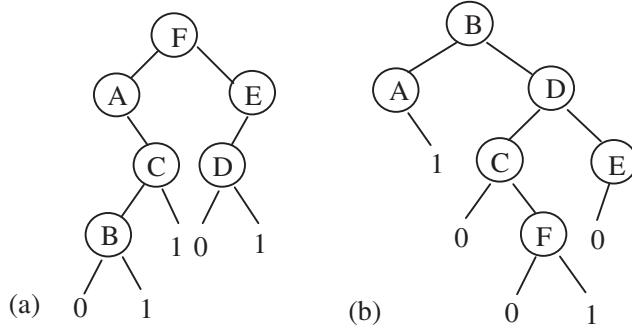

FIGURE 54.14 Extended trees.

However, it is insufficient to recover the two binary trees just from π and α , so we need two more lists, β and β' . If the i -th element in π is the left child of its parent in the first tree or the root of the tree, we set the i -th element in β to be “0,” otherwise we set it “1.” In the similar way β' is constructed according to the second tree. Thus we use a group of linear lists $\{\pi, \alpha, \beta, \beta'\}$, called the twin binary sequence [8], to express the twin binary tree, and equivalently the floorplan.

Finally, we give the main properties of twin binary tree representation:

1. The memory required for storing the twin binary sequence is $\log_2 n + 3n - 1$, because $|\pi| = \log_2 n$, $|\alpha| = n - 1$, and $|\beta| = |\beta'| = n$.
2. Twin binary tree is a non-redundancy floorplan representation.
3. The complexity of the translation between twin binary sequence and floorplan is $O(n)$.

54.2.4 Single Tree Representations

An ordered-tree (O-tree) [13,14], or equivalently the B^* tree [15] representation uses a spanning tree of the constraint graph and the dimensions of the blocks. Because the widths and heights of the blocks are given, the representation can describe one kind of general floorplan termed LB-compact. With a proper encoding, a great enhancement on the storage efficiency and the perturbation easiness is obtained.

A horizontal O-tree is derived with the following rules:

1. If block A lies adjacent to the left side of block B, or, $X_a + W_a = X_b$ (here X_a is the coordinate of block A on the X-axis and W_a is the width of block A), then on the O-tree, B is A's child. If there happens to exist more than one block adjacent to the left side of block B (satisfying the requirement $X_i + W_i = X_b$), one of them is assigned to be the parent of block B.
2. If block A lies on top of block B and the two blocks have the same parents on the O-tree, then B is A's elder brother.
3. A virtual block is presumed to have the left most position, and therefore serves as the root of the O-tree.

Figure 54.15 shows an example of an O-tree representation for the same mosaic floorplan shown in Figure 54.13. If we show the pointer of every block pointing to its parent in the O-tree (Figure 54.15b), we can find that the pointers are in fact a subset of those in twin binary tree. Similarly a vertical O-tree can be built up. Without the loss of generality, hereafter we only discuss the horizontal O-tree.

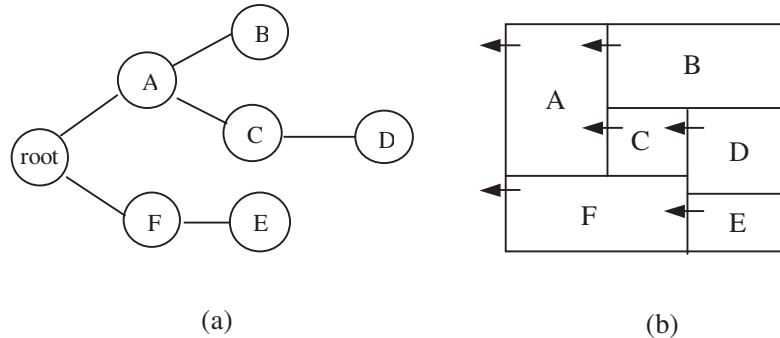

FIGURE 54.15 Building an O-tree.

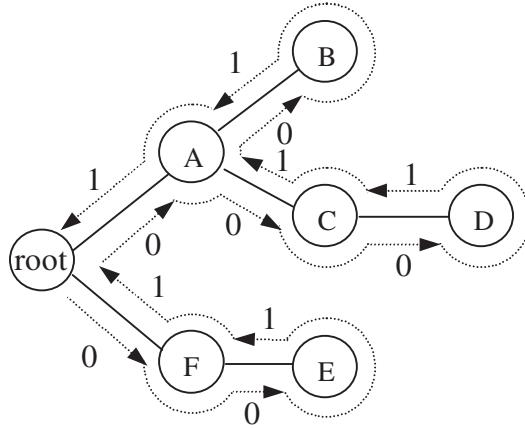

FIGURE 54.16 Derivation of T, π .

Next, let's describe the O-tree with linear lists: a bit string (denoted with T) and a label string (denoted with π). The bit string records the structure of an O-tree. We make a depth-first traverse on the O-tree. A "0" is inserted into T for descending an edge while a "1" for ascending an edge. For example, the O-tree in Figure 54.16 corresponds to the bit string $T = "001100011011"$. Inversely, given the bit string, the structure of the O-tree is solely determined. To get the complete description of an O-tree, we need a second linear list, the label string, to record the labels of the tree's nodes. Not only should the label string include all the labels of the tree's nodes, but also reflect the labels' positions on the tree. A depth-first traverse generates such a linear list. For the example in Figure 54.16, we have $\pi = "FEACDB"$.

Given a horizontal O-tree, or $\{T, \pi\}$, and the dimensions of blocks, the positions of blocks can be derived with the following rules:

1. Each block has to be placed to the left of its children.
2. If two blocks overlap along their x-coordinate projection, then the block having a higher index in π must be placed on top of the other one.

In fact the second rule applies to the situation in which none of the two blocks is a descendant of the other, like blocks " f " and " a ," or " b " and " d ," in Figure 54.16. The way we derive π indicates that the block with higher index always stands "higher." To get to a placement, we need to locate all the blocks. The following operation is executed on blocks according to their orders in π . Here B_i refers to the i -th block, and (x_i, y_i) refers to the coordinate of B_i 's left-bottom corner.

1. Find B_i 's parent, B_j , and then we have $x_i = x_j + w_j$, here w_j is the width of block B_j .
2. Let ψ be a set of blocks who have a lower index than B_i in π and have an projection overlap with B_i in the X-axis, find the maximum $y_k + w_k$ for $B_k \in \psi$, then we have $y_i = \max(y_k + w_k)$.

Now we analyze the performance of O-tree:

1. The bit string has a length of $2n$ for an O-tree of n blocks, because each node except the root has an edge towards its parents and each edge is traversed twice during the construction of the bit string. The label string takes $n \log_2 n$ bits for we have to use $\log_2 n$ bits to distinguish the n blocks. So the total memory occupied by an O-tree is $n(2 + \log_2 n)$. By comparison, a sequence pair takes $2n \log_2 n$ bits and a slicing structure takes $n(6 + \log_2 n)$ bits.
2. The time needed to transform $\{T, \pi\}$ to a placement is linear to the number of blocks, or we can say the complexity of transforming $\{T, \pi\}$ to a placement is $O(n)$. For a sequence pair or a slicing structure, the complexity is $O(n \log_2 \log_2 n)$ or $O(n)$ respectively. Upon this point, O-tree has the same performance as the slicing structure but is more powerful for representing a placement.
3. The number of combinations is $O(n! \cdot 2^{2n-2} / n^{1.5})$, which is smaller than any other representation that has ever been discussed.

The floorplan of an arbitrarily given O-tree is not necessarily LB-compact. Yet in this case, we can compact the floorplan to reduce the chip area. Notice that an O-tree-to-placement transform tightens the blocks, with one direction having the priority. For example, in a placement transformed from a horizontal O-tree, the blocks are placed tighter along the X-axis than along the Y-axis. It would be undoubted that a placement transformed from a vertical O-tree will give Y-axis the priority. Thus, by

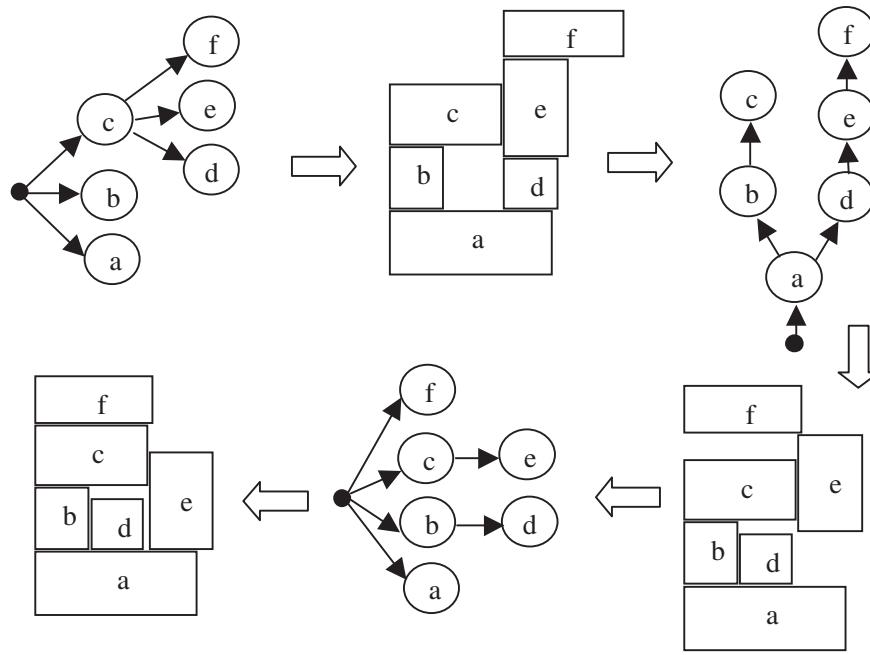

FIGURE 54.17 Transformation between horizontal and vertical O-trees.

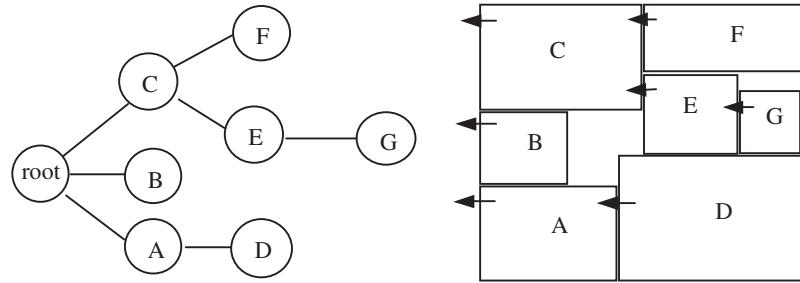

FIGURE 54.18 An O-tree representation of a general floorplan.

iteratively making the transforms between horizontal O-trees and vertical O-trees via placements, we can finally reach an LB-compact floorplan (Figure 54.17).

On the other hand, given an LB-compact floorplan, we can always derive an O-tree representation. For example, Figure 54.18 illustrates a general floorplan with seven blocks and the corresponding O-tree. O-tree is able to cover LB-compact floorplan with the smallest number of combinations in Table 54.1 and Figure 54.2 because the O-tree structure avoids redundancy and screens improper floorplans by taking advantage of the knowledge of the block dimensions. For example, given an O-tree, we can convert it to a binary tree and find many other possible trees to pair up as twin binary trees, which correspond to many different mosaic floorplans. In the perspective of O-tree representation, these floorplans are the variations due to the differences of the block sizes.

The B* tree and the O-tree are equivalent because the transformation between the two is one to one mapping. The merit of the B tree is a different data structure and implementation.

In summary, among the constraint-graphs based representations, from the point of view of the pointers necessary for representing the floorplans, O-tree is a subset of twin binary tree; twin binary is a subset of corner stitching; and corner stitching is a subset of constraint graphs, as demonstrated in Figure 54.19.

54.3 Placement Based Representations

The placement-based representations include sequence pair, bounded-sliceline grid, corner block list and slicing tree. With the dimensions of all the blocks known, the sequence pair and bounded-sliceline grid can be applied to general floorplans. The corner

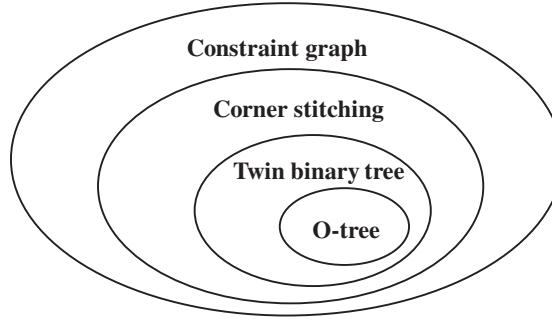

FIGURE 54.19 Relationship between the constraint graph based representation.

block list records the relative position of adjacent blocks, and is applicable to mosaic floorplan only. The slicing tree is for slicing floorplan, which is a special case of mosaic floorplan.

54.3.1 Sequence-Pair

Sequence-pair expresses the topological positions of blocks with a pair of block lists [16,17]. For each pair of blocks, there are four possible relations, left-right, right-left, above-below, and below-above. We use a pair of sequences $\{\pi_1, \pi_2\}$ to record the order of the two blocks. We can record two blocks A, B in four different orders: (AB, AB), (AB, BA), (BA, AB), (BA, BA). Hence, we use the four orders to represent the four placement relations. Figure 54.20 shows the four possible relations between a pair of blocks A and B and the corresponding sequence pair for each relation.

The two sequences can be viewed as two coordinate systems that define a grid placement of the blocks. To see it more clearly, we construct a grid system illustrated in Figure 54.21. The slopes are denoted with the labels of blocks according to their orders in the two sequences. The intersections of two perpendicular lines that have the same label indicate the topological positions of the blocks.

The grid placement defines the floorplan relation between blocks. For each node in the grid placement, we divide the whole space into four quadrants, quadrant I: -45 to 45° , quadrant II: 45 – 135 , quadrant III: 135 – 225 , quadrant IV: 225 – 315 . Block B's floorplan relation with block A can be derived from block B's location in block A's quadrants.

1. Quadrant I: block B is on the right of block A
2. Quadrant II: block B is above block A

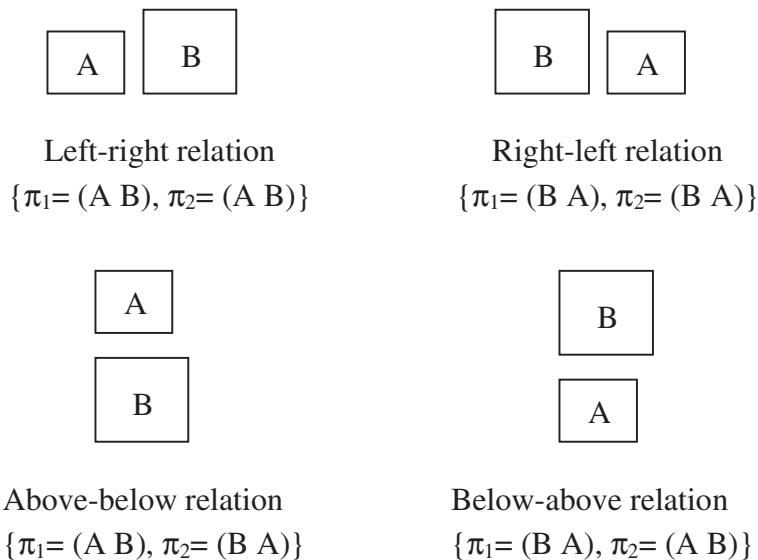

FIGURE 54.20 Four possible relations between a pair of blocks.

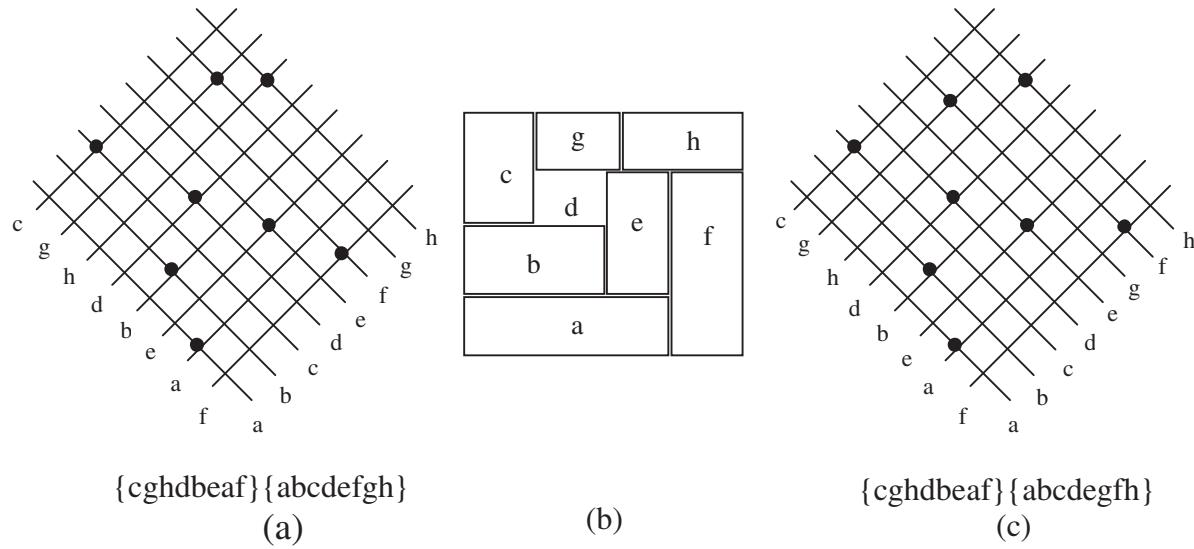

FIGURE 54.21 The grid system and the redundancy.

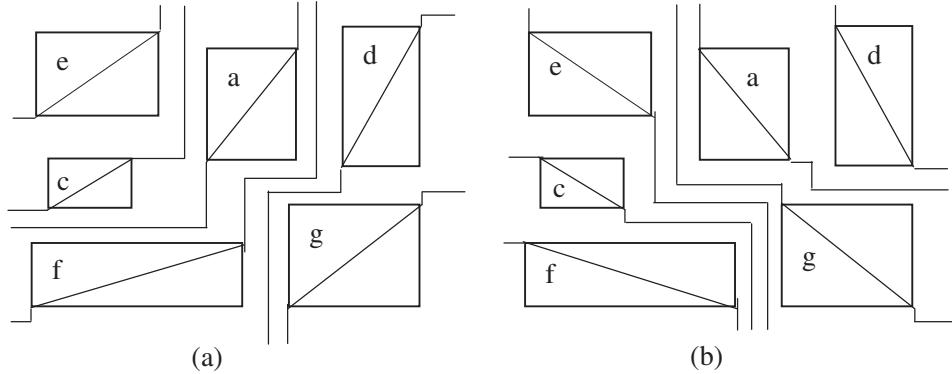

FIGURE 54.22 Derivation of sequence-pair.

3. Quadrant III: block B is on the left of block A
4. Quadrant IV: block B is below block A

For example, from the grid placement in Figure 54.22, using node d as a reference, blocks e and f are on the right of block d; blocks g and h are above; blocks c is on the left; and blocks a and b are below.

We can derive the sequence-pair from a floorplan by tracing the blocks through two directions. We first extend the boundary of each block by drawing lines from its four corners (Figure 54.22). In Figure 54.22a, we draw a line from the upper-right corner of each block that goes either rightward or upward. When the line is obstructed with a block or an already existing line, it changes its direction. The extension of the line ends when it reaches the boundary of the chip. We also draw a line from the lower-left corner of each block that goes either downwards or leftwards. The extended lines partition the chip into zones. Following the order of the zones, we get a label sequence. For instance, we have $\pi_1 = 'ecafdg'$ for Figure 54.22a. With similar operations, the second sequence is derived in the orthogonal direction ($\pi_2 = 'fciegad'$ in Figure 54.22b). π_1 and π_2 consist of a sequence-pair, which involves all the information of the topological positions of blocks.

For translating a sequence-pair into a topological floorplan with n blocks, a brute force implementation requires time complexity $O(n^2)$, since there are $O(n^2)$ pairs of blocks and we need to scan all the pairs to get the constraint graph and then derive the floorplan by performing a longest path computation. In Reference 3, a fast algorithm with $O(n \log n)$ time complexity is proposed to complete the transformation of a sequence pair to the floorplan. The fast algorithm takes advantage of the longest common sequence of the two sequences in a sequence-pair. They show that the longest common sequence calculation is equivalent to the longest path computation in the constraint graph for a sequence-pair. The authors use a priority queue data structure

to record the longest common sequence, thus reduce the time for calculating the position of a single block to $O(\log n)$ by amortizing.

The representation of a sequence-pair has the following properties:

1. The number of bits for storing a sequence-pair is $2n \log_2 n$, where n is the number of blocks in the placement.
2. The time complexity of translating a sequence-pair into a topological floorplan is $n \log_2 \log_2 n$ by the newest report.
3. There are totally $(n!)^2$ possible sequence-pairs for n blocks. However, there exists the redundancy. For example, the sequence-pairs in Figure 54.21a and c actually correspond to the same placement (Figure 54.21b).

54.3.2 Bounded-Sliceline Grid

Another method rising from the same idea as sequence-pair is BSG [4], where, instead of the intersections of grid lines, the squares surrounded by the grid lines, called rooms, are used to assign the blocks (Figure 54.23). Although put forward aiming at the packing problem, BSG can also act as a compacting algorithm to determine the accurate positions of blocks.

In BSG, grid lines are separated into vertical and horizontal segments (Figure 54.23). Two constraint graphs are set up with their vertexes corresponding to the grid segments and their directed edges corresponding to the relative positions of the grid segments (Figure 54.24). The vertexes “source” and “sink” are added to make the operation on the graph easy. Every room is crossed by one edge of the constraint graph (respectively in the vertical and horizontal constraint graphs). If the room is not empty, or there is a block assigned into the room, the crossing edge has a weight equal to the width (in the horizontal graph) or the height (in the vertical graph) of the assigned block, otherwise the crossing edge has a weight of zero. Figure 54.24 shows the weights derived from the example in Figure 54.23. By calculating the longest path lengths between the source and the other vertexes in the constraint graphs the real coordinates of the grid segments can be determined and in fact the translation to the placement is implemented. Table 54.4 gives the final results of the example in Figure 54.23 and Figure 54.24. Notice that segment (1, 3) and (2, 2) have the same position, for the edge between the two vertexes in the horizontal constraint graph has the weight of zero.

Due to the homology, BSG has the similar performance as sequence-pair, except that the complexity of the translation into placement, or finding the longest path lengths for all the vertexes in the constraint graphs, is $O(pq)$, provided that the grid array has p columns and q rows.

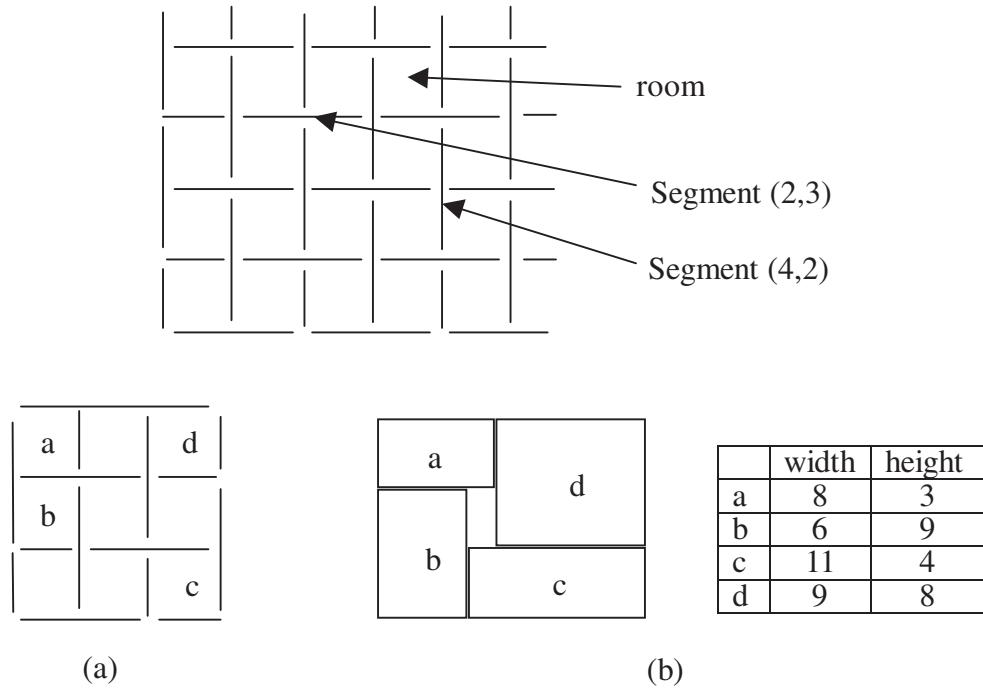

FIGURE 54.23 Basic structure of BSG.

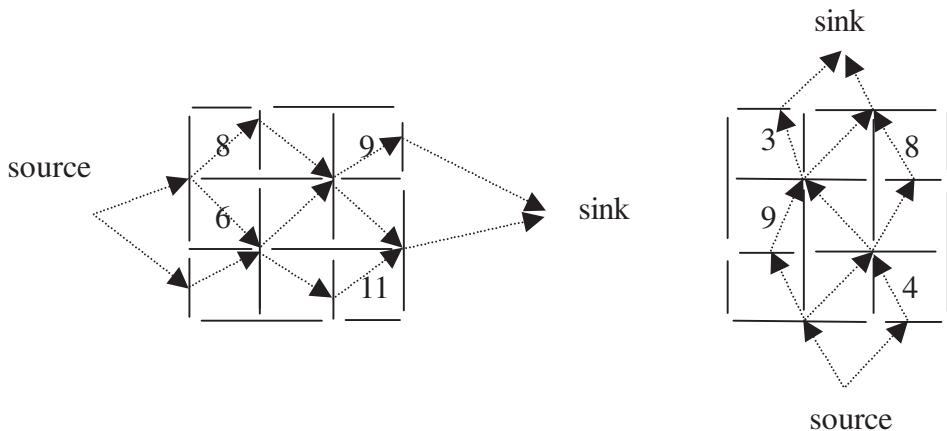

FIGURE 54.24 Constraint graphs.

TABLE 54.4 Physical Positions of Segments

Segment	0,1	1,1	0,2	1,2	1,3	0,3	2,2	2,3	3,3	3,2	2,1	2,0	3,1	3,0
Position (X or Y)	0 Y	6 X	0 X	9 Y	8 X	12 Y	8 X	12 Y	17 X	4 Y	4 Y	6 X	17 X	0 Y

54.3.3 Corner Block List

Corner block list is a third method of representing non-slicing structures [5,18,19]. Refer to Figure 54.25. The floorplan is required to be mosaic and without degeneration.

For every block, the T-junction at the bottom-left corner can be in either of the two directions. Accordingly we say the orientation of the block is 1 or 0 respectively. Now let's observe the most upper-right blocks in Figure 54.25a and (b), both denoted with "d." If we push the bottom boundary of block "d" in (a) upwards, or the left boundary in (b) rightwards, then block "d" is squeezed and finally deleted (Figure 54.25c and d), and thereafter block "a" becomes the most upper-right block. The operation of squeezing and deleting can be repeatedly performed until there is only one block left in the placement.

According to the order in which the blocks are squeezed out, we get two lists. The labels of blocks are stored in list "S" while the orientations of the blocks in list "L." For example, for Figure 54.25a, S = "fcegbad" and L = "001100." S and L are not sufficient to recover the placement, so we need the third list, T. Each time we squeeze a block, we record the number of T-junctions on the moving boundary, excluding the two at its ends, then add the same number of "1"s and one "0" into T. For example, in Figure 54.25a, when squeezing block d, we have T = "01," for there is only one T-junction on the bottom boundary, which separates the blocks a, d and g. Next, while squeezing block a, only a "0" is added to T, for there is no T-junction on the bottom boundary of block a. Consequently, we have T = "001" after the deletion of block a, and T = "00101001" after the deletion of block c. With an inverse process, the placement can be recovered from S, L and T.

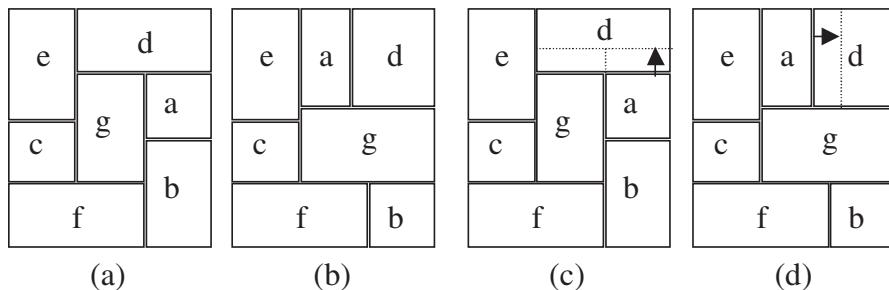

FIGURE 54.25 Corner block list.

The performance of corner block list is:

1. The storage of the 3 lists needs at most $n(3 + \log n)$ bits.
2. The number of combinations is *TRIALRESTRICTION*, which is the same as that of a slicing tree. However, slicing structure only covers part of all possible combinations, therefore has larger redundancy than corner block list.
3. The complexity of the translation between placement and lists is *TRIALRESTRICTION*.

54.3.4 Slicing Tree

A floorplan is called a slicing structure [20,21] if it can be iteratively partitioned into two parts with vertical or horizontal cut lines throughout the separated parts of the area, until the individual blocks. Figure 54.26a gives an example. Line 1 splits the whole layout into two parts. The left half involves only one block but the right half can be further split by line 2. Then follows line 3, line 4, and so on. On the contrary, Figure 54.26b is a non-slicing structure. We can't find a cut line throughout the floorplan to split it into two parts.

Now that a slicing floorplan can be iteratively split into two parts with vertical or horizontal cut lines, a binary tree can be structured according to the splitting process [22].

Figure 54.27 gives an example of a slicing floorplan and its binary tree. The internal nodes on the tree denote with “H” or “V” indicate the direction of the line splitting the areas, while the leaf nodes correspond to the blocks. We call the binary tree a slicing tree.

Just as in twin binary tree, we hope to find a simple data structure to express the slicing tree. Polish Expression is a good solution. It is the result of a post-order traversal on the slicing tree. As an example, the Polish Expression of Figure 54.27 is: $123V56V8H47HVHV$. We regard “H” and “V” as operators and the blocks as operands.

Formally, we have the following definition for a Polish expression:

A sequence $b_1 b_2 \dots b_{2n-1}$ of elements from $\{1, 2, \dots, n, V, H\}$ is a Polish expression of length $2n - 1$ iff:

1. Every subscript i appears exactly once in the sequence, $1 \leq i \leq 2n - 1$.
2. The number of operators is less than the number of the components for any prefix sub-string.

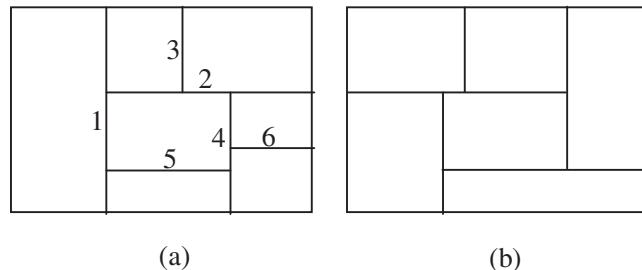

FIGURE 54.26 Slicing structure and non-slicing structure.

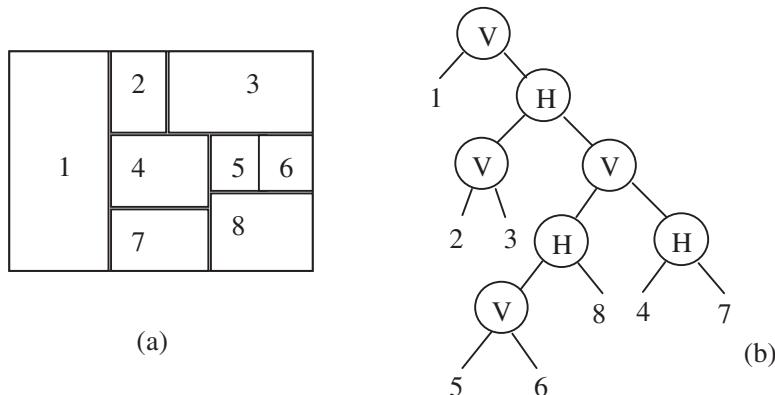

FIGURE 54.27 Slicing structure and its binary tree representation.

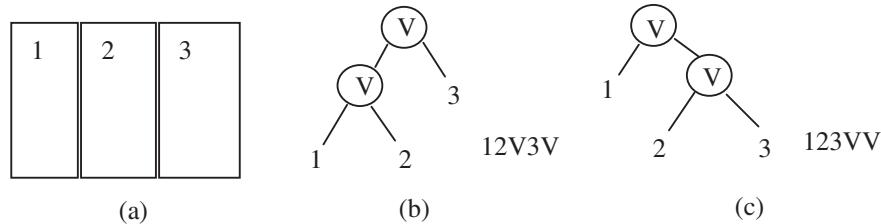

FIGURE 54.28 Redundancy of slicing trees.

So needless to re-construct the slicing tree, we are able to judge a legal Polish Expression. For example, $21H57V43H6HVH$ and $215H7V43H6HVH$ are legal Polish Expressions while $215HVHV7436HV$ and $2H15437VVVHH$ are not. An illegal Polish Expression can't be converted to a binary tree.

It is obvious that for a given slicing tree, we have a unique Polish Expression. Inversely, we can easily conduct the slicing tree according to its Polish Expression. So we conclude that there is a one-to-one correspondence between the slicing tree and Polish Expression. However, there may be more than one slicing tree corresponding to one floorplan, as shown in Figure 54.28. Thus there exists redundancy. To compact the solution space, we define the skewed slicing tree to be a slicing tree without a node that has the same operator as its right son. Correspondingly, a normalized Polish expression is defined:

A Polish expression $b_1b_2\dots b_{2n-1}$ is called to be normalized iff there is no consecutive "V" or "H" in the sequence.

In Figure 54.28, (b) is a normalized Polish expression while (c) is not. There is a one-to-one correspondence between the set of normalized Polish expressions and the set of slicing structures.

To perturb the blocks to get new solutions, we define three types of perturbations on polish expressions:

M1: Swap two adjacent operands. For example, $12V3H \rightarrow 13V2H$

M2: Complement some chain of operators. For example, $12V3H \rightarrow 12V3V$;

M3: Swap two adjacent operand and operator. For example, $12V3H \rightarrow 123VH$;

The operation of M3 may result in a non-normalized Polish Expression. So a check is necessary after an operation of M3 to guarantee that a normalized expression is generated.

Figure 54.29 illustrates two sequences of polish expression transformations as well as their corresponding floorplans. We can see that a slight modification on the Polish Expression can result in a completely different floorplan topology. This is just what we want.

Finally, we analyze the performance of slicing tree.

- Given a floorplan of n blocks, the slicing tree contains n leaves and $n - 1$ internal nodes.
 - The number of possible configurations for the tree is $O(n! \cdot 2^{3n-3} \cdot n^{1.5})$.
 - The storage of a Polish Expression needs a $3n$ -bit stream plus a permutation of n blocks.
 - It will take linear time to transform a floorplan into a slicing tree, and vice versa.

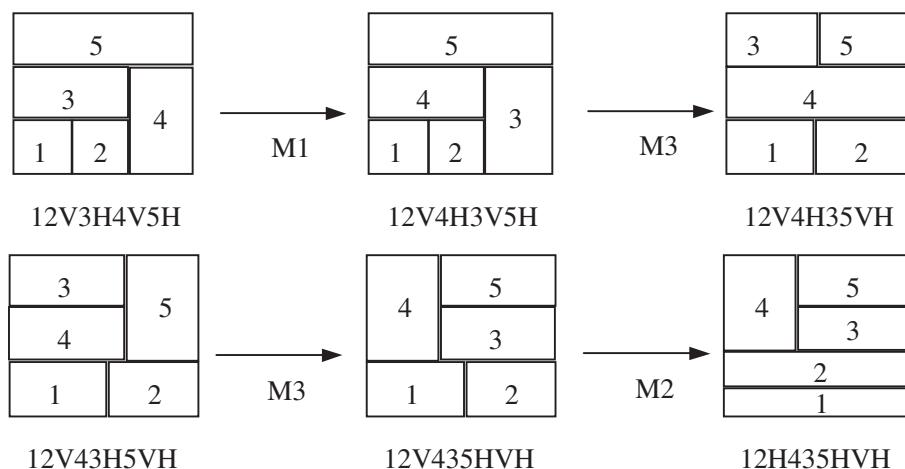

FIGURE 54.29 Slicing structure moves.

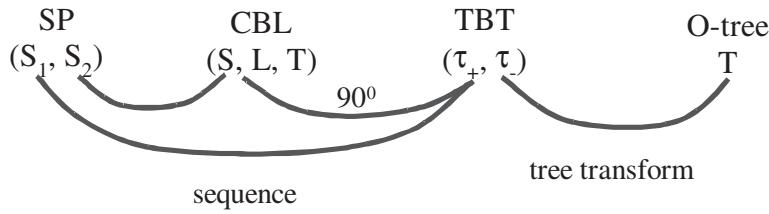

FIGURE 54.30 Summary of the relationships between floorplan representations.

54.4 Relationships of the Representations

We summarize the relationships between the representations in this section. A mosaic floorplan example and a general floorplan example are also discussed in detail to show the relationships.

54.4.1 Summary of the Relationships

According to the definitions of the representations, we have four relationships between the sequence-pair (SP), the corner block list (CBL), the twin binary tree (TBT) and the O-Tree representations.

For further discussions, we first define the 90° rotation of a floorplan as follows:

Definition 90° rotation of a floorplan: We use F^{90} to denote the floorplan obtained by rotating floorplan F , 90 degrees counter-clockwise.

The four relationships are as follows and summarized in Figure 54.30.

1. Given a mosaic floorplan and its corresponding corner block list $CB = (S, L, T)$, there exists a sequence pair $SP = (S_1, S_2)$ corresponding to the same floorplan such that the second sequence of SP is same as the sequence S of the corner block list.
2. Given a mosaic floorplan and its corresponding twin binary trees (τ_+, τ_-) , there exists a sequence pair $SP = (S_1, S_2)$ corresponding to the same floorplan such that the first sequence of SP is the same as the node sequence of in-order traversal in tree τ_+ .
3. Given a mosaic floorplan and its corresponding twin binary trees $TBT(\tau_+, \tau_-)$, there exists an O-tree corresponding to the same floorplan such that τ_- is identical to the O-tree after the tree conversion from a binary tree to an ordered tree.
4. Given a mosaic floorplan F , and its corresponding twin binary trees $TBT(\tau_+, \tau_-)$, the node sequence of in-order traversal in tree τ_+ is identical to the sequence S in the corner block list $CB = (S, L, T)$ of the floorplan F^{90} .

54.4.2 A Mosaic Floorplan Example

Figure 54.31 describes an example of a mosaic floorplan. We illustrate the four representations. The twin binary trees are marked with circles and crosses as shown in Figure 54.31. Two SPs, SP1 and SP2, out of many possible choices, are described in the figure.

The in-order traversal of the τ_+ in the twin binary trees representation produces the sequence $\pi(\tau_+) = ABCDFE$, which is same as the first sequence of SP1 and SP2. In Figure 54.31, an O-tree representation is also given. Its binary tree representation is identical to the τ_- of the twin binary trees after tree conversion. The corner block list representation is next to the O-tree representation in Figure 54.31. Its sequence $S = FADEBC$ is same as the second sequence of SP1.

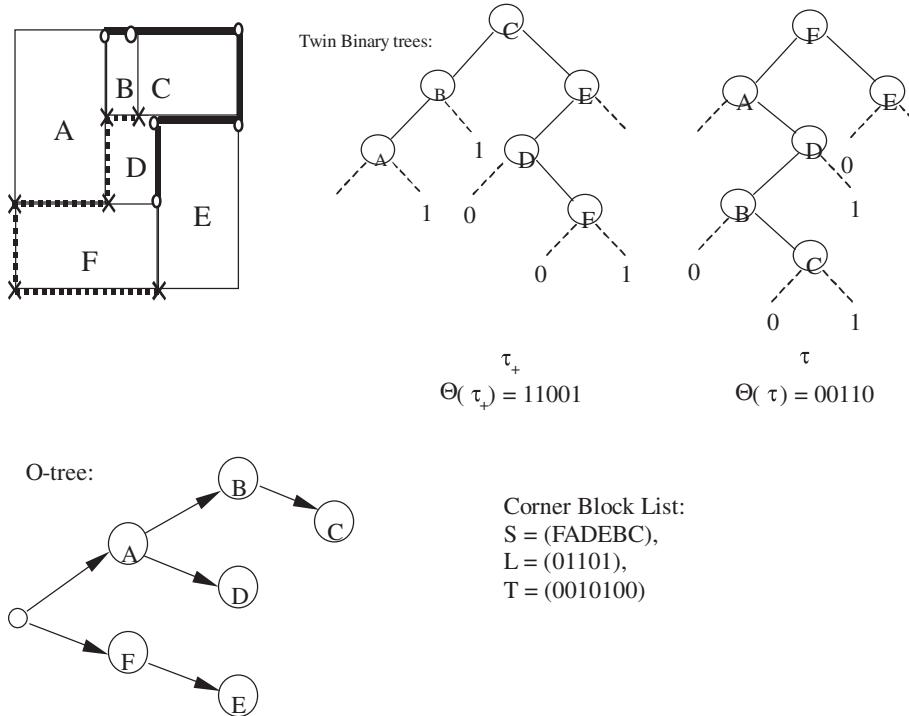

Figure 54.32 shows the 90° rotation of the mosaic floorplan in Figure 54.31. The $CB (S, L, T)$ representation of F^{90} has $S = ABCDFE$ (Figure 54.32), which is identical to $\pi(\tau)$, the order of the twin binary trees representation (τ_+, τ_-) of the floorplan in Figure 54.31.

54.4.3 A General Floorplan Example

Figure 54.33 illustrates a general floorplan. Only the O-tree and the sequence pair are capable of representing this general floorplan. The O-tree and SP representations are shown in the figure.

54.5 Rectilinear Shape Handling

Shape handling makes feasible the treating of blocks with arbitrary shapes. It makes sense especially in deep sub-micron technology, where, with the number of routing layers increasing, wires are placed in layers other than the device layer, and the placement

Sequence Pair: $SP_1 = (S_1, S_2) = (\text{ABCDFE}, \text{FADEBC})$. Also $SP_2 = (S_1, S_2) = (\text{ABCDFE}, \text{FADBEC})$ refers to the same floorplan

FIGURE 54.31 A mosaic floorplan and its different representations.

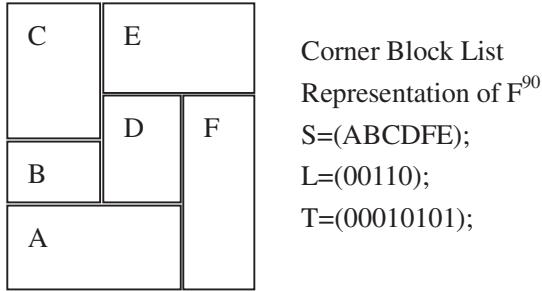

FIGURE 54.32 90° rotation of the floorplan in Figure 54.31.

becomes more like a packing problem: a set of macro blocks are packed together without overlaps, with some objective functions minimized.

The basic idea to handle the arbitrary-shaped blocks is to partition them into rectangles, and then the representations and the optimizing strategies described above can be used. Figure 54.34a and b demonstrate two schemes of partitioning, the horizontal one and the vertical one. However, if the generated rectangle blocks were treated as individual ones, it would be quite impossible to recover the original blocks. The generated rectangle blocks may be shifted (Figure 54.34c) or separated (Figure 54.34d). So extra constraints have to be imposed on the generated rectangle blocks in order to keep the original blocks' shapes.

One proposed method of adding extra constraints is illustrated with Figure 54.35b for horizontal and (c) for vertical. The vertexes in the constraint graph correspond to the generated rectangle blocks, while the direct edges denote the relative positions of the blocks. For example, an edge from "a" to "b" with a weight of 1 means that block "b" lies to the right of "a," the distance

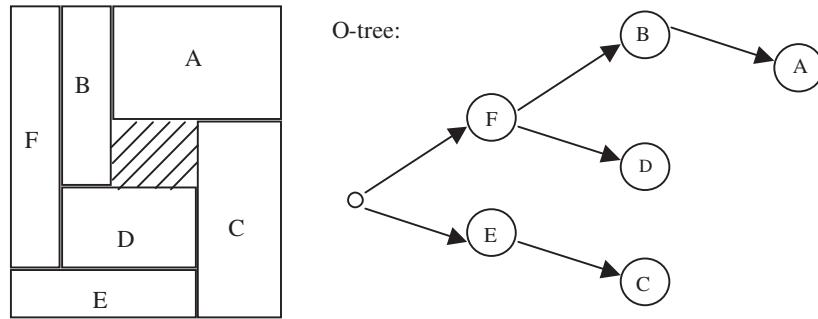

FIGURE 54.33 A general floorplan with its O-tree and SP representation.

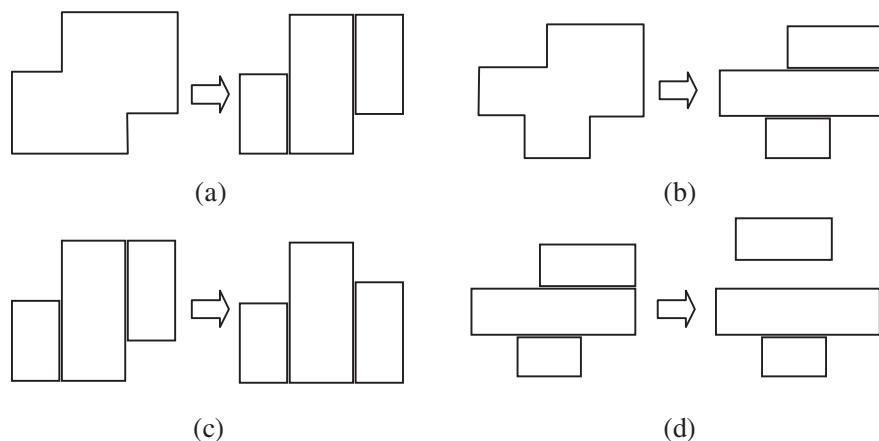

FIGURE 54.34 Shape handling.

between their left boundaries is 1, which is exactly the width of “a.” Because the relative-position constraints are always represented with the format such as “larger than or equal to” during optimization, inversely directed edges, such as the edge from “a” with a negative weight, helps to determine the position relationships solely.

54.6 Conclusions

Floorplan representation is an important issue for floorplan optimization. We classify the representations into graph based and placement based methods based on the different strategies used in deriving the representations. The graph-based methods are based on the constraint graphs, which include the constraint graphs, the corner stitching, the twin binary tree and the O-tree. The placement-based methods are based on the local topology relations in deriving the floorplans, which include the sequence pair, the bounded sliceline grid, the corner block list and the slicing tree.

The floorplans can also be classified into different categories: general, mosaic and slicing floorplans. Slicing floorplan is a subset of mosaic floorplan, which is again a subset of the general floorplan. We have different representations for different types of floorplans. The constraint graphs, the corner stitching, the sequence pair, the bounded sliceline grid and the O-trees are for general floorplans. The twin binary tree and the corner block list are for mosaic floorplans. The slicing tree is for slicing floorplans. Different representations have different solution spaces and time complexities to derive a floorplan.

Acknowledgments

The authors are grateful to Mr. Simon Chu of Sun Microsystems for his thorough review of the chapter.

55.1 Introduction

Like all major applications within the vast arenas of computer science and technology, the computer graphics industry depends on the efficient synergy of hardware and software to deliver to the growing demands of computer users. From computer gaming to engineering to medicine, computer graphics applications are pervasive. As hardware capabilities grow, the potential for new feasible uses for computer graphics emerge.

In recent years, the exponential growth of chipset speeds and memory capacities in personal computers have made commonplace the applications that were once only available to individuals and companies with specialized graphical needs. One excellent example is flight simulators. As recently as twenty years ago, an aviation company would have purchased a flight simulator, capable of rendering one thousand shaded polygons per second, for ten million dollars. Even with a room full of processing hardware and rendering equipment, it would be primitive by today's graphics standards. With today's graphics cards and software, one renders tens of millions of shaded polygons every second for two hundred dollars.

As the needs for graphics applications grow and change, research takes the industry in many different directions. However, even though the applications may evolve, what happens under the scenes is much more static; the way graphics primitives are represented, or stored in computer memory, have stayed relatively constant. This can be mainly attributed to the continued use of many standard, stable data structures, algorithms, and models. As this chapter will illustrate, data and algorithmic standards familiar to computer science lend themselves quite well to turning the mathematics and geometries of computer graphics into impressive images.

55.1.1 Hardware and Pipeline

Graphics hardware plays an important role in nearly all applications of computer graphics. The ability for systems to map 3-D vertices to 2-D locations on a monitor screen is critical. Once the object or "model" is interpreted by the CPU, the hardware draws and shades the object according to a user's viewpoint. The "pipeline" [1], or order in which the computer turns mathematical expressions into a graphics scene, governs this process. Several complex sub-processes define the pipeline. [Figure 55.1](#) illustrates a typical example.

The Model View is the point where the models are created, constructed as a combination of meshes and mapped textures. The Projection point is where the models are transformed (scaled, rotated, and moved) through a series of affine transformations to

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

† We have used this author's affiliation from the first edition of this handbook, but note that this may have changed since then.

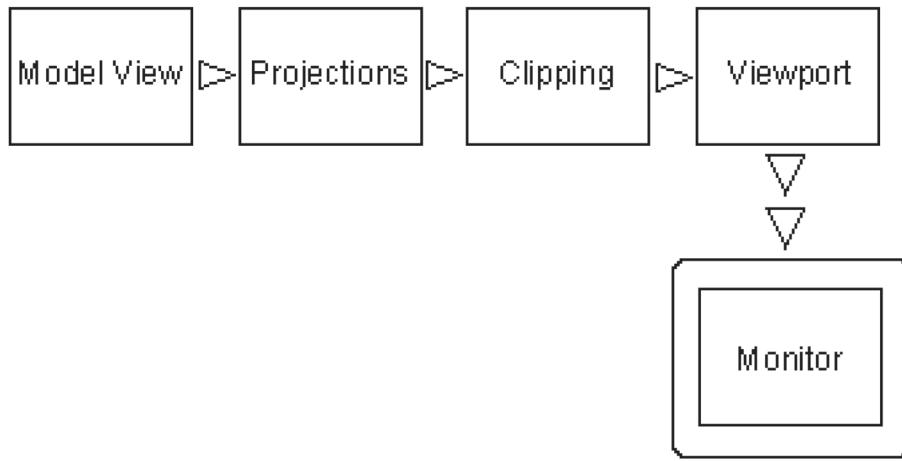

FIGURE 55.1 Graphics pipeline.

their final position. Clipping involves invoking algorithms to determine perspective, and what objects are visible in the Viewport. The Viewport readies the scene for display on the computer's monitor. The final scene is “rasterized” to the monitor [1].

Standard data structures and algorithms apply to all steps in the pipeline process. Since the speed of most rendering hardware (and hence the pipeline) is directly dependent on the number of models to be drawn, it becomes important to utilize structures that are as efficient as possible. In fact, graphics hardware is often designed and engineered to cater to a specific, standard form of data representation.

55.2 Basic Applications

55.2.1 Meshes

In both 2-D and 3-D applications, objects are modeled with polygons and polygon meshes. The basic elements of a polygon mesh include the vertex, the edge, and the face. An edge is composed of the line segment between two vertices, and a face is defined by the closed polygon of three or more edges. A mesh is formed when two or more faces are connected by shared vertices and edges. A typical polygon (triangle) mesh is shown in Figure 55.2.

Specific examples of meshes include “triangle meshes, polygon meshes, and polygon meshes with holes.” [2] However, the triangle is currently the most popular face geometry in standard meshes. This is mainly because of its simplicity, direct application to trigonometric calculations, and ease of mesh storage (as we will see).

55.2.2 CAD/CAM Drawings

In Computer Aided Design (CAD), Computer Aided Manufacturing (CAM), and other channels of engineering design, we see the same basic elements. During the design process of everything from automobiles to telephones, applications are used to “see”

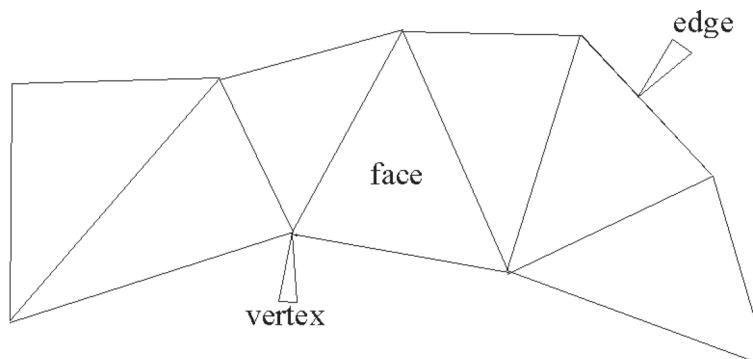

FIGURE 55.2 A triangle mesh.

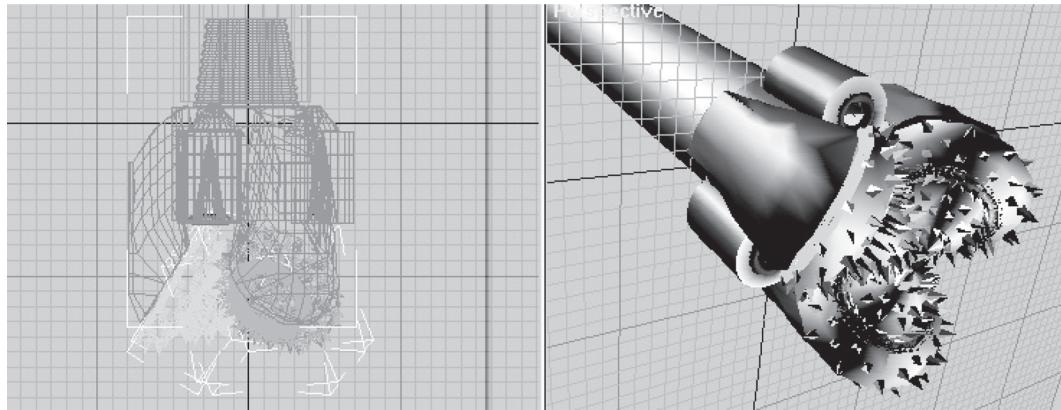

FIGURE 55.3 Models of a drill bit.

$$M \alpha \beta \gamma \Delta \delta \phi T$$

FIGURE 55.4 Fonts.

the parts before they are manufactured. The physical interactions and assemblies of parts can be tested before any steel is milled or plastic is poured.

Figure 55.3 illustrates a wire-frame (and fully rendered) model of a drill bit used in the oil and gas industry. Every modeled element of this design requires a definition of vertices and edges. These vertices define single-line edges, polyline edges, and the curved edges. The proximity of vertices to edges, edges to edges, and vertices to vertices may be tested for tolerances and potential problems. The software makes the stored model visible to the user within the current coordinate system and viewpoint. It is then up to the user to interface the visual medium with his or her engineering (or design) training to create a useful design.

Even in wire frame models, we see the application of more sophisticated graphics practices. Note how many of the contours of the drill bit parts are not connected line segments, but actual smooth curves. This is an example of where vertices have been used not to define edges, but the “control points” of a Bezier Curve. How curves like the B-Spline and Bezier utilize vertices in their structures is discussed later in this chapter. For now it is sufficient to mention that these types of curves are present in nearly all corners of the graphics industry.

55.2.3 Fonts

Fonts are another example of where the vertex is used, in two dimensions, as the basis of a data structure in order to define the appearance of each character and number in various languages. Several examples of interesting Greek characters, each defined by a different font definition file, and at different sizes, are shown in Figure 55.4.

The typical Postscript font is defined by a number of points, read in as control points for each curve (or line) in the font character. The “Postscript” driver software is then used to interpret the control points and render the characters with Bezier curves (see Section 55.3.5).

Perhaps the most important concept is that each pixel of the font character does not have to be stored, only a small number of vertex definitions. As the control points are transformed through operations like italicizing, the curves remain aligned in the proper proportion to the original character. Note the “M” character in the above figure has been italicized. The “Postscript” font representation serves as a very effective example of how a single standardized data structure of specific size can be utilized to define a potentially infinite number of characters.

55.2.4 Bitmaps

Bitmaps are a cornerstone to computer graphics. In fact, the name “bitmap” has become a commodity to most computer users in the way that it describes a computer generated picture. A bitmap is a very simple, yet versatile, way to store a graphic image as a binary file. The file header structure of a bitmap [3] in itself is a standard data structure, as the following illustrates:

```
struct _BITMAP
{
    Uint8 bmType;
```

```

Uint8 bmBitsPerPixel;
Uint8 bmBytesPerPixel;
Uint8 bmReserved;

Uint32 bmColorKey;

Uint32 bmWidth;
Uint32 bmHeight;
Uint32 bmPitch;

void* bmBits;
};

```

The bitmap is initially defined by a number of parameters that define the type, width, height, etc. of the graphic image. These properties are stored in the header of the file as shown. The actual “pixels” required to fill that space is then defined in the “bmBits” pointer. As a rule, the total number of pixels in the image memory will equal the width times the height divided by the “bits per pixel” property. The “bytes per pixel” property determines how the “bits per pixel” are divided among the individual color components of each pixel. For instance, a bitmap with RGB color map is commonly defined by twenty four (24) bits per pixel and three (3) bytes per pixel. Each of the three bytes for each pixel use 8 of the twenty four bits to define red, green, and blue values respectively.

Early bitmaps, when color monitors were first being used, were defined with 4-bit color. In other words, each color was defined by a 4-bit (or half-byte) word. Since a half-byte has a maximum value of 24 or 16, 4-bit bitmaps were capable of supporting sixteen (16) different colors. The required disk space to store a 100×100 4-bit bitmap would then be $10,000^*.5$ bytes or 5,000 Bytes (5kB).

In the past fifteen years, the need for more realistic graphics has driven the increase in the memory used for color. Today 24-bit (also called true color) and 32-bit color, which both represent 16.7 million colors (32-bit adds an extra byte for the alpha channel), are the most commonly supported formats in today’s hardware. The alpha channel refers to a single byte used to store the transparency of the color. Bitmap files in these formats now require 3 and 4 bytes per pixel. Additionally, current monitor resolutions require over 1,000 pixels in width or height, and thus graphic files are growing even larger. [Figure 55.5](#) is a photograph that has been scanned in and stored as a bitmap file.

A typical 5×7 photograph, at 100 dpi (dots per inch), and 24-bit color, would require $500 \times 700 \times 3$ or 1.05 megabytes (MB) to store in a conventional bitmap format. Because of the increased size requirements in bitmaps, compression algorithms have become common-place. File formats such as JPG (jpeg) and PNG (ping) are examples of widely used formats. However, there is a tradeoff. When a compression algorithm is applied to a bitmap, a degree of image quality is inevitably lost. Consequently, in applications like publishing and graphic art, uncompressed bitmaps are still required where high image quality is expected.

FIGURE 55.5 Bitmap file.

55.2.5 Texture Mapping

The processes of texture and surface mapping represent an application where bitmaps and polygonal meshes are combined to create more realistic models. Texture mapping has become a cornerstone of graphics applications in recent years because of its versatility, ease of implementation, and speed in graphical environments with a high number of objects and polygons. In fact, today's graphics hardware ships with the tools necessary to implement the texture and surface mapping processes on the local chipset, and the data structures used in rendering environments are largely standardized.

Prior to texture mapping, 3-D polygonal meshes were processed through shading models such as Gouraud and Phong to provide realism. Each shading model provides the means for providing color, shadows, and even reflection (glare) to individual components of the model. This was accomplished through a mathematical model of how light behaves within specular, diffuse, reflective, and refractive contexts. The general shading equation for light intensity, I , based on the individual ambient, diffuse, and specular components is shown below.

$$I = I_a p_a + (I_d p_d \times \text{lambert}) + (I_s p_s \times \text{phong})$$

where

$$\text{lambert} = \max\left(0, \frac{\mathbf{s} \cdot \mathbf{m}}{|\mathbf{s}| |\mathbf{m}|}\right)$$

$$\text{phong} = \max\left(0, \frac{\mathbf{h} \cdot \mathbf{m}}{|\mathbf{h}| |\mathbf{m}|}\right)$$

$$p_a = \text{ambient coefficient} \quad 0 \leq p_a \leq 1$$

$$p_d = \text{diffuse coefficient} \quad 0 \leq p_d \leq 1$$

$$p_s = \text{specular coefficient} \quad 0 \leq p_s \leq 1$$

The primary difference between Gouraud and Phong is in that Phong provides the additional component for specular reflection, which gives objects a more realistic glare when desired. Also, because the Phong model requires more detail, the intensity values are calculated (interpolated) at each pixel rather than each polygon. The vectors \mathbf{m} , \mathbf{s} , and \mathbf{h} represent the normal, reflected, and diffuse light from a given polygonal surface (or face). Linear interpolation, a widely used algorithm in graphics, is discussed in Section 55.3.5.

Although still used today, these shading models have limitations when more realistic results are desired. Because color and light reflection are modeled on individual model components, the model would have to be constructed as a composite of many different components, each with different color (or material) properties, in order to achieve a more realistic effect. This requires models to be much more complex, and increasingly difficult to construct. If changes in surface appearance or continuity were desired, they would have to be physically modeled in the mesh itself in order to be viewed.

Texture and surface mapping have provided a practical solution to these model complexity dilemmas. The mapping methods involve taking the input from a bitmap file, like those described previously, and “stretching” them over a polygonal mesh. The end result is a meshed object which takes on the texture properties (or appearance) of the bitmap. The figure below illustrates a simple example of how the mesh and bitmap can be combined to create a more interesting object. [Figure 55.6](#) shows how [Figure 55.5](#) has been “mapped” onto a sphere.

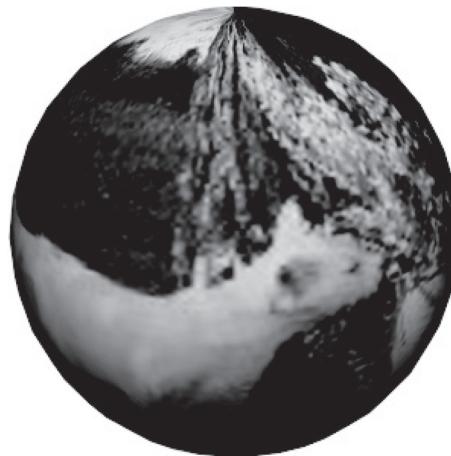

FIGURE 55.6 Combination of mesh and bitmap.

FIGURE 55.7 Texture mapping.

The object seems to take on a more realistic appearance even when modeled by a very simple polygonal mesh. This technology has made fast rendering of realistic environments much more feasible, especially in computer games.

Texture, or “bump,” mapping utilizes a similar process as surface mapping, where a bitmap is stretched over a polygonal mesh. However, the pixels, commonly called “texels” [1], are used to alter how the light intensity interacts with the surface. Initially, the lighting model shown above would calculate an intensity, I , for a given surface. With texture mapping, individual grayscale values at each texel are used to alter the intensity vectors across each polygon in order to produce roughness effects.

Figure 55.7 illustrates a model of a sphere that has been rendered with the traditional Gouraud model, then Phong, and then finally rendered again with a texture map. This approach to improving model realism through mapping applies also to reflection, light intensity, and others.

55.3 Data Structures

55.3.1 Vertices, Edges, and Faces

As mentioned previously, vertices, edges, and faces form the most basic elements of all polygonal representations in computer graphics. The simplest point can be represented in Cartesian coordinates in two (2D) and three dimensions (3D) as (x, y) and (x, y, z) respectively (Figure 55.8).

As a simple data structure, each vertex may then be stored as a two or three-dimensional array. Edges may then be represented by two-dimensional arrays containing the indexes of two points. Further, a face may be dimensioned based on the number of desired sides per face, and contain the indices of those edges. At first, this approach may seem acceptable, and in basic applications it is common to model each vertex, edge, and face as a separate class. Relative relationships between classes are then governed by the software to build meshes. However, modeling objects in this manner does have disadvantages.

Firstly, important information becomes difficult to track, such as the normal at each vertex, adjacency of faces, and other properties required for blending and achieving realism. Furthermore, the number of intersecting edges at each vertex may vary throughout the model, and mesh sizes between objects may be unpredictable. The ability to manage this approach then becomes increasingly difficult, with the potential for unnecessary overhead and housekeeping of relationships within the model. It then becomes necessary to create higher level data structures that go beyond these basic elements, and provide the elements necessary for efficient graphics applications.

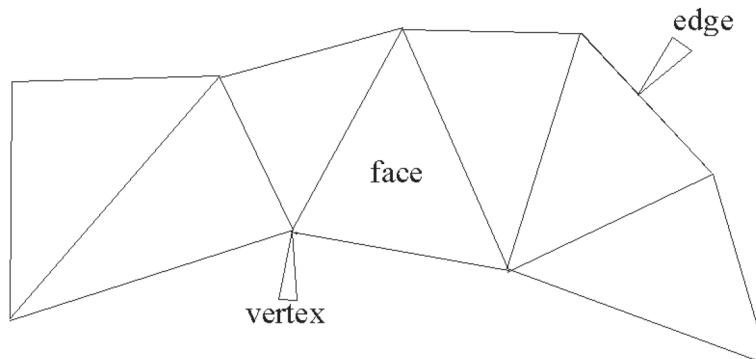

FIGURE 55.8 Vertices, edges, and faces.

55.3.2 Vertex, Normal, and Face Lists

In this storage method, list structures are used to store three, inter-dependent lists of data. The first list defines the vertexes contained in the scene as follows. Each vertex is assigned an index, and a coordinate location, or (x, y, z) point. The second list defines the normals for each vertex. Again, each normal is assigned a numbered index and a 3-D coordinate point. The final list serves to integrate the first two. Each face is identified by a numbered index, an array of vertex indexes, and an array of indexed normals for each vertex. [Figure 55.9](#) illustrates typical examples of a similar application with vertex, face, and edge lists.

In the table, three specific lists are evident. The first list represents each vertex in the model as it is defined in 3D space. The “vertex” column defines the id, index, or label of the vertex. The x , y , and z coordinates are then defined in the adjacent columns.

In the second list, six faces are defined. Each face has a label or index similar to the vertex list. However, rather than specifying coordinates in space, the adjacent column stores the id’s of the vertexes that enclose the face. Note that each face consists of four vertices, indicating that the each face will be defined by a quadrilateral.

The final list defines edges. Again, each edge definition contains a label or index column, followed by two adjacent vertex columns. The vertices of each edge define the start point and end point of each edge. In many applications of graphics, it is important to define the direction of an edge. In right handed coordinate systems, the direction of an edge will determine the direction of the normal vector which is orthogonal to the face surrounded by the edges.

55.3.3 Winged Edge

Although one of the oldest data structures relating to polygonal structures, the Winged Edge approach is very effective, and still widely used [4]. This structure is different from the wireframe model in that edges are the primary focal point of organization.

In the structure, each edge is stored in an indexed array, with its vertices, adjacent faces, previous, and successive edges. This allows the critical information for each edge to be stored in an array of eight integer indexes; it is both consistent and scalable between applications. The structure is

[Figure 55.11](#) illustrates a typical layout for a winged edge.

An important aspect of the Winged Edge structure is the order in which entries are listed. The edge itself has a direction, from the start vertex to the end vertex. The other entries are then defined by their proximity to the edge. If the direction of the edge were reversed, the right and left faces would change accordingly, as would the previous and succeeding entries of both the left and right traverse.

There is a time/space trade-off in using this model. What is saved in storage space adds to the needed time to find previous and successive edges. See [Chapter 18](#) for more details.

vertex	x	Y	Z	face	vertex number	edge	vertex begin	vertex end
0	0	0	0	0	4, 5, 6, 7	0	0	1
1	0	1	0	1	0, 1, 2, 3	1	1	2
2	1	1	0	2	3, 2, 6, 5	2	2	3
3	1	0	0	3	4, 7, 1, 0	3	3	0
4	0	0	1	4	2, 1, 7, 6	4	4	5
5	1	0	1	5	4, 0, 3, 5	5	5	6
6	1	1	1			6	6	7
7	0	1	1			7	7	4

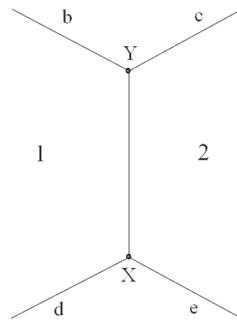

FIGURE 55.11 Winged edge.

55.3.4 Tiled, Multidimensional Array

In this section we will discuss a data structure that is important to most geometric implementations. In many ways, the tiled array behaves identically to matrix data structures. For instance, a p by q matrix is normally stored as a single dimension array. However, since the matrix has p -rows and q -columns, the array needs to be addressed by creating an “offset” of size q in order to traverse each row. The following example should illustrate this concept.

Consider a matrix with $p = 3$ rows and $q = 3$ columns:

is stored as:

$$A = [1, 3, 4, 5, 2, 7, 3, 9, 3]$$

This represents where a 3×3 matrix is stored as an array with $(3)(3) = 9$ entries. In order to find the entry at $\text{row}(i) = 3$ and $\text{column}(j) = 2$ we employ the following method on the array:

$$\text{Entry} = j + (i - 1)q$$

Or in this case, $\text{Entry} = A[2 + (3 - 1)(3)] = A[8] = 9$

We use a similar method for tiling a single bitmap into several smaller images. This is analogous to each number entry in the above array being replaced by a bitmap with n by n pixels.

“Utilizing cache hierarchy is a crucial task in designing algorithms for modern architectures.” [1] In other words, tiling is a crucial step to ensuring multi-dimensional arrays are stored in an efficient, useful manner. Indexing mechanisms are used to locate data in each dimension. For example, a p by q array is stored in a one-dimensional array of length $p * q$, and indexed in row-column fashion as above.

When we wish to tile a p by q matrix into n by n tiles, the number of blocks in x is defined by q/n and the number of blocks in y is defined by p/n . Therefore, to find the “tile index” or the row and column of the tile for a value (x, y) we first calculate the tile location, or bitmap within the matrix of bitmaps. Then once the bitmap is located, the pixel location within that bitmap tile is found (sub-indexed). The entire two-step process can be simplified into a single equation that is executed once. [Figure 55.12](#) illustrates this concept.

The final formula for locating x, y in a p by q array divided into n, n tiles is:

$$n^2 \left(\left(\frac{q}{n} \right) \left(\frac{y}{n} \right) + \frac{x}{n} \right) + (y \bmod n)n + (x \bmod n)$$

When dealing with matrices and combining multiple bitmaps and/or data into a Tile Multidimensional Array, performance and speed can both improve substantially.

55.3.5 Linear Interpolation and Bezier Curves

This section will introduce one of the most significant contributions to design and graphics: the interpolated curve structure.

Linear interpolation refers to the parameterization of a straight line as a function of t , or:

$$L(t) = (1 - t)a + tb$$

where a, b are points in space. This equation represents both an affine invariant and barycentric combination of the points a and b . Affine invariance means that the point $L(t)$ will always be collinear with the straight line through the point set $\{a, b\}$, regardless of the positioning of a and b . Describing this set as barycentric simply means that for t values between 0 and 1, $L(t)$ will always

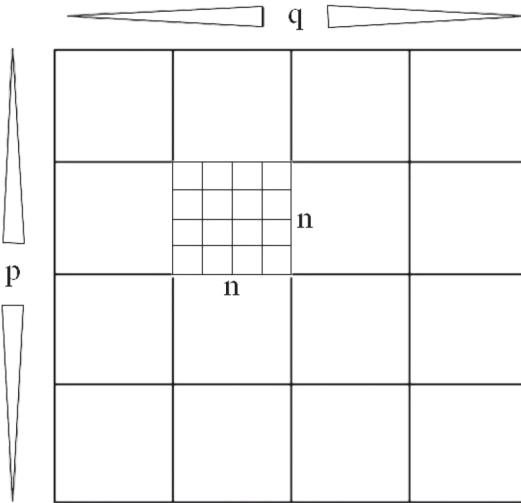

FIGURE 55.12 Tiled array.

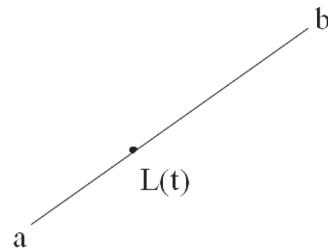

FIGURE 55.13 Linear interpolation.

occur between a and b . Another accurate description is that the equation $L(t)$ is a linear “mapping” of t into some arbitrary region of space. [Figure 55.13](#) illustrates this concept.

Linear interpolation is an extremely powerful concept. It is not only the foundation of many curve approximation algorithms, but the method is also used in many non-geometric applications as well, including calculating individual pixel intensities in the Phong shading method mentioned previously.

The basic Bezier curve derivation is based on an expanded form of linear interpolation. This concept uses the parameterization of t to represent two connected lines. The curve is then derived by performing a linear interpolation between the points interpolated on each line; a sort of linear interpolation in n parts, where n is the number of control points. The following example should illustrate:

Given are three points in space, $\{a, b, c\}$. These three points form the two line segments ab and bc ([Figure 55.14](#)).

During the first “iteration” of the Bezier curve derivation, linear interpolation is performed on each line segment for a given t value. These points are then connected by an additional line segment. The resulting equations (illustrated in [Figure 55.15](#)) are:

$$\begin{aligned} x &= (1 - t)a + tb \\ y &= (1 - t)b + tc \end{aligned}$$

The linear interpolation is performed one last time, with the same t value between the new points $\{x, y\}$ ([Figure 55.16](#)):

$$z = (1 - t)x + ty$$

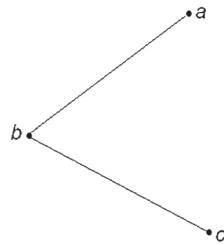

FIGURE 55.14 Expanded form of linear interpolation.

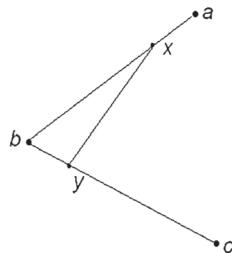

FIGURE 55.15 First iteration of Bezier curve derivation.

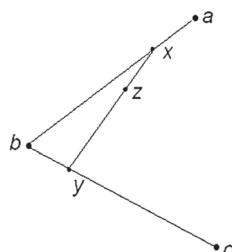

FIGURE 55.16 Result of three linear interpolations.

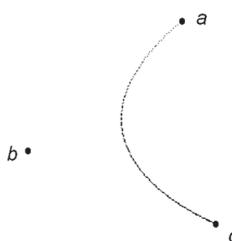

FIGURE 55.17 Smooth curve.

This final point z , after three linear interpolations, is on the curve. Following this 3-step process for several “stepped” values for t between 0 and 1 would result in a smooth curve of z -values from a to c , and is illustrated in Figure 55.17:

This is a quadratic Bezier curve, and is represented mathematically by a linear interpolation between each set of x and y points, which were also derived through linear interpolation, for every t . By substituting the equations for x and y into the basic form, we obtain:

$$z(t) = (1 - t)[(1 - t)a + tb] + t[(1 - t)b + tc]$$

Simplified, we obtain a quadratic polynomial for a , b , and c as a function of the parameter t , or

$$z(t) = (1 - t)^2 a + 2(1 - t)tb + t^2 c$$

The “string art” algorithm described previously is also referred to as the de Casteljau algorithm. Programmatically, the algorithm performs an n -step process for each value of t , where n is the number of “control points” in the curve. In this example, $\{a, b, c\}$ are the control points of the curve.

Because of their ease of implementation and versatility, Bezier curves are invaluable in CAD, CAM, and graphic design. Also, Bezier curves require only a small number of control points for an accurate definition, so the data structure is ideal for compact storage. As mentioned previously, the Bezier form is the foundation for the Postscript font definition structure.

However, the Bezier form has limitations. When several attached curves are required in a design component, it takes considerable effort, or pre-calculation, to ensure the connected curves are “fair” or continuous with each other. Merely joining the end points of the curves may not be enough, resulting in “kinks” and other undesirable effects. For this reason, the B-spline curve provides an alternative to the Bezier where continuity is important. In fact, B-spline curves have often been referred to as a “user interface” for the Bezier form.

The goal of this section was to illustrate the versatility of linear interpolation and basic iteration structures in graphics and design. If more information is desired, numerous texts are currently available which describe the properties, mathematics, and applications of Bezier and B-spline curves, including the references listed at the end of this chapter.

55.4 Applications of Previously Discussed Structures

55.4.1 Hidden Surface Removal: An Application of the BSP Tree

In addition to other algorithms, BSP (Binary Space Partitioning) trees are one example where a specific, widely used, data structure has direct application in computer graphics. Hidden surface removal is essential to realistic 3-D graphics, and a primary application of BSP trees.

Hidden surface removal is used anywhere 3-dimensional objects must be made visible from multiple, if not infinite view points within a graphics scene. Whether a scene is being viewed in a 3-D design application, or the latest sci-fi game, the problem is the same: objects furthest away from the user’s viewpoint may be hidden by closer objects. Therefore, the algorithm used to determine visibility must effectively sort the objects prior to rendering. This has been a hot topic until recent years, with researchers finding new and creative ways to tackle the problem. The z-buffer is now undeniably the most widely used algorithm. Tree algorithms are, on the other hand, also widely used where time-based rendering (animation) is not an issue, especially where the object positions are static. BSP trees are discussed in greater detail in [Chapter 21](#).

The BSP tree is an example of a “painter’s algorithm.” [2] The basic concept of this algorithm involves sorting the objects (polygons) from back to front “relative to [the] viewpoint” and then drawing them in order. The key to the BSP algorithm in hidden surface removal is in the pre-processing, and encoding of the objects into a data structure that is later used to determine visibility. In other words, the data structure does not change, only the way it is viewed.

For hidden surface removal, the BSP tree is built by passing a plane through each polygon in the scene. For each point p in front of the plane, $f(p) > 0$ and for each point behind the plane, $f(p) < 0$. The tree structure is created by applying this object to each polygon, and defining a “negative branch” and “positive branch” for each polygon relative to the current position in the tree. Also called the “half space” on each side of the plane, each vertex position in the tree is dictated by its position relative to the passing planes. One plane is treated as the root of the tree, and successive branches are defined from that root.

Because the relative position of vertices to each other is defined by the tree, regardless of position, the entire BSP tree can be pre-computed. Whether or not polygons in the tree are visible is then a function of their position in the viewer’s plane. [Figure 55.19](#) demonstrates a BSP tree for vertices A through E shown in [Figure 55.18](#).

Note how each vertex can be located relative to at least two planes. For a viewpoint along h_3 , it is immediately apparent that vertex D is on the right, while A and E are on the left. Vertices C and B are located in the half space of h_1 and h_2 , and are therefore of no interest. Vertices C and B will not be rendered. This relative method works for all positions in the BSP tree.

As mentioned, BSP trees are not a universal solution for hidden surface removal, mainly because of the pre-processing requirement. There is a major caveat; if the objects in the scene are moving, the pre-processing of the BSP tree is no longer valid as the polygons change relative position. The tree must be built every time the relative positions of objects within the tree change. Recalculating the tree at each time step is often too slow, especially in 3-D gaming, where several million polygons must be rendered every second.

Another problem is that the BSP tree works in hidden surface removal only when “no polygon crosses the plane defined by any other polygon.” In other words, no object can be both behind and in front of another object for the BSP sorting algorithm to work. In gaming, it is common for objects to “collide” so this algorithm becomes even less desirable in these unpredictable conditions.

55.4.2 Proximity and Collision: Other Applications of the BSP Tree

Although BSP Tree structures are not as useful for determining the rendering order of moving polygons, they have other applications in graphics and gaming. For instance, trees are commonly used for collision detection, line-of sight, and other algorithms

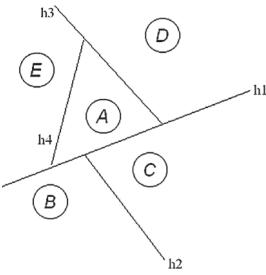

FIGURE 55.18 Objects in a plane.

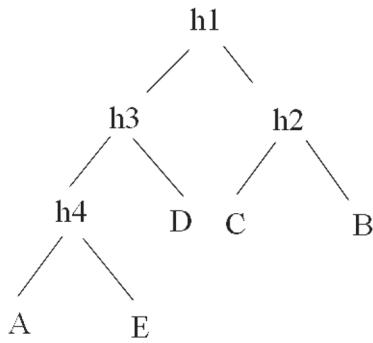

FIGURE 55.19 BSP tree for Figure 55.18.

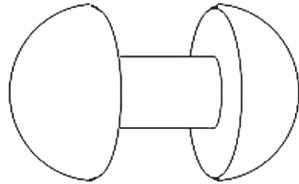

FIGURE 55.20 CSG object.

where the number of required calculations is lower. Determining between time-steps the relative positions of several (or several hundred) models, rather than several hundred million polygons, is much more feasible with today's hardware. Enhanced Tree structures are even used in many of today's more innovative artificial intelligence algorithms for gaming. These structures are used within the game space to quickly determine how an object sees, touches, and ultimately reacts with other objects.

55.4.3 More With Trees: CSG Modeling

Another widely used application of tree-based structures is application of Boolean operations to object construction. Constructive Solid Geometry, or CSG, modeling involves the construction of complex objects using only simple, primitive shapes. These shapes are added and subtracted to each other through "set operations," or "Boolean operations." The final objects are referred to as "compound," "Boolean," or "CSG" objects [5].

[Figure 55.20](#) of a dumbbell illustrates a typical example of a CSG object.

To construct this object in a CSG environment, Boolean operations are applied to primitive objects. These operations are "intersection," "union," and "difference" [5]. Each step in the tree represents a boolean combination between two objects. The resulting object at each point in the tree is then combined again with another Boolean operation at the next step. This type of progression is continued until the finished object is created. [Figure 55.21](#) illustrates the CSG tree used to construct this dumbbell using two spheres, a cylinder, and a half-plane.

A union operation is analogous to gluing two primitives together. An intersection operation results in only the portion (or volume) that both primitives occupy. Finally, a difference operation in effect removes the intersected section of one primitive from another. Armed with these three Boolean operations, modeling and displaying very complex shapes are possible. However,

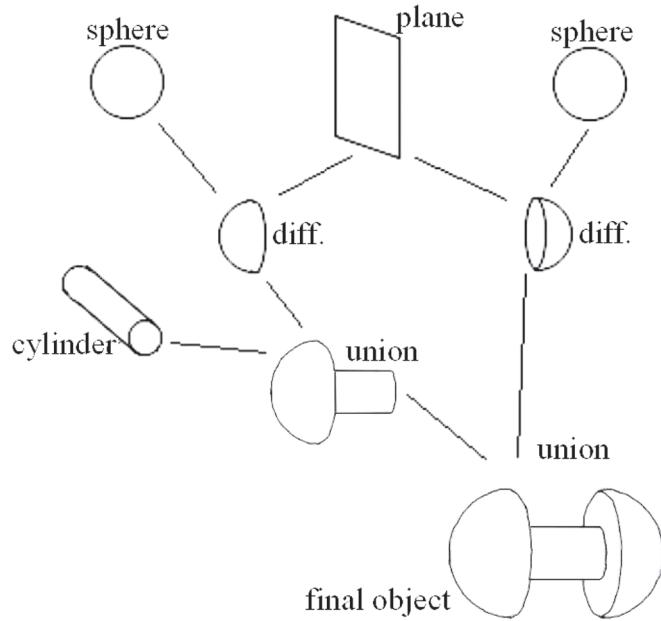

FIGURE 55.21 CSG tree corresponding to [Figure 55.20](#).

attempting to cover the surface of a final shape with a continuous mesh is another problem entirely, and the subject of numerous texts and papers. Consequently, CSG objects are largely used for initial visualization of a complete model. This solid model is then sent to another application that converts the model to a polygonal mesh.

From a data structure and algorithm standpoint, CSG trees are quite useful. Firstly, and most obvious, the method utilizes the tree structure already mentioned throughout the text. Secondly, the final objects do not require individual mesh models to define them. Rather, each object is simply defined by its tree, where each node of the tree references primitives, such as the sphere, cone, cylinder, cube, and plane. With the basic models for the sphere, cone, etc. preprocessed and stored in memory, the overhead of CSG applications is kept to a minimum.

Many commercially available solid modeling and animation packages still provide CSG as a standard user-interface.

56.1 Geographic Information Systems: What They Are All About

Geographic Information Systems (GISs) serve the purpose of maintaining, analyzing, and visualizing spatial data that represent geographic objects, such as mountains, lakes, houses, roads, and tunnels. For spatial data, geometric (spatial) attributes play a key role, representing, for example, points, lines, and regions in the plane or volumes in three-dimensional space. They model geographical features of the real world, such as geodesic measurement points, boundary lines between adjacent pieces of land (in a cadastral database), trajectories of mobile users, lakes or recreational park regions (in a tourist information system). In three dimensions, spatial data describe tunnels, underground pipe systems in cities, mountain ranges, or quarries. In addition, spatial data in a GIS possess nongeometric, so-called thematic attributes, such as the time when a geodesic measurement was taken, the name of the owner of a piece of land in a cadastral database, the usage history of a park.

This chapter aims to highlight some of the data structures and algorithms aspects of GISs that define challenging research problems, and some that show interesting solutions. More background information and deeper technical expositions can be found in books [1–10].

56.1.1 Geometric Objects

Our technical exposition will be limited to geometric objects with a vector representation. Here, a point is described by its coordinates in the Euclidean plane with a Cartesian coordinate system. We deliberately ignore the geographic reality that the earth is (almost) spherical, to keep things simple. A line segment is defined by its two end points. A polygonal line is a sequence of line segments with coinciding endpoints along the way. A (simple) polygonal region is described by its corner points, in clockwise (or counterclockwise) order around its interior. In contrast, in a raster representation of a region, each point in the region, discretized at some resolution, has an individual representation, just like a pixel in a raster image. Satellites take raster images at an amazing rate, and hence raster data abound in GISs, challenging current storage technology with terabytes of incoming data per day. Nevertheless, we are not concerned with raster images in this chapter, even though some of the techniques that we describe have implications for raster data [11]. The reason for our choice is the different flavor that operations with raster images have, as compared with vector data, requiring a chapter of their own.

56.1.2 Topological versus Metric Data

For some purposes, not even metric information is needed; it is sufficient to model the topology of a spatial dataset. *How many states share a border with Iowa?* is an example of a question of this topological type. In this chapter, however, we will not specifically study the implications that this limitation has. There is a risk of confusing the limitation to topological aspects only with the explicit representation of topology in the data structure. Here, the term explicit refers to the fact that a topological relationship need not be computed with substantial effort. As an example, assume that a partition of the plane into polygons is stored so that each polygon individually is a separate clockwise sequence of points around its interior. In this case, it is not easy to find the polygons that are neighbors of a given polygon, that is, share some boundary. If, however, the partition is stored so that each edge of the polygon explicitly references both adjacent polygons (just like the *doubly connected edge list* in computational geometry [12]), then a simple traversal around the given polygon will reveal its neighbors. It will always be an important design decision for a data structure which representation to pick.

56.1.3 Geometric Operations

Given this range of applications and geometric objects, it is no surprise that a GIS is expected to support a large variety of operations. We will discuss a few of them now, and then proceed to explain in detail how to perform two fundamental types of operations in the remainder of the chapter, spatial searching and spatial join. Spatial searching refers to rather elementary geometric operations without which no GIS can function. Here are a few examples, always working on a collection of geometric objects, such as points, lines, polygonal lines, or polygons. A *nearest neighbor query* for a query point asks for an object in the collection that is closest to the query point, among all objects in the collection. A *distance query* for a query point and a certain distance asks for all objects in the collection that are within the given distance from the query point. A *range query* (or window query) for a query range asks for all objects in the collection that intersect the given orthogonal window. A *ray shooting query* for a point and a direction asks for the object in the collection that is hit first if the ray starts at the given point and shoots in the given direction. A *point-in-polygon query* for a query point asks for all polygons in the collection in which the query point lies. These five types of queries are illustrations only; many more query types are just as relevant. For a more extensive discussion on geometric operations, see the chapters on geometric data structures in this Handbook. In particular, it is well understood that great care must be taken in geometric computations to avoid numeric problems, because already tiny numerical inaccuracies can have catastrophic effects on computational results. Practically all books on geometric computation devote some attention to this problem [12–14], and geometric software libraries such as CGAL [15] take care of the problem by offering exact geometric computation.

56.1.4 Geometric Data Structures

Naturally, we can only hope to respond to queries of this nature quickly, if we devise and make use of appropriate data structures. An extra complication arises here due to the fact that GISs maintain data sets too large for internal memory. So far, GIS have also not been designed for large distributed computer networks that would allow to exploit the internal memory of many nodes as it is known from the recently emerged Big Data technologies [16]. Data maintenance and analysis operations on a central system can therefore be efficient only if they take external memory properties into account, as discussed also in other chapters in this Handbook. We will limit ourselves here to external storage media with direct access to storage blocks, such as disks and flash memory. A block access to a random block on disk takes time to move the read–write–head to the proper position (the latency), and then to read or write the data in the block (the transfer). With today’s disks, where block sizes are on the order of several kilobytes, latency is a few milliseconds, and transfer time is less by a factor of about 100. Therefore, it pays to read a number of blocks in consecution, because they require the head movement only once, and in this way amortize its cost over more than one block. We will discuss in detail how to make use of this cost savings possibility.

All of the above geometric operations (see Section 56.1.3) on an external memory geometric data structure follow the general *filter-refinement* pattern [17] that first, all relevant blocks are read from disk. This step is a first (potentially rough) *filter* that makes a superset of the relevant set of geometric objects available for processing in main memory. In a second step, a refinement *identifies* the exact set of relevant objects. Even though complicated geometric operators can make this refinement step quite time-consuming, in this chapter we limit our considerations to the filter step. Because queries are the dominant operations in GISs by far, we do not explicitly discuss updates (see the chapters on external memory spatial data structures in this Handbook for more information).

56.1.5 Applications of Geographic Information

Before we go into technical detail, let us mention a few of the applications that make GISs a challenging research area up until today, with more fascinating problems to expect than what we can solve.

56.1.5.1 Map Overlay

Maps are the most well-known visualizations of geographical data. In its simplest form, a map is a partition of the plane into simple polygons. Each polygon may represent, for instance, an area with a specific thematic attribute value. For the attribute *land use*, polygons can stand for *forest*, *savanna*, *lake* areas in a simplistic example, whereas for the attribute *state*, polygons represent *Arizona*, *New Mexico*, *Texas*. In a GIS, each separable aspect of the data (such as the planar polygonal partitions just mentioned) is said to define a *layer*. This makes it easy to think about certain analysis and viewing operations, by just superimposing (overlaid) layers or, more generally, by applying Boolean operations on sets of layers. In our example, an overlay of a *land use* map with a *state* map defines a new map, where each new polygon is (some part of) the intersection of two given polygons, one from each layer. In *map overlay* in general, a Boolean combination of all involved thematic attributes together defines polygons of the resulting map, and one resulting attribute value in our example is the *savannas of Texas*. Map overlay has been studied in many different contexts, ranging from the special case of convex polygons in the partition and an internal memory plane-sweep computation [18] to the general case that we will describe in the context of spatial join processing later in this chapter.

56.1.5.2 Map Labeling

Map visualization is an entire field of its own (traditionally called cartography), with the general task to layout a map in such a way that it provides just the information that is desired, no more and no less; one might simply say, the map *looks right*. What that means in general is hard to say. For maps with texts that label cities, rivers, and the like, *looking right* implies that the labels are in proper position and size, that they do not run into each other or into important geometric features, and that it is obvious to which geometric object a label refers. Many simply stated problems in map labeling turn out to be NP-hard to solve exactly, and as a whole, map labeling is an active research area with a variety of unresolved questions (see Reference 19 for a tutorial introduction). In particular, the boundary-labeling problem [20] has attracted research attention assuming that labels are placed around an iso-oriented rectangle that contains a set of point objects. Dynamic map labeling [21] is another recently addressed problem of maps that are generated in an ad hoc manner using a set of operations such as zooming and panning. The underlying goal is to preserve a consistent layout of the labels among source and target maps.

56.1.5.3 Cartographic Generalization

If cartographers believe that automatically labeled maps will never look really good, they believe even more that another aspect that plays a role in map visualization will always need human intervention, namely map generalization. Generalization of a map is the process of reducing the complexity and contents of a map by discarding less important information and retaining the more essential characteristics. This is most prominently used in producing a map at a low resolution, given a map at a high resolution. Generalization ensures that the reader of the produced low resolution map is not overwhelmed with all the details from the high resolution map, displayed in small size in a densely filled area. Generalization is viewed to belong to the art of map making, with a whole body of rules of its own that can guide the artist [22,23]. The collection [24] provides a summary of the various flavors of generalization. Nevertheless, computational solutions of some subproblem help a lot, such as the simplification of a high resolution polygonal line to a polygonal line with fewer corner points that does not deviate too much from the given line. For line simplification, old algorithmic ideas [25] have seen efficient implementations [26]. A survey and an extensive experimental comparison of various algorithms is given in Reference 27 in terms of positional accuracy and processing time. Interesting extensions of the classical problem exist with the goal of preserving topological consistency [24,28].

Maps on demand, with a selected viewing window, to be shown on a screen with given resolution, imply the choice of a corresponding scale and therefore need the support of data structures that allow the retrieval up to a desired degree of detail [29]. More recently, van Oosterom and Meijers [30] have proposed a vario-scale structure that supports a continuous generalization while preserving consistency [110]. Apart from the simplest aspects, automatic map generalization, access support and labeling [21] are still open problems.

56.1.5.4 Road Maps

Maps have been used for ages to plan trips. Hence, we want networks of roads, railways, and the like to be represented in a GIS, in addition to the data described earlier. This fits naturally with the geometric objects that are present in a GIS in any case, such as polygonal lines. A point where polygonal lines meet (a node) can then represent an intersection of roads (edges), with a choice which road to take as we move along. The specialty in storing roads comes from the fact that we want to be able to find paths between nodes efficiently, for instance in car navigation systems, while we are driving. The fact that not all roads are equally important can be expressed by weights on the edges. Because a shortest path computation is carried out as a breadth first search on the edge weighted graph, in one way or another (e.g., bidirectional), it makes sense to partition the graph into pages so as

to minimize the weight of edges that cross the cuts induced by the partition. Whenever we want to maintain road data together with other thematic data, such as land use data, it also makes sense to store all the data in one structure, instead of using an extra structure for the road network. It may come as no surprise that for some data structures, partitioning the graph and partitioning the other thematic aspects go together very well (compromising a little on both sides), while for others this is not easily the case. The compromise in partitioning the graph does almost no harm, because it is NP-complete to find the optimum partition, and hence a suboptimal solution of some sort is all we can get anyway. An excellent recent survey on road networks and algorithms for shortest-paths can be found in Reference 31. It does not only provide a concise summary of various methods for different problem settings but also contains a very detailed experimental evaluation in terms of multiple factors such as query time, preprocessing cost, and space usage.

56.1.5.5 Spatiotemporal Data

Just like for many other database applications, a *time* component brings a new dimension to spatial data (even in the mathematical sense of the word, if you wish). *How did the forest areas in New Mexico develop over the last 20 years?* Questions like this one demonstrate that for environmental information systems, a specific branch of GISs, keeping track of developments over time is a must. Spatiotemporal database research is concerned with all problems that the combination of space with time raises, from models and languages, all the way through data structures and query algorithms, to architectures and implementations of systems [32]. In this chapter, we refrain from the temptation to discuss spatiotemporal data structures in detail; see Chapter 23 for an introduction into this lively field.

56.1.5.6 Data Mining

The development of spatial data over time is interesting not only for explicit queries but also for data mining. Here, one tries to find relevant patterns in the data, without knowing beforehand the character of the pattern (for an introduction to the field of data mining, see Reference 4). For more advanced topics, the reader is referred to Reference 33. Let us briefly look at a historic example for spatial data mining. A London epidemiologist identified a water pump as the centroid of the locations of cholera cases, and after the water pump was shut down, the cholera subsided. This and other examples are described in Reference 9. If we want to find patterns in quite some generality, we need a large data store that keeps track of data extracted from different data sources over time, a so-called data warehouse. It remains as an important, challenging open problem to efficiently run a spatial data warehouse and mine the spatial data. The spatial nature of the data seems to add the extra complexity that comes from the high autocorrelation present in typical spatial data sets, with the effect that most knowledge discovery techniques today perform poorly. This omnipresent tendency for data to cluster in space has been stated nicely [34]: *Everything is related to everything else but nearby things are more related than distant things.*

Due to the ubiquitous availability of GPS devices and their capability of tracking arbitrary movements, mining algorithms for trajectories have emerged over the last decade [35]. In addition to clustering and classification of trajectories, one of the most challenging spatial mining tasks is to extract behavioral patterns from very large set of trajectories [36]. A typical pattern is to identify sequences of regions, frequently visited by trajectories in a specified order with similar average stays. The work on trajectories differentiates between physical and semantic ones. A physical trajectory consists of typical physical measurements, such as position, speed, and acceleration, while a semantic or conceptual trajectory [37] adds annotations to the physical trajectory representing semantically richer patterns that are more relevant to a user. For example, someone might be interested in trajectories with high frequency of stops at touristic points. We refer to a recent survey [38] that gives an excellent summary of mining techniques for semantic trajectories.

56.2 Space Filling Curves: Order in Many Dimensions

As explained above, our interest in space filling curves (SFCs) comes from two sources. The first one is the fact that we aim at exploiting the typical database support mechanisms that a conventional database management system (DBMS) offers, such as support for transactions and recovery. On the data structures level, this support is automatic if we resort to a data structure that is inherently supported by a DBMS. These days, this is the case for a number of one-dimensional data structures, such as those of the B-tree family (see Chapter 16). In addition, spatial DBMS support one of a small number of multidimensional data structures, such as those of the R-tree family (see Chapter 22) or of a grid-based structure. The second reason for our interest in SFCs is the general curiosity in the gap between one dimension and many: In what way and to what degree can we bridge this gap for the sake of supporting spatial operations of the kind described above? In our setting, the gap between one dimension and many goes back to the lack of a linear order in many dimensions that is useful for all purposes. An SFC tries to overcome this problem at least to some degree, by defining an artificial linear order on a regular grid that is as useful as possible for the intended purpose.

Limiting ourselves in this section to two-dimensional space, we define an SFC more formally as a bijective mapping p from an index pair of a grid cell to its number in the linear order:

$$p : N \times N \longrightarrow \{1, \dots, N^2\}.$$

For the sake of simplicity, we limit ourselves to numbers $N = 2^n$ for some positive integer n .

Our main attention is on the choice of the linear order in such a way that range queries are efficient. In the GIS setting, it is not worst-case efficiency that counts, but efficiency in expectation. It is, unfortunately, hard to say what queries can be expected. Therefore, a number of criteria are conceivable according to which the quality of an SFC should be measured. Before entering the discussion about these criteria, let us present some of the most prominent SFCs that have been investigated for GIS data structures.

56.2.1 Recursively Defined SFCs

Two SFCs have been investigated most closely for the purpose of producing a linear ordering suitable for data structures for GIS, the z -curve, by some also called Peano curve or Morton encoding, and the Hilbert curve. We depict them in Figures 56.1 and 56.2. They can both be defined recursively with a simple refinement rule. To obtain a $2^{n+1} \times 2^{n+1}$ grid from a $2^n \times 2^n$ grid, replace each cell by the elementary pattern of four cells as in Figure 56.1, with the appropriate rotation for the Hilbert curve, as indicated in Figure 56.2 for the four by four grid (i.e., for $n=2$). In the same way, a slightly less popular SFC can be defined, the Gray code curve (see Figure 56.3).

For all recursively defined SFCs, there is an obvious way to compute the mapping p (and also its inverse), namely just along the recursive definition. Any such computation therefore takes time proportional to the logarithm of the grid size. Without going to great lengths in explaining how this computation is carried out in detail (refer [39] for this and other mathematical aspects of SFCs), let us just mention that there is a particularly nice way of viewing it for the z -curve: Here, p simply alternately interleaves the bits of both of its arguments, when these are expressed in binary. This may have made the z -curve popular among geographers at an early stage, even though our subsequent discussion will reveal that it is not necessarily the best choice.

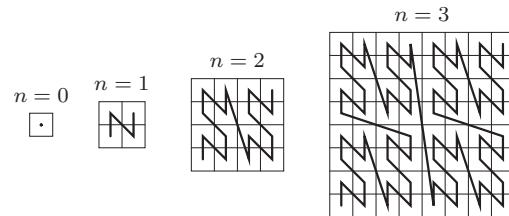

FIGURE 56.1 The z -curve for a $2^n \times 2^n$ grid, for $n = 0, \dots, 3$.

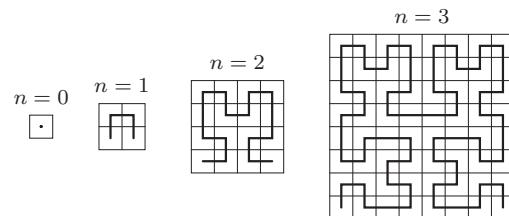

FIGURE 56.2 The Hilbert curve for a $2^n \times 2^n$ grid, for $n = 0, \dots, 3$.

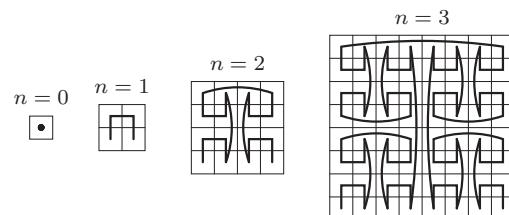

FIGURE 56.3 The Gray curve for a $2^n \times 2^n$ grid, for $n = 0, \dots, 3$.

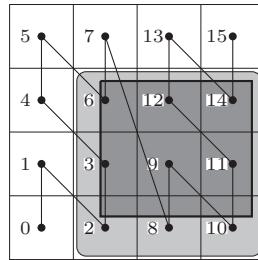

FIGURE 56.4 Range queries and disk seek operations.

56.2.2 Range Queries for SFC Data Structures

An SFC defines a linear order that is used to store the geographical data objects. We distinguish between two extreme storage paradigms that can be found in spatial data structures, namely a partition of the data space according to the objects present in the data set (such as in R-trees or in B-trees for a single dimension), or a partition of the space only, regardless of the objects (such as in regular cell partitions). The latter makes sense if the distribution of objects is somewhat uniform (see the spatial data structures chapters in this Handbook), and in this case achieves considerable efficiency. Naturally, a multitude of data structures that operate in between both extremes have been proposed, such as the grid file (see the spatial data structures chapters in this Handbook). As to the objects, let us limit ourselves to points in the plane, so that we can focus on a single partition of the plane into grid cells and need not worry about objects that cross cell boundaries (these are dealt with elsewhere in this Handbook, see, e.g., the chapter on R-trees or the survey chapter). For simplicity, let us restrict our attention to partitions of the data space into a $2^n \times 2^n$ grid, for some integer n . Partitions into other numbers of grid cells (i.e., not powers of 4) can be achieved dynamically for some data structures (see, e.g., z-Hashing [40]), but are not always easy to obtain; we will ignore that aspect for now.

Corresponding to both extreme data structuring principles, there are two ways to associate data with external storage blocks for SFCs. The simplest way is to identify a grid cell with a disk block. This is the usual setting. Grid cell numbers correspond to physical disk block addresses, and a range query translates into the need to access the corresponding set of disk blocks. In the example of Figure 56.4, for instance, the dark query range results in the need to read disk blocks corresponding to cells with numbers 2–3, 6, 8–12, 14, that is, cell numbers come in four consecutive sequences. In the best case, the cells to be read have consecutive numbers, and hence a single disk seek operation will suffice, followed by a number of successive block read operations. In the worst case, the sequence of disk cell numbers to be read breaks into a large number of consecutive pieces. It is one concern in the choice of an SFC to bound this number or some measure related to it (see the next subsection).

The association of a grid cell with exactly one disk block gives a data structure based on an SFC very little flexibility to adapt to a not so uniform data set. A different and more adaptive way of associating disk blocks with grid cells is based on a partition of the data space into cells so that for each cell, the objects in the cell fit on a disk block (as before), but a disk block stores the union of the sets of objects in a consecutive number of cells. This method has the advantage that relatively sparsely populated cells can go together in one disk block, but has the potential disadvantage that disk block maintenance becomes more complex. Not too complex, though, because a disk block can simply be maintained as a node of a B-tree (or, more specifically, a leaf, depending on the B-tree variety), with the content of a cell limiting the granularity of the data in the node. Under this assumption, the adaptation of the data structure to a dynamically changing population of data objects simply translates to split and merge operations of B-tree nodes. In this setting, the measure of efficiency for range queries may well be different from the above. One might be interested in running a range query on the B-tree representation, and ignoring (skipping) the contents of retrieved cells that do not contribute to the result. Hence, for a range query to be efficient, the consecutive single piece of the SFC that includes all cells of the query range should not run outside the query range for too long, that is, for too high a number of cells. We will discuss the effect of a requirement of this type on the design of an SFC in more detail below.

Obviously, there are many other ways in which an SFC can be the basis for a spatial data structure, but we will abstain from a more detailed discussion here and limit ourselves to the two extremes described so far.

56.2.3 Are All SFCs Created Equal?

Consider an SFC that visits the cells of a grid by visiting next an orthogonal neighbor of the cell just visited. The Hilbert curve is of this *orthogonal neighbor* type, but the z-curve is not. Now consider a square query region of some fixed (but arbitrary) size, say k by k grid cells, and study the number of consecutive pieces of the SFC that this query region defines (see Figure 56.5 for a

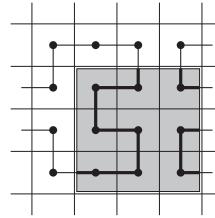

FIGURE 56.5 Disk seeks for an orthogonal curve.

range query region of 3×3 grid cells that defines three consecutive pieces of a Hilbert curve). We are interested in the average number of curve pieces over all locations of the query range.

For a fixed location of the query range, the number of curve pieces that the range defines is half the number of orthogonal neighbor links that cross the range boundary (ignoring the starting or ending cell of the entire curve). The reason is that when we start at the first cell of the entire curve and follow the curve, it is an orthogonal neighbor on the curve that leads into the query range and another one that leads out, repeatedly until the query range is exhausted. To obtain the average number of curve pieces per query range, we sum the number of boundary crossing orthogonal neighbors over all query range locations (and then divide that number by twice the number of locations, but this step is of no relevance in our argument).

This sum, however, amounts to the same as summing up for every orthogonal neighbor link the number of range query locations in which it is a crossing link. We content ourselves for the sake of simplicity with an approximate average, by ignoring cells close to the boundary of the data space, an assumption that will introduce only a small inaccuracy whenever k is much less than N (and this is the only interesting case). Hence, each orthogonal link will be a crossing link for $2k$ query range positions, namely k positions for the query range on each of both sides. The interesting observation now is that this summation disregards the position of the orthogonal link completely (apart from the fact that we ignore an area of size $O(kN)$ along the boundary of the universe). Hence, for any square range query, the average number of pieces of an SFC in the query range is the same across all SFCs of the orthogonal neighbor type.

In this sense, therefore, all SFCs of the orthogonal neighbor type have the same quality. This includes snake like curves such as row-major zigzag snakes and spiral snakes. Orthogonal neighbors are not a painful limitation here: If we allow for other than orthogonal neighbors, this measure of quality can become only worse, because a nonorthogonal neighbor is a crossing link for more query range locations. In rough terms, this indicates that the choice of SFC may not really matter that much. Nevertheless, it also shows that the above measure of quality is not perfectly chosen, since it captures the situation only for square query ranges, and that is not fully adequate for GISs. A recent measure of curve quality looks at a contiguous piece of the SFC and divides the area of its bounding box by the area that this piece of the curve covers. The quality of the curve is then the maximum of these ratios, taken over all contiguous pieces of the curve, appropriately called *worst-case bounding-box area ratio* (WBA) [41]. When instead of the area of the curve, its perimeter is taken as a basis, it needs to be properly normalized to be comparable to the area of the bounding box. When we normalize by pretending the perimeter belongs to a square, we get the ratio between the area of the bounding box and 1/16th of the squared perimeter. This view results in the *worst-case bounding-box squared perimeter ratio* (WBP) [41] as another quality measure, taking into account how wiggly the SFC is. For quite a few SFCs, WBA and WBP are at least 2, and the Peano curve comes very close to this bound [41]. These are not the only quality measures; for other measures and a thorough discussion of a variety of SFCs (also in higher dimension) and their qualities, see References 41 and 42. High dimension is useful when spatial objects have a high number of descriptive coordinates, such as four coordinates that describe an axis parallel rectangle, but high dimensional SFCs turn out to be far more complex to understand than those in two dimensions [43–45]. In this chapter, we will continue to discuss the basics for two dimensions only.

56.2.4 Many Curve Pieces for a Query Range

The properties that recursively definable SFCs entail for spatial data structure design have been studied from a theoretical perspective [46,47]. The performance of square range queries has been studied [46] on the basis that range queries in a GIS can have any size, but are most likely to not deviate from a square shape by too much. Based on the external storage access model in which disk seek and latency time by far dominates the time to read a block, they allow a range query to skip blocks for efficiency's sake. Skipping a block amounts to reading it in a sequence of blocks, without making use of the information thus obtained. In the example of Figure 56.4, skipping the blocks of cells 4, 5, 7, and 13 leads to a single sequence of the consecutive blocks 2–14. This can obviously be preferable to just reading consecutive sequences of relevant cell blocks only and therefore performing more disk seek operations, provided that the number of skipped blocks is not too large. In an attempt to quantify one against the other, consider a range query algorithm that is allowed to read a linear number of additional cells [46], as compared with those in the

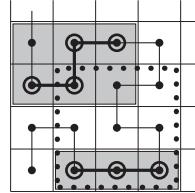

FIGURE 56.6 Bounding a piece of a curve.

query range. It turns out that for square range query regions of arbitrary size and the permission to read at most a linear number of extra cells, each recursive SFC needs at least three disk seek operations in the worst case. While no recursive SFC needs more than four disk seeks in the worst case, none of the very popular recursive SFCs, including the z -curve, the Hilbert curve, and the Gray code curve, can cope with less than four. One can define a recursive SFC that needs only three disk seeks in the worst case [46], and hence the lower and upper bounds match. This result is only a basis for data structure design, though, because its quality criterion is still too far from GIS reality to guide the design of practical SFCs. Nevertheless, this type of fragmentation has been studied in depth for a number of SFCs [48].

Along the same lines, one can refine the cost measure and account explicitly for disk seek cost [47]. For a sufficiently short sequence of cells, it is cheaper to skip them, but as soon as the sequence length exceeds a constant (that is defined by the disk seek cost, relative to the cost of reading a block), it is cheaper to stop reading and perform a disk seek. A refinement of the simple observation from above leads to performance formulas expressed in the numbers of links of the various types that the SFC uses, taking the relative disk seek cost into consideration [47]. It turns out that the local behavior of SFCs can be modeled well by random walks, again perhaps an indication that at least locally, the choice of a particular SFC is not crucial for the performance.

56.2.5 One Curve Piece for a Query Range

The second approach described above reads a single consecutive piece of the SFC to respond to a range query, from the lowest numbered cell in the range to the highest numbered. In general, this implies that a high number of irrelevant cells will be read. As we explained above, such an approach can be attractive, because it allows immediately to make use of well-established data structures such as the B-tree, including all access algorithms. We need to make sure, however, that the inefficiency that results from the extra accessed cells remains tolerable. Let us therefore now calculate this inefficiency approximately. To this end, we change our perspective and calculate for any consecutive sequence of cells along the SFC its shape in two-dimensional space. The shape itself may be quite complicated, but for our purpose a simple rectangular bounding box of all grid cells in question will suffice. The example in Figure 56.6 shows a set of 3 and a set of 4 consecutive cells along the curve, together with their bounding boxes (shaded), residing in a corner of a Hilbert curve. Given this example, a simple measure of quality suggests itself: The fewer useless cells we get in the bounding box, the better. A quick thought reveals that this measure is all too crude, because it does not take into consideration that square ranges are more important than skinny ranges. This bias can be taken into account by placing a piece of the SFC into its smallest enclosing square (see the dotted outline of a 3×3 square in Figure 56.6 for a bounding square of the 3 cells), and by taking the occupancy (i.e., percentage of relevant cells) of that square as the measure of quality. The question we now face is to bound the occupancy for a given SFC, across all possible pieces of the curve, and further, to find a best possible curve with respect to this bound. For simplicity's sake, let us again limit ourselves to curves with orthogonal links.

Let us first argue that the lower bound on the occupancy, for any SFC, cannot be higher than one-third. This is easy to see by contradiction. Assume to this end that there is an SFC that guarantees an occupancy of more than one-third. In particular, this implies that there cannot be two vertical links immediately after each other, nor can there be two consecutive horizontal links (the reason is that the three cells defining these two consecutive links define a smallest enclosing square of size 3 by 3 cells, with only 3 of these 9 cells being useful, and hence with an occupancy of only one-third). But this finishes the argument, because no SFC can always alternate between vertical and horizontal links (the reason is that a corner of the space that is traversed by the curve makes two consecutive links of the same type unavoidable, see Figure 56.7).

On the positive side, the Hilbert curve guarantees an occupancy of one-third. The reason is that the Hilbert curve gives this guarantee for the 4×4 grid, and that this property is preserved in the recursive refinement.

This leads to the conclusion that in terms of the worst-case occupancy guarantee, the Hilbert curve is a best possible basis for a spatial data structure.

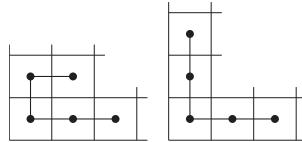

FIGURE 56.7 All possible corner cell traversals (excluding symmetry).

56.3 Spatial Join

In order to compute map overlays, a GIS provides an operator called spatial join that allows flexible combinations of multiple inputs according to a spatial predicate. The spatial join computes a subset of the Cartesian product of the inputs. Therefore, it is closely related to the join operator of a DBMS. A (binary) join on two sets of spatial objects, say R and S , according to a binary spatial predicate P is given by

$$SJ_P(R, S) = \{(r, s) \mid r \in R \wedge s \in S \wedge P(r, s)\}$$

The join is called a spatial join if the binary predicate P refers to spatial attributes of the objects. Among the most important ones are the following:

- Intersection predicate: $P_{\cap}(r, s) = (r \cap s \neq \emptyset)$.
- Distance predicate: Let DF be a distance function and $\epsilon > 0$. Then, $P_{DF}(r, s) = (DF(r, s) < \epsilon)$.

In the following we assume that R and S consist of N two-dimensional spatial objects and that the join returns a total of T pairs of objects. N is assumed being sufficiently large such that the problem cannot be solved entirely in main memory of size M . Therefore, we are particularly interested in external memory algorithms. Due to today's large main memory, the reader might question this assumption. However, remember that a GIS is a resource-intensive multiuser system where multiple complex queries are running concurrently. Thus the memory assigned to a specific join algorithm might be substantially lower than the total physically available. Given a block size of B , we use the following notations: $n = N/B$, $m = M/B$, and $t = T/B$. Without loss of generality, we assume that B is a divisor of N , M , and T .

A naive approach to processing a spatial join is simply to perform a so-called nested-loop algorithm, which checks the spatial predicate for each pair of objects. The nested-loop algorithm is generally applicable, but requires $O(N^2)$ time and $O(n^2)$ I/O operations. For special predicates, however, we are able to design new algorithms that provide substantial improvements in runtime compared to the naive approach. Among those is the intersection predicate, which is also the most frequently used predicate in GIS. We therefore will restrict our discussion to the intersection predicate to which the term spatial join will refer to by default. The discussion of other predicates is postponed to the end of the section. We refer to Reference 49 for an excellent survey on spatial joins.

The processing of spatial joins follows the general paradigm of multistep query processing [50] that consists at least of the following two processing steps. In the filter step, a spatial join is performed using conservative approximations of the spatial objects like their minimum bounding rectangles (MBRs). In the refinement step, the candidates of the filter step are checked against the join predicate using their exact geometry. In this section, we limit our discussion on the filter step that utilizes the MBR of the spatial objects. The reader is referred to References 51 and 52 for a detailed discussion of the refinement step and intermediate processing steps that are additionally introduced.

If main memory is large enough to keep R and S entirely in memory, the filter step is (almost) equivalent to the rectangle intersection problem, one of the elementary problems in computational geometry. The problem can be solved in $O(N \log N + T)$ runtime where T denotes the size of the output. This can be accomplished by using either a sweep-line algorithm [53] or a divide-and-conquer algorithm [54]. However, the disadvantage of these algorithms is their high overhead that results in a high constant factor. For real-life spatial data, it is generally advisable, see Reference 55 for example, to employ an algorithm that is not optimal in the worst case. The problem of computing spatial joins in main memory has attracted research attention again [56]. In comparison to external algorithms, it has been recognized that performance of main memory solutions is more sensitive to specific implementation details.

56.3.1 External Algorithms

In this subsection, we assume that the spatial relations are larger than main memory. According to the availability of indices on both relations, on one of the relations, or on none of the relations, we obtain three different classes of spatial join algorithms for the filter step. This common classification scheme also serves as a foundation in the most recent survey on spatial joins [49].

56.3.1.1 Index on Both Spatial Relations

In References 57 and 58, spatial join algorithms were presented where each of the relations is indexed by an R-tree. Starting at the roots, this algorithm synchronously traverses the trees node by node and joins all pairs of overlapping MBRs. If the nodes are leaves, the associated spatial objects are further examined in the refinement step. Otherwise, the algorithm is called recursively for each qualifying pair of entries. As pointed out in Reference 59, this algorithm is not limited to R-trees, but can be applied to a broad class of index structures. Important to both, I/O and CPU cost, is the traversal strategy. In Reference 58, a depth-first strategy was proposed where the qualifying pairs of nodes are visited according to a spatial ordering. If large buffers are available, a breadth-first traversal strategy was shown to be superior [60] in an experimental comparison. Though experimental studies have shown that these algorithms provide fast runtime in practice, the worst-case complexity of the algorithm is $O(n^2)$. The general problem of computing an optimal schedule for reading pages from disk is shown [61] to be NP-hard for spatial joins. For specific situations where two arbitrary rectangles from R and S do not share boundaries, the optimal solution can be computed in linear time. This is generally satisfied for bounding boxes of the leaves of R-trees.

56.3.1.2 Index on One Spatial Relation

Next, we assume that only one of the relations, say R , is equipped with a spatial index. We distinguish between the following three approaches. The first approach is to issue a range query against the index on R for each MBR of S . By using worst-case optimal spatial index structures, this already results in algorithms with subquadratic runtime. When a page buffer is available, it is also beneficial to sort the MBRs of S according to a criterion that preserves locality, for example, Hilbert value of the center of the MBRs. Then, two consecutive queries will access the same pages with high probability and therefore, the overall number of disk accesses decreases. The second approach as proposed in Reference 62 first creates a spatial index on S , the relation without spatial index. The basic idea for the creation of the index is to use the upper levels of the available index on R as a skeleton. Thereafter, one of the algorithms is applied that requires an index on both of the relations. In Reference 63, an improvement of the algorithm is presented that makes better use of the available main memory. A third approach is presented in References 64 and 65 where the spatial index is used for sorting the data according to one of the minimum boundaries of the rectangles. The sorted sequence then serves as input to an external plane-sweep algorithm.

56.3.1.3 Index on None of the Inputs

There are two early proposals on spatial join processing that require no index. The first one [66] suggests using an external version of a computational geometry algorithm. This is basically achieved by employing an external segment tree. The other [17] can be viewed as a sweep-line algorithm where the ordering is derived from z -order. Though the algorithm was originally not designed for rectangles, this can be accomplished in a straightforward manner [67,68]. Like any other sweep-line algorithm, R and S are first sorted, where the z -order serves as criterion in the following way. A rectangle receives the z -value of the smallest cell that still covers the entire rectangle. Let x be a z -value and $b(x) = (x_0, x_1, \dots, x_k)$ its binary representation where $k = l(x)$ denotes the level of the corresponding cell. Then, $x <_z y$, if $b(x) <_{lexi} b(y)$ where $<_{lexi}$ denotes the lexicographical order on strings. Note that if x is a prefix of y , x will precede y in lexicographical order. After sorting the input, the processing continues while maintaining a stack for each input. The stacks satisfy the following invariant. The z -value of each element (except the last) is a prefix of its successor. The algorithm simply takes the next element from the sorted inputs, say x from input R . Before x is pushed to the stack, all elements from both stacks are removed that are not prefix of $b(x)$. Thereafter, the entire stack of S is checked for overlap. The worst case of the join occurs when each of the rectangles belongs to the cell that represents the entire data space. Then, the join runs like a nested loop and requires $O(n^2)$ I/O operations. This can practically be improved by introducing redundancy [67,69]. However, the worst-case bound remains the same.

Other methods like the Partition Based Spatial-Merge Join (PBSM) [70] and the Spatial Hash-Join [71] are based on the principles of divide-and-conquer where spatial relations are partitioned into buckets that fit into main memory and the join is computed for each pair of corresponding buckets. Let us discuss PBSM in more detail. PBSM performs in four phases. In the first phase, the number of partitions p is computed such that the join for each pair of partitions is likely to be processed in main memory. Then, a grid is introduced with g cells, $g \geq p$ and each of the cells is then associated with a partition. A rectangle is then assigned to a partition if it intersects with at least one of its cells. In the second phase, pairs of partitions have to be processed that still contain too much data. This usually requires repartitioning of the data into smaller partitions. In the third phase, the join is processed in main memory for every pair of related partitions. The fourth phase consists of sorting, in order to get rid of duplicates in the response set. This however can be replaced by applying an inexpensive check of the result whenever it is produced [72]. Overall, the worst case is $O(n^2)$ I/O operations for PBSM.

Spatial Hash-Joins [71] differ from PBSM in the following way. One of the relations is first partitioned using a spatial index structure like an R-tree which uniquely assigns rectangles to leaves, where each of them corresponds to a partition. The other

relation is then partitioned using the index of the first relation. Each rectangle has to be stored in all partitions where an overlap with the MBR of the partition exists. Overall, this guarantees the avoidance of duplicate results.

At the end of the 1990s, Arge et al. [55] proposed the first spatial join algorithm that meets the lower I/O bound $O(n \log_m n + t)$. The method is an external sweep-line algorithm that is also related to the divide-and-conquer algorithm of Reference 66. Rather than partitioning the problem recursively into two, it is proposed to partition the input recursively into $k = \sqrt{m}$ strips of almost equal size until the problem is small enough for being solved in memory. This results in a recursion tree of height $O(\log_m n)$. At each level, $O(m)$ sorted lists of size $\Theta(B)$ are maintained where simultaneously an interval join is performed. Since each of the interval joins runs in $O(n' + t')$ (n' and t' denote the input size and result size of the join, respectively) and at most $O(N)$ intervals are maintained on each level of the recursion, it follows that at most $O(n)$ accesses are required for each level.

Instead of using the optimal algorithm, Arge et al. [55] employs a plane-sweep algorithm in their experiments where the sweep-line is organized by a dynamic interval tree. This is justified by the observation that the sweep-line is small as it holds only a small fraction of the entire spatial relations. If the algorithm really runs out of memory, it is recommended invoking the optimal algorithm for the entire problem. A different overflow strategy has been presented in Reference 73 where multiple iterations over the spatial relations might be necessary. The advantage of this strategy is that each result element is computed exactly once.

56.3.2 Advanced Issues

There are various extensions for spatial joins which are discussed in the following. We first address the processing of spatial joins on multiple inputs. Next, we discuss the processing of distance joins. Eventually, we conclude the section with a brief summary of requirements on the implementation of algorithms within a system.

The problem of joining more than two spatial relations according to a set of binary spatial predicates has been addressed in References 74 and 75. Such a join can be represented by a connected graph where its nodes represent the spatial relations and its edges binary join predicates. A first approach, called pairwise join method (PJM), is to decompose the multiway join into an operator tree of binary joins. The graphs with cycles therefore need to be transformed into a tree by ignoring the edges with lowest selectivity. Depending on the availability of spatial indexes, it is then advantageous to use from each class of spatial join algorithms the most efficient one. A different approach generalizes synchronous traversal to multiple inputs. The most important problem is not related to I/O, but to the processing cost of checking the join predicates. In Reference 74, different strategies are examined for an efficient processing of the join predicates. Results of an experimental study revealed that neither PJM nor synchronous traversal performs best in all situations. Therefore, an algorithm is presented for computing a hybrid of these approaches by using dynamic programming.

In addition to the intersection predicate, there are many other spatial predicates that are of practical relevance for spatial joins in a GIS, see Reference 76 for a survey. Among those, the distance predicate has received most attention. The distance join of R and S computes all pairs within a given distance. This problem has been even more extended in the following directions. First, pairs should be reported in an increasing order of the distances of the spatial objects. Second, only a fixed number of pairs should be reported. Third, answers should be produced on demand one at a time (without any limitations on the total number of answers). This problem has been addressed in References 77 and 78 where R-trees are assumed to be available on the spatial relations. The synchronized traversal is then controlled by two priority queues, where one maintains pairs of nodes according to their minimum distance and the other is primarily used for pruning irrelevant pairs of entries. In Reference 78, it was recognized that there are many overlapping nodes which are not distinguishable in the priority queues. In order to break ties, a secondary ordering has been introduced that assigns a high priority to such pairs that are likely to contribute to the final result. The problem of distance joins is not only important for spatial data in two dimensions, but it is possible to extend it to high dimensional spaces [79] and metric spaces [80]. Another member of the distance join family is the k -nearest neighbor join [81] that returns for each object of the one set the k -nearest neighbors in the other sets. This operation is of particular interest for moving object databases [82,83] where the one set refers to moving users and the other set consists of a spatial set with points of interest like restaurants.

Recently, the problem of iterated distance joins has been studied in the literature for supporting extensive simulations on a two-dimensional point set [84]. First, a distance self join returns for every point p of the input all points within distance ϵ to p . Then, these neighbors trigger a positional update of p . These two steps are recursively repeated on the updated input until the user quits the processing.

The design of algorithms for processing spatial joins largely depends on the specific system requirements. Similar to DBMSs, a complex query in a GIS is translated into an operator tree where nodes may correspond to spatial joins or other operators. There are two important issues that arise in this setting. First, an operator for processing spatial joins should have the ability to produce an estimation of the processing cost before the actual processing starts. Therefore, cost formulas [85] are required that are inexpensive to compute, only depend on a few parameters of the input and produce sufficiently accurate estimations. In general, accuracy of selectivity estimation can be largely improved using histograms [86]. Special spatial histograms have been proposed for estimating the selectivity of intersection joins [87–89] and k -nearest neighbor joins [90].

Second, it is generally advantageous to use join methods that are nonblocking, that is, first results are produced without having the entire input available. Nonblocking supports the production of early results and leads to small intermediate results in processing pipelines consisting of a large number of operators. This is a necessity for continuously arriving spatial streams [91] where the arrival of new data items triggers the processing and the corresponding results are immediately forwarded to the next consuming operator. A nonblocking operator is also beneficial for traditional demand-driven data processing engines [92] where an explicit request for the next result triggers the next processing steps of a query pipeline.

56.4 Models, Toolboxes, and Systems for Geographic Information

GISs differ substantially with respect to their specific functionality, which makes a comparison of the different systems quite difficult. We restrict our evaluation to the core functionality of a GIS related to manipulating vector data. Moreover, we stress the following three criteria in our comparison:

Data Model: The spatial data model offered by the system is very important to a user since it provides the geometric data types and the operations.

Spatial indexing: Spatial index structures are crucial for efficiently supporting the most important spatial queries. It is therefore important what kind of index structures are actually available, particularly for applications that deal with very large databases.

Spatial Join: Since spatial joins are the most meaningful operations for combining different maps, system performance depends on the efficiency of the underlying algorithm.

These criteria are among the most relevant ones for spatial query processing in a GIS [93].

Though we already have restricted our considerations to specific aspects, we limit our comparison to a few important systems and libraries. We actually start our discussion with introducing common standardized data models that are implemented by many commercial systems. Thereafter, we will discuss a few commercial systems that are used in the context of GIS in industry. Next, we present a few spatial libraries, some of them serve as plug-ins in systems.

56.4.1 Standardized Data Models

The most important standard for GIS [94,95] is published by Open Geospatial Consortium (OGC). This so-called simple feature model of OGC provides an object-oriented vector model and basic geometric data types. The actual implementations of commercial vendors like Oracle are closely related to the OGC standard. All of the geometric data types are subclasses of the class Geometry that provides an attribute that specifies the spatial reference system. One of the methods of Geometry delivers the so-called envelope of an object that is called MBR in our terminology. The data model distinguishes between atomic geometric types, such as points, curves and surfaces, and the corresponding collection types. The most complex atomic type is a polygonal surface that consists of an exterior polygonal ring and a set of internal polygonal rings where each of them represents a hole in the surface. Certain assertions have to be obeyed for such a polygonal surface to be in a consistent state.

The topological relationships of two spatial objects are expressed by using the nine-intersection model [96]. This model distinguishes between the exterior, interior, and boundary of an object. Spatial predicates like overlaps are then defined by specifying which of the assertions has to be satisfied. In addition to predicates, the OGC specification defines different constructive methods like the one for computing the convex hull of a spatial object. Another important function allows to compute the buffer object which contains those points that are within distance ε of a given object. Moreover, there are methods for computing the intersection (and other set operations) on two objects.

The OGC standard has also largely influenced other ones for geographic data like the standard for storing, retrieving, and processing spatial data using SQL [97] and the standard for the Geography Markup Language (GML) that is based on XML. The latest published version of the GML standard [98] additionally provides functionality to support three-dimensional objects and spatiotemporal applications. Because GML is often considered to be too complex, syntactically simpler markup languages, such as WKT [94] and GeoJSON [99], have gained popularity. For example, WKT serves in many database systems for supporting spatial data types. Users can express objects and functions in WKT, while the internal storage format is in a more compressed binary representation. The open standard format GeoJSON has become popular for the specification of vector data. Today, many front-end tools use GeoJSON to import and export spatial data in an easy way.

Due to the great variety of spatial data models, GDAL (Geospatial Data Abstraction Library)^{*} becomes an indispensable C++-library today. Originally designed for the conversion of raster data, it also comes with routines to convert vector models in its package OGR. While similar libraries exists, GDAL is undoubtedly the one with the largest support of data models so far.

56.4.2 Spatial Database Systems

In this section, we give an overview on the geographic query processing features of spatial database systems. We first start our discussion with the Oracle system that is still the first choice for the management of spatial data. Then, we introduce other important database systems with spatial support.

56.4.2.1 Oracle

Among the big database vendors, Oracle currently offers the richest support for the management of spatial data. The data model of Oracle [100] is conformant to the simple feature model of OGC. Oracle additionally offers curves where the arcs might be circular. The spatial functionality is implemented on top of Oracle's DBMS and therefore, it is not fully integrated. This is most notable when SQL is used for specifying spatial queries where the declarative flavor of SQL is in contrast to the imperative procedural calls of the spatial functionality.

The processing of spatial queries is performed by using the filter-refinement approach. Moreover, intermediate filters might be employed where a kernel approximation of the object is used. This kind of processing is applied to spatial selection queries and to spatial joins.

There are R-trees and quadtrees in Oracle for indexing spatial data. In contrast to R-trees, (linear) quadtrees are built on a grid decomposition of the data space into tiles, each of them keep a list of its intersecting objects. The linear quadtree is implemented within Oracle's B+-tree. In case of fixed indexing, the tiles are all of the same size. Oracle provides a function to enable users to determine a good setting of the tile size. In the case of hybrid indexing, tiles may vary in size. This is accomplished by locally increasing the grid resolution if the number of tiles is still below a given threshold. A comparison of Oracle's spatial index structures [101] shows that the query performance of the R-tree is superior compared to the quadtree.

56.4.2.2 Open Source Systems and Research Prototypes

Today, there is a plethora of database systems coming with spatial query processing support. The most well-known open source system is probably PostGIS,[†] a spatial extension of PostgreSQL. Similar to Oracle, PostGIS implements the simple feature model of OGC and supports the common topological 9-intersection model. For spatial indexing, R-trees are offered as a specialization of a more generic indexing framework. There is a large number of GIS products, such as ArcGIS and QGIS [102], that can use PostGIS as their underlying spatial data store. Among those is also CartoDB,[‡] a unique GIS system running in a cloud infrastructure and using PostGIS instances on the computing nodes. Another remarkable spatial database systems is MonetDB/GIS.[§] The unique features of this system are its column architecture, data compression, and in-memory processing. As mentioned before, main-memory processing is only possible if memory is also sufficiently available. Note however that compression rates in column stores tend to be extremely high such that this assumption is not anymore unrealistic for specific applications. Finally, systems are becoming of interest not running in server mode, but within the application process. Examples of such systems are SQLite[¶] and its spatial extender SpatiaLite. Both of them come with an R*-tree as spatial index. In a similar direction, H2GIS is the spatial extension of the open source system H2^{||} that is fully implemented in Java. Java applications can take advantage of H2GIS as the high communication and serialization overhead can be avoided.

56.4.3 Spatial Libraries

The success in rapidly developing spatial extensions of database systems is also due to the availability of powerful spatial libraries that already offer the building blocks for spatial query processing. We already mentioned the C++ library GDAL that supports a large number of spatial data models (raster and vector). However, the processing capabilities are not sufficient in GDAL. Therefore, other tools have been developed over the last decade.

56.4.3.1 JTS Topology Suite, GeoTools, and GEOS

The JTS Topology Suite (JTS) [103] is a Java class library providing fundamental geometric functions according to the geometry model defined by OGC [95]. Hence, it provides the basic spatial data types like polygonal surfaces and spatial predicates and operations like buffer and convex hull. The library also supports a user-definable precision model and contains code for robust geometric computation. There are also a few classes available for indexing MBRs (envelopes). The one structure is the MX-CIF

^{||} www.h2database.com.

quadtree [8] that is a specialized quadtree for organizing a dynamic set of rectangles. The other structure is a static R-tree that is created by using a bulk-loading technique [104]. So far, there has been no support of managing data on disk efficiently. The JTS library did not change for a long time until recently when the project was reactivated and a new version was published.

There are two important extensions of JTS. GEOS (Geometry Engine, Open Source) is a C++ library port of JTS Topology Suite. GEOS is a very active open source project and it can be viewed as the successor of JTS. It makes use of JTS and its mature numerically stable geometry operations, and also added extensions like support for raster data.

56.4.3.2 LEDA and CGAL

LEDA [105] and CGAL [15] are C++ libraries (see Chapter 42 for more on LEDA) that offer a rich collection of data structures and algorithms. Among the more advanced structures are spatial data types suitable for being used for the implementation of GIS. Most interesting to GIS is LEDA's and CGAL's ability to compute the geometry exactly by using a so-called rational kernel, that is, spatial data types whose coordinates are rational numbers. LEDA provides the most important two-dimensional data types such as points, iso-oriented rectangles, polygons, and planar subdivisions. Moreover, LEDA provides efficient implementations of important geometric algorithms such as convex hull, triangulations, and line intersection. AlgoComs, a companion product of LEDA, also provides a richer functionality for polygons that is closely related to a map overlay. In contrast to LEDA, the focus of CGAL is limited to computational geometry algorithms where CGAL's functionality is generally richer in comparison to LEDA. CGAL contains kd-trees for indexing multidimensional point data and supports incremental nearest neighbor queries.

Both, LEDA and CGAL, do not support external algorithms and spatial index structures. Therefore, they only partly cover the functionality required for a GIS. There has been an extension of LEDA, called LEDA-SM [106], that supports the most important external data structures.

56.4.3.3 XXL

XXL (eXtensible and fleXible Library) [107] is a pure Java library that does not originally support spatial data types, but only points and rectangles. Similar to GeoTools, this missing functionality is added by making use of JTS. XXL provides powerful support for various kinds of (spatial) indexes. There are different kinds of implementations of R-trees [108] as well as B-trees that might be combined with SFCs (e.g., z-order and Hilbert order). The concept of containers is introduced in XXL to provide an abstract view on external memory. Implementations of containers exist that are based on main memory, files, and raw disks. XXL offers a rich source of different kinds of spatial joins [72,109] that are based on using SFCs and the sort-merge paradigm. XXL is equipped with an object-relational algebra of query operators and a query optimizer that is able to rewrite Java programs. Query operators are iterators that deliver the answers of a query on demand, one by one. XXL is available under an open source licensing agreement (GNU LGPL).

57.1 Introduction

In a geometric context, collision detection refers to checking the relative configuration of two or more objects. The goal of collision detection, also known as interference detection or contact determination, is to automatically report a geometric contact when it is about to occur or has actually occurred. The objects may be represented as polygonal objects, spline or algebraic surfaces, deformable models, etc. Moreover, the objects may be static or dynamic.

Collision detection is a fundamental problem in computational geometry and frequently arises in different applications. These include:

1. *Physically-based Modeling and Dynamic Simulation*: The goal is to simulate dynamical systems and the physical behavior of objects subject to dynamic constraints. The mathematical model of the system is specified using geometric representations of the objects and the differential equations that govern the dynamics. The objects may undergo rigid or non-rigid motion. The contact interactions and trajectories of the objects are affected by collisions. It is important to model object interactions precisely and compute all the contacts accurately [1].
2. *Motion Planning*: The goal of motion planning is to compute a collision free path for a robot from a start configuration to a goal configuration. Motion planning is a fundamental problem in algorithmic robotics [2]. Most of the practical algorithms for motion planning compute different configurations of the robot and check whether these configurations are collision-free, that is, no collision between the robot and the objects in the environment. For example, probabilistic roadmap planners can spend up to 90% of the running time in collision checking.
3. *Virtual Environments and Walkthroughs*: A large-scale virtual environment, like a walkthrough, creates a computer-generated world, filled with real, simulated or virtual entities. Such an environment should give the user a feeling of presence, which includes making the images of both the user and the surrounding objects feel solid. For example, the objects should not pass through each other, and things should move as expected when pushed, pulled or grasped. Such actions require accurate and interactive collision detection. Moreover, runtime performance is critical in a virtual environment and all collision computations need to be performed at less than 1/30th of a second to give a sense of presence [3].
4. *Haptic Rendering*: Haptic interfaces, or force feedback devices, improve the quality of human-computer interaction by accommodating the sense of touch. In order to maintain a stable haptic system while displaying smooth and realistic forces and torques, haptic update rates must be as high as 1000 Hz. This involves accurately computing all contacts between the

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

object attached to the probe and the simulated environment, as well as the restoring forces and torques—all in less than one millisecond [4].

In each of these applications, collision detection is one of the major computational bottlenecks.

Collision detection has been extensively studied in the literature for more than four decades. Hundreds of papers have been published on different aspects in computational geometry and related areas like robotics, computer graphics, virtual environments and computer-aided design. Most of the algorithms are designed to check whether a pair of objects collide. Some algorithms have been proposed for large environments composed of multiple objects and perform some form of culling or localize pairs of objects that are potentially colliding. At a broad level, different algorithms for collision detection can be classified based on the following characteristics:

- *Query Type*: The basic collision query checks whether two objects, described as set of points, polygons or other geometric primitives, overlap. This is the boolean form of the query. The enumerative version of the query yields some representations of the intersection set. Other queries compute the separation distance between two non-overlapping objects or the penetration distance between two overlapping objects.
- *Object Types*: Different algorithms have been proposed for convex polytopes, general polygonal models, curved objects described using parametric splines or implicit functions, set-theoretic combinations of objects, deformable models, etc.
- *Motion Formulation*: The collision query can be augmented by adding the element of time. If the trajectories of two objects are known, then we can determine when is the next time that a particular boolean query will become true or false. These queries are called *dynamic queries*, whereas the ones that do not use motion information are called *static queries*. In the case where the motion of an object can not be represented as a closed form function of time, the underlying application often performs static queries at specific time steps in the application.

In this chapter, we give a brief survey of different collision detection algorithms for convex polytopes, general polygonal models, penetration computations and large-scaled environments composed of multiple objects. In each category, we give a detailed description of one of the algorithms and the underlying data structures.

57.2 Convex Polytopes

In this section, we give a brief survey of algorithms for collision detection between a pair of convex polytopes. This problem has been extensively studied and a number of algorithms with good asymptotic performance have been proposed. The best known runtime algorithm for boolean collision queries takes $O(\log^2 n)$ time, where n is the number of features [5]. It precomputes the Dobkin-Kirkpatrick hierarchy for each polytope and uses it to perform the runtime query. In practice, three classes of algorithms are commonly used for convex polytopes. These are linear programming, Minkowski sums, and tracking closest features based on Voronoi diagrams.

57.2.1 Linear Programming

The problem of checking whether two convex polytopes intersect or not can be posed as a linear programming (LP) problem. In particular, two convex polytopes do not overlap, if and only if there exists a separation plane between them. The coefficients of the separation plane equation are treated as unknowns. The linear constraints are formulated by imposing that all the vertices of the first polytope lie in one half-space of this plane and those of the other polytope lie in the other half-space. The linear programming algorithms are used to check whether there is any feasible solution to the given set of constraints. Given the fixed dimension of the problem, some of the well-known linear programming algorithms [6] can be used to perform the boolean collision query in expected linear time.

57.2.2 Voronoi-Based Marching Algorithm

An expected constant time algorithm for collision detection was proposed by Lin and Canny [7,8]. This algorithm tracks the closest features between two convex polytopes. The features may correspond to a vertex, an edge or a face of each polytope. Variants of this algorithm have also been presented in References 9,10. The original algorithm basically works by traversing the external Voronoi regions induced by the features of each convex polyhedron toward the pair of the closest features between the two given polytopes. The invariant is that at each step, either the inter-feature distance is reduced or the dimensionality of one or both of the features decreases by one, that is, a move from a face to an edge or from an edge to a vertex.

The algorithm terminates when the pair of testing features contain a pair of points that lie within the Voronoi regions of the other feature. It returns the pair of closest features and the Euclidean distance between them, as well as the contact status (i.e., colliding or not). This algorithm uses a modified boundary representation to represent convex polytopes and a data structure for describing “Voronoi regions” of convex polytopes.

57.2.2.1 Polytope Representation

Let A be a polytope. A is partitioned into “features” f_1, \dots, f_n where n is the total number of features, that is, $n = f + e + v$ where f, e, v stands for the total number of faces, edges, vertices respectively. Each feature (except vertex) is an open subset of an affine plane and does not contain its boundary.

Definition: B is in the *boundary* of F and F is in *coboundary* of B , if and only if B is in the closure of F , that is, $B \subseteq \bar{F}$ and B has one fewer dimension than F does.

For example, the coboundary of a vertex is the set of edges touching it and the coboundary of an edge are the two faces adjacent to it. The boundary of a face is the set of edges in the closure of the face. It uses winged edge representation, commonly used for boundary evaluation of boolean combinations of solid models [11]. The edge is oriented by giving two incident vertices (the head and tail). The edge points from tail to head. It has two adjacent faces cobounding it as well. Looking from the tail end toward the head, the adjacent face lying to the right hand side is labeled as the “right face” and similarly for the “left face.”

Each polytope’s data structure has a field for its features (faces, edges, vertices) and Voronoi cells to be described below. Each feature is described by its geometric parameters. Its data structure also includes a list of its boundary, coboundary, and *Voronoi regions*.

Definition: A *Voronoi region* associated with a *feature* is a set of points exterior to the polyhedron which are closer to that feature than any other. The Voronoi regions form a partition of space outside the polyhedron according to the closest feature. The collection of Voronoi regions of each polyhedron is the generalized Voronoi diagram of the polyhedron. Note that the Voronoi diagram of a convex polyhedron has linear size and consists of polyhedral regions.

Definition: A *Voronoi cell* is the data structure for a Voronoi region. It has a set of constraint planes that bound its Voronoi region with pointers to the neighboring cells (each of which shares a common constraint plane with the given Voronoi cell) in its data structure.

Using the geometric properties of convex sets, “applicability criteria” are established based upon the Voronoi regions. That is, if a point P on object A lies inside the Voronoi region of f_B on object B , then f_B is a closest feature to the point P . If a point lies on a constraint plane, then it is equi-distant from the two features that share this constraint plane in their Voronoi cells.

57.2.2.2 Local Walk

The algorithm incrementally traverses the features of each polytope to compute the closest features. For example, given a pair of features, *Face 1* and *vertex V_a* on objects A and B , respectively, as the pair of initial features (Figure 57.1). The algorithm verifies if the vertex V_a lies within *Cell 1* of *Face 1*. However, V_a violates the constraint plane imposed by *CP* of *Cell 1*, that is, V_a does not lie in the half-space defined by *CP* which contains *Cell 1*. The constraint plane *CP* has a pointer to its adjacent cell *Cell 2*, so the walk proceeds to test whether V_a is contained within *Cell 2*. In similar fashion, vertex V_a has a cell of its own, and the algorithm checks whether the nearest point P_a on the edge to the vertex V_a lies within V_a ’s Voronoi cell. Basically, the algorithm checks whether a point is contained within a Voronoi region defined by the constraint planes of the region. The constraint plane, which causes this test to fail, points to the next pair of closest features. Eventually, the algorithm computes the closest pair of features.

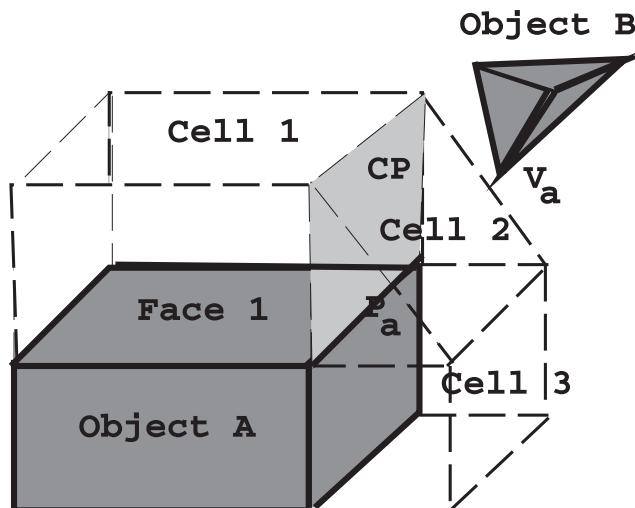

FIGURE 57.1 A walk across Voronoi cells. Initially, the algorithm checks whether the vertex V_a lies in *Cell 1*. After it fails the containment test with respect to the plane *CP*, it walks to *Cell 2* and checks for containment in *Cell 2*.

Since the polytopes and its faces are convex, the containment test involves only the neighboring features of the current candidate features. If either feature fails the test, the algorithm steps to a neighboring feature of one or both candidates, and tries again. With some simple preprocessing, the algorithm can guarantee that every feature of a polytope has a constant number of neighboring features. As a result, it takes a constant number of operations to check whether two features are the closest features.

This approach can be used in a static environment, but is especially well-suited for dynamic environments in which objects move in a sequence of small, discrete steps. The method takes advantage of coherence within two successive static queries: that is, the closest features change infrequently as the polytopes move along finely discretized paths. The closest features computed from the previous positions of the polytopes are used as the initial features for the current positions. The algorithm runs in *expected constant time* if the polytopes are not moving quickly. Even when a closest feature pair is changing rapidly, the algorithm takes only slightly longer. The running time is proportional to the number of feature pairs traversed, which is a function of the relative motion the polytopes undergo.

57.2.2.3 Implementation and Application

The Lin-Canny algorithm has been implemented as part of several public-domain libraries, include I-COLLIDE and SWIFT [12]. It has been used for different applications including dynamic simulation [13], interactive walkthrough of architectural models [3] and haptic display (including force and torque computation) of polyhedral models [14].

57.2.3 Minkowski Sums and Convex Optimization

The collision and distance queries can be performed based on the Minkowski sum of two objects. Given two sets of points, P and Q , their Minkowski sum is the set of points:

$$\{\mathbf{p} + \mathbf{q} \mid \mathbf{p} \in P, \mathbf{q} \in Q.\}$$

It has been shown in Reference 15, that the minimum separation distance between two objects is the same as the minimum distance from the origin of the Minkowski sums of A and $-B$ to the surface of the sums. The Minkowski sum is also referred to as the *translational C-space obstacle* (TCSO). If we take the TCSO of two convex polyhedra, A and B , then the TCSO is another convex polyhedra, and each vertex of the TCSO correspond to the vector difference of a vertex from A and a vertex from B . While the Minkowski sum of two convex polytopes can have $O(n^2)$ features [16], a fast algorithm for separation distance computation based on convex optimization that exhibits linear-time performance in practice has been proposed by Gilbert et al. [17]. It is also known as the GJK algorithm. It uses pairs of vertices from each object that define simplices (i.e., a point, bounded line, triangle or tetrahedron) within each polyhedra and a corresponding simplex in the TCSO. Initially the simplex is set randomly and the algorithm refines it using local optimization, till it computes the closest point on the TCSO from the origin of the Minkowski sums. The algorithm assumes that the origin is not inside the TCSO.

By taking the similar philosophy as the Lin-Canny algorithm [8], Cameron [18] presented an extension to the basic GJK algorithm by exploiting motion coherence and geometric locality in terms of connectivity between neighboring features. It keeps track of the *witness points*, a pair of points from the two objects that realize the minimum separation distance between them. As opposed to starting from a random simplex in the TCSO, the algorithm starts with the witness points from the previous iteration and performs hill climbing to compute a new set of witness points for the current configuration. The running time of this algorithm is a function of the number of refinement steps that the algorithm has to perform.

57.3 General Polygonal Models

Algorithms for collision and separation distance queries between general polygons models can be classified based on the fact whether they are closed polyhedral models or represented as a collection of polygons. The latter, also referred to as “polygon soups,” make no assumption related to the connectivity among different faces or whether they represent a closed set.

Some of the commonly known algorithms for collision detection and separation distance computation use spatial partitioning or bounding volume hierarchies (BVHs). The spatial subdivisions are a recursive partitioning of the embedding space, whereas bounding volume hierarchies are based on a recursive partitioning of the primitives of an object. These algorithms are based on the divide-and-conquer paradigm. Examples of spatial partitioning hierarchies include k-D trees and octrees [19], R-trees and their variants [20], cone trees, BSPs [21] and their extensions to multi-space partitions [22]. The BVHs use bounding volumes (BVs) to bound or contain sets of geometric primitives, such as triangles, polygons, curved surfaces, etc. In a BVH, BVs are stored at the internal nodes of a tree structure. The root BV contains all the primitives of a model, and children BVs each contain separate partitions of the primitives enclosed by the parent. Each of the leaf node BVs typically contains one primitive. In some variations, one may place several primitives at a leaf node, or use several volumes to contain a single primitive. The BVHs are

used to perform collision and separation distance queries. These include sphere-trees [23,24], AABB-trees [20,25, 26], OBB-trees [27–29], spherical shell-trees [30,31], k -DOP-trees [32,33], SSV-trees [34], and convex hull-trees [35]. Different BVHs can be classified based on:

- *Choice of BV*: The AABB-tree uses an axis-aligned bounding box (AABB) as the underlying BV. The AABB for a set of primitives can be easily computed from the extremal points along the X , Y and Z direction. The sphere tree uses a sphere as the underlying BV. Algorithms to compute a minimal bounding sphere for a set of points in 3D are well known in computational geometry. The k -DOP-tree is an extension of the AABB-tree, where each BV is computed from extremal points along k fixed directions, as opposed to the 3 orthogonal axes. A spherical shell is a subset of the volume contained between two concentric spheres and is a tight fitting BV. A SSV (swept sphere volume) is defined by taking the Minkowski sum of a point, line or a rectangle in 3D with a sphere. The SSV-tree corresponds to a hybrid hierarchy, where the BVs may correspond to a point-swept sphere (PSS), a line-swept sphere (LSS) or a rectangle-swept sphere (RSS). Finally, the BV in the convex-hull tree is a convex polytope.
- *Hierarchy generation*: Most of the algorithms for building hierarchies fall into two categories: bottom-up and top-down. Bottom-up methods begin with a BV for each primitive and merge volumes into larger volumes until the tree is complete. Top-down methods begin with a group of all primitive, and recursively subdivide until all leaf nodes are indivisible. In practice, top-down algorithms are easier to implement and typically take $O(n \lg n)$ time, where n is the number of primitives. On the other hand, the bottom-up methods use clustering techniques to group the primitives at each level and can lead to tighter-fitting hierarchies.

The collision detection queries are performed by traversing the BVHs. Two models are compared by recursively traversing their BVHs in tandem. Each recursive step tests whether BVs A and B , one from each hierarchy, overlap. If A and B do not overlap, the recursion branch is terminated. But if A and B overlap, the enclosed primitives may overlap and the algorithm is applied recursively to their children. If A and B are both leaf nodes, the primitives within them are compared directly. The running time of the algorithm is dominated by the overlap tests between two BVs and a BV and a primitive. It is relatively simple to check whether two AABBs overlap or two spheres overlap or two k -DOPs overlap. Specialized algorithms have also been proposed to check whether two OBBs, two SSVs, two spherical shells or two convex polytopes overlap. Next, we described a commonly used interference detection algorithm that uses hierarchies of oriented bounding boxes.

57.3.1 Interference Detection Using Trees of Oriented Bounding Boxes

In this section we describe an algorithm for building a BVH of OBBs (called OBBTree) and using them to perform fast interference queries between polygonal models. More details about the algorithm are available in References 27,29.

The underlying algorithm is applicable to all triangulated models. They need not represent a compact set or have a manifold boundary representation. As part of a preprocess, the algorithm computes a hierarchy of oriented bounding boxes (OBBs) for each object. At runtime, it traverses the hierarchies to check whether the primitives overlap.

57.3.1.1 OBBTree Construction

An OBBTree is a bounding volume tree of OBBs. Given a collection of triangles, the algorithm initially approximates them with an OBB of similar dimensions and orientation. Next, it computes a hierarchy of OBBs.

The OBB computation algorithm makes use of first and second order statistics summarizing the vertex coordinates. They are the mean, μ , and the covariance matrix, C , respectively [36]. If the vertices of the i 'th triangle are the points \mathbf{p}^i , \mathbf{q}^i , and \mathbf{r}^i , then the mean and covariance matrix can be expressed in vector notation as:

$$\begin{aligned}\boldsymbol{\mu} &= \frac{1}{3n} \sum_{i=0}^n (\mathbf{p}^i + \mathbf{q}^i + \mathbf{r}^i), \\ \mathbf{C}_{jk} &= \frac{1}{3n} \sum_{i=0}^n (\bar{\mathbf{p}}_j^i \bar{\mathbf{p}}_k^i + \bar{\mathbf{q}}_j^i \bar{\mathbf{q}}_k^i + \bar{\mathbf{r}}_j^i \bar{\mathbf{r}}_k^i), \quad 1 \leq j, k \leq 3\end{aligned}$$

where n is the number of triangles, $\bar{\mathbf{p}}^i = \mathbf{p}^i - \boldsymbol{\mu}$, $\bar{\mathbf{q}}^i = \mathbf{q}^i - \boldsymbol{\mu}$, and $\bar{\mathbf{r}}^i = \mathbf{r}^i - \boldsymbol{\mu}$. Each of them is a 3×1 vector, for example, $\bar{\mathbf{p}}^i = (\bar{\mathbf{p}}_1^i, \bar{\mathbf{p}}_2^i, \bar{\mathbf{p}}_3^i)^T$ and \mathbf{C}_{jk} are the elements of the 3 by 3 covariance matrix.

The eigenvectors of a symmetric matrix, such as C , are mutually orthogonal. After normalizing them, they are used as a basis. The algorithm finds the extremal vertices along each axis of this basis. Two of the three eigenvectors of the covariance matrix are the axes of maximum and of minimum variance, so they will tend to align the box with the geometry of a tube or a flat surface patch.

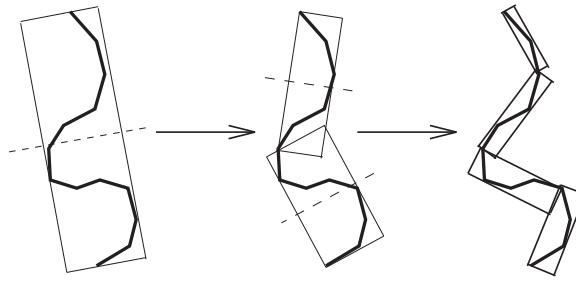

FIGURE 57.2 Building the OBBTree: recursively partition the bounded polygons and bound the resulting groups. This figure shows three levels of an OBBTree of a polygonal chain.

The algorithm's performance can be improved by using the convex hull of the vertices of the triangles. To get a better fit, we can sample the surface of the convex hull densely, taking the mean and covariance of the sample points. The uniform sampling of the convex hull surface normalizes for triangle size and distribution.

One can sample the convex hull “infinitely densely” by integrating over the surface of each triangle, and allowing each differential patch to contribute to the covariance matrix. The resulting integral has a closed form solution. Let the area of the i 'th triangle in the convex hull be denoted by

$$A^i = \frac{1}{2} |(\mathbf{p}^i - \mathbf{q}^i) \times (\mathbf{p}^i - \mathbf{r}^i)|$$

Let the surface area of the entire convex hull be denoted by

$$A^H = \sum_i A^i$$

Let the centroid of the i 'th convex hull triangle be denoted by

$$\mathbf{c}^i = (\mathbf{p}^i + \mathbf{q}^i + \mathbf{r}^i)/3$$

Let the centroid of the convex hull, which is a weighted average of the triangle centroids (the weights are the areas of the triangles), be denoted by

$$\mathbf{c}^H = \frac{\sum_i A^i \mathbf{c}^i}{\sum_i A^i} = \frac{\sum_i A^i \mathbf{c}^i}{A^H}$$

The elements of the covariance matrix \mathbf{C} have the following closed-form,

$$\mathbf{C}_{jk} = \sum_{i=1}^n \frac{A^i}{12A^H} (9\mathbf{c}_j^i \mathbf{c}_k^i + \mathbf{p}_j^i \mathbf{p}_k^i + \mathbf{q}_j^i \mathbf{q}_k^i + \mathbf{r}_j^i \mathbf{r}_k^i) - \mathbf{c}_j^H \mathbf{c}_k^H$$

Given an algorithm to compute tight-fitting OBBs around a group of polygons, we need to represent them hierarchically. The simplest algorithm for OBBTree computation uses a top-down method. It is based on a subdivision rule that splits the longest axis of a box with a plane orthogonal to one of its axes, partitioning the polygons according to which side of the plane their center point lies on (a 2-D analog is shown in Figure 57.2). The subdivision coordinate along that axis is chosen to be that of the mean point, μ , of the vertices. If the longest axis cannot not be subdivided, the second longest axis is chosen. Otherwise, the shortest one is used. If the group of polygons cannot be partitioned along any axis by this criterion, then the group is considered indivisible.

Given a model with n triangles, the overall time to build the tree is $O(n \log^2 n)$ if we use convex hulls, and $O(n \log n)$ if we don't. The recursion is similar to that of quicksort. Fitting a box to a group of n triangles and partitioning them into two subgroups takes $O(n \log n)$ with a convex hull and $O(n)$ without it. Applying the process recursively creates a tree with leaf nodes $O(\log n)$ levels deep.

57.3.1.2 Interference Detection

Given OBBTrees of two objects, the interference algorithm typically spends most of its time testing pairs of OBBs for overlap. The algorithm computes axial projections of the bounding boxes and check for disjointness along those axes. Under this projection, each box forms an interval on the axis (a line in 3D). If the intervals don't overlap, then the axis is called a ‘separating axis’ for the boxes, and the boxes must then be disjoint.

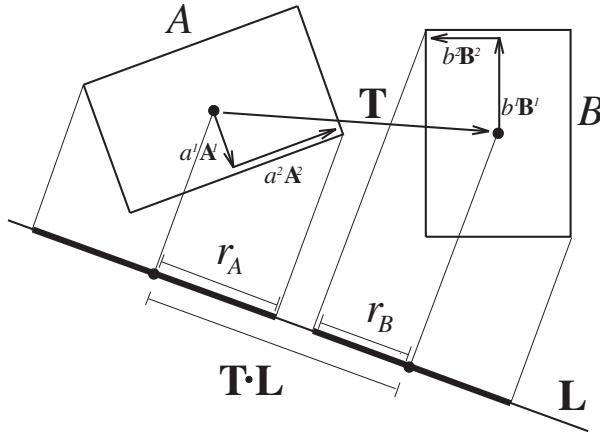

FIGURE 57.3 \vec{L} is a separating axis for OBBs A and B because A and B become disjoint intervals under projection (shown as r_A and r_B , respectively) onto \vec{L} .

It has been shown that we need to perform at most 15 axial projections in 3D to check whether two OBBs overlap or not [29]. These 15 directions correspond to the face normals of each OBB, as well as 9 pairwise combinations obtained by taking the cross-product of the vectors representing their edges.

To perform the test, the algorithm projects the centers of the boxes onto the axis, and also to compute the radii of the intervals. If the distance between the box centers as projected onto the axis is greater than the sum of the radii, then the intervals (and the boxes as well) are disjoint. This is shown in 2D in [Figure 57.3](#).

57.3.1.3 OBB Representation and Overlap Test

We assume we are given two OBBs, A and B , with B placed relative to A by rotation matrix \vec{R} and translation vector \vec{T} . The half-dimensions (or “radii”) of A and B are a_i and b_i , where $i = 1, 2, 3$. We will denote the axes of A and B as the unit vectors \vec{A}^i and \vec{B}^i , for $i = 1, 2, 3$. These will be referred to as the 6 box axes. Note that if we use the box axes of A as a basis, then the three columns of \vec{R} are the same as the three \vec{B}^i vectors.

The centers of each box projects onto the midpoint of its interval. By projecting the box radii onto the axis, and summing the length of their images, we obtain the radius of the interval. If the axis is parallel to the unit vector \vec{L} , then the radius of box A ’s interval is

$$r_A = \sum_i |a_i \vec{A}^i \cdot \vec{L}|$$

A similar expression is used to compute r_B .

The placement of the axis is immaterial, so we assume it passes through the center of box A . The distance between the midpoints of the intervals is $|\vec{T} \cdot \vec{L}|$. So, the intervals are disjoint if and only if

$$|\vec{T} \cdot \vec{L}| > \sum_i |a_i \vec{A}^i \cdot \vec{L}| + \sum_i |b_i \vec{B}^i \cdot \vec{L}|$$

This simplifies when \vec{L} is a box axis or cross product of box axes. For example, consider $\vec{L} = \vec{A}^1 \times \vec{B}^2$. The second term in the first summation is

$$\begin{aligned} |a_2 \vec{A}^2 \cdot (\vec{A}^1 \times \vec{B}^2)| &= |a_2 \vec{B}^2 \cdot (\vec{A}^2 \times \vec{A}^1)| \\ &= |a_2 \vec{B}^2 \cdot \vec{A}^3| \\ &= |a_2 \vec{B}_3^2| \\ &= a_2 |\vec{R}_{32}| \end{aligned}$$

The last step is due to the fact that the columns of the rotation matrix are also the axes of the frame of B . The original term consisted of a dot product and cross product, but reduced to a multiplication and an absolute value. Some terms reduce to zero

and are eliminated. After simplifying all the terms, this axis test looks like:

$$|\vec{T}_3\vec{R}_{22} - \vec{T}_2\vec{R}_{32}| > a_2|\vec{R}_{32}| + a_3|\vec{R}_{22}| + b_1|\vec{R}_{13}| + b_3|\vec{R}_{11}|$$

All 15 axis tests simplify in similar fashion. Among all the tests, the absolute value of each element of \vec{R} is used four times, so those expressions can be computed once before beginning the axis tests. If any one of the expressions is satisfied, the boxes are known to be disjoint, and the remainder of the 15 axis tests are unnecessary. This permits early exit from the series of tests. In practice, it takes up to 200 arithmetic operations in the worst case to check whether two OBBs overlap.

57.3.1.4 Implementation and Application

The OBBTree interference detection algorithm has been implemented and used as part of the following packages: RAPID, V-COLLIDE and PQP [12]. These implementations have been used for robot motion planning, dynamic simulation and virtual prototyping.

57.3.2 Performance of Bounding Volume Hierarchies

The performance of BVHs on proximity queries is governed by a number of design parameters. These include techniques to build the trees, number of children each node can have, and the choice of BV type. An additional design choice is the descent rule. This is the policy for generating recursive calls when a comparison of two BVs does not prune the recursion branch. For instance, if BVs A and B failed to prune, one may recursively compare A with each of the children of B , B with each of the children of A , or each of the children of A with each of the children of B . This choice does not affect the correctness of the algorithm, but may impact the performance. Some of the commonly used algorithms assume that the BVHs are binary trees and each primitive is a single triangle or a polygon. The cost of performing the collision query is given as [27,34]:

$$T = N_{bv} \times C_{bv} + N_p \times C_p,$$

where T is the total cost function for collision queries, N_{bv} is the number of bounding volume pair operations, and C_{bv} is the total cost of a BV pair operation, including the cost of transforming and updating (including resizing) each BV for use in a given configuration of the models, and other per BV-operation overhead. N_p is the number of primitive pairs tested for proximity, and C_p is the cost of testing a pair of primitives for proximity (e.g., overlaps or distance computation).

Typically for tight fitting bounding volumes, for example, oriented bounding boxes (OBBs), N_{bv} and N_p are relatively low, whereas C_{bv} is relatively high. In contrast, C_{bv} is low while N_{bv} and N_p may be higher for simple BV types like spheres and axis-aligned bounding boxes (AABBs). Due to these opposing trends, no single BV yields optimum performance for collision detection in all possible cases.

57.4 Penetration Depth Computation

In this section, we give a brief overview of penetration depth (PD) computation algorithms between convex polytopes and general polyhedral models. The PD of two inter-penetrating objects A and B is defined as the minimum translation distance that one object undergoes to make the interiors of A and B disjoint. It can be also defined in terms of the TCSO. When two objects are overlapping, the origin of the Minkowski sum of A and $-B$ is contained inside the TCSO. The penetration depth corresponds to the minimum distance from the origin to the surface of TCSO [18]. PD computation is often used in motion planning [37], contact resolution for dynamic simulation [38,39] and force computation in haptic rendering [40]. For example, computation of dynamic response in penalty-based methods often needs to perform PD queries for imposing the non-penetration constraint for rigid body simulation. In addition, many applications, such as motion planning and dynamic simulation, require a continuous distance measure when two (non-convex) objects collide, in order to have a well-posed computation.

Some of the algorithms for PD computation involve computing the Minkowski sums and computing the closest point on its surface from the origin. The worst case complexity of the overall PD algorithm is governed by the complexity of computing Minkowski sums, which can be $O(n^2)$ for convex polytopes and $O(n^6)$ for general (or non-convex) polyhedral models [16]. Given the complexity of Minkowski sums, many approximation algorithms have been proposed in the literature for fast PD estimation.

57.4.1 Convex Polytopes

Dobkin et al. [16] have proposed a hierarchical algorithm to compute the directional PD using Dobkin and Kirkpatrick polyhedral hierarchy. For any direction d , it computes the directional penetration depth in $O(\log n \log m)$ time for polytopes with m and n vertices. Agarwal et al. [41] have presented a randomized approach to compute the PD values [41]. It runs in

$O(m^{\frac{3}{4}+\epsilon} n^{\frac{3}{4}+\epsilon} + m^{1+\epsilon} + n^{1+\epsilon})$ expected time for any positive constant ϵ . Cameron [18] has presented an extension to the GJK algorithm [17] to compute upper and lower bounds on the PD between convex polytopes. Bergen has further elaborated this idea in an expanding polytope algorithm [42]. The algorithm iteratively improves the result of the PD computation by expanding a polyhedral approximation of the Minkowski sums of two polytopes.

57.4.2 Incremental Penetration Depth Computation

Kim et al. [43] have presented an incremental penetration depth (PD) algorithm that marches towards a “locally optimal” solution by walking on the surface of the Minkowski sum. The surface of the TCSO is implicitly computed by constructing a local Gauss map and performing a local walk on the polytopes.

This algorithm uses the concept of width computation from computational geometry. Given a set of points $P = \{p_1, p_2, \dots, p_n\}$ in 3D, the *width* of P , $W(P)$, is defined as the minimum distance between parallel planes supporting P . The width $W(P)$ of convex polytopes A and B is closely related to the penetration depth $PD(A, B)$, since it is easy to show that $W(P) = PD(P, P)$. It can be shown that width and penetration depth computation can be reduced to searching only the VF and EE antipodal pairs (where V, E and F denote a vertex, edge and face, respectively, of the polytopes). This is accomplished by using the standard dual mapping on the Gauss map (or normal diagram). The mapping is defined from object space to the surface of a unit sphere S^2 as: a vertex is mapped to a region, a face to a point, and an edge to a great arc. The algorithm finds the antipodal pairs by overlaying the upper hemisphere of the Gauss map on the lower hemisphere and computing the intersections between them.

57.4.2.1 Local Walk

The incremental PD computation algorithm does not compute the entire Gauss map for each polytope or the entire boundary of the Minkowski sum. Rather it computes them in a lazy manner based on local walking and optimization. Starting from some feature on the surface of the Minkowski sum, the algorithm computes the direction in which it can decrease the PD value and proceeds towards that direction by extending the surface of the Minkowski sum.

At each iteration of the algorithm, a vertex is chosen from each polytope to form a pair. It is called a *vertex hub pair* and the algorithm uses it as a hub for the expansion of the local Minkowski sum. The vertex hub pair is chosen in such a way that there exists a plane supporting each polytope, and is incident on each vertex. It turns out that the vertex hub pair corresponds to two intersected convex regions on a Gauss map, which later become intersecting convex polygons on the plane after *central projection*. The intersection of convex polygons corresponds to the VF or EE antipodal pairs that are used to reconstruct the local surface of the Minkowski sum around the vertex hub pair. Given these pairs, the algorithm chooses the one that corresponds to the shortest distance from the origin of the Minkowski sum to their surface. If this pair decreases the estimated PD value, the algorithm updates the current vertex hub pair to the new adjacent pair. This procedure is repeated until the algorithm can not decrease the current PD value and converges to a local minima.

57.4.2.2 Initialization and Refinement

The algorithm starts with an initial guess on the vertex hub pair. A good estimate to the penetration direction can be obtained by taking the centroid difference between the objects, and computing an extremal vertex pair for the difference direction. In other cases, the penetrating features (for overlapping polytopes) or the closest features (from non-overlapping polytopes) from the previous instance can also suggest a good initial guess.

After the algorithm obtains a initial guess for a VV pair, it iteratively seeks to improve the PD estimate by jumping from one VV pair to an adjacent VV pair. This is accomplished by looking around the neighborhood of the current VV pair and walking to a pair which provides the greatest improvement in the PD value. Let the current vertex hub pair be $v_1 v'_1$. The next vertex hub pair $v_2 v'_2$ is computed as follows:

1. Construct a local Gauss map each for v_1 and v'_1 ,
2. Project the Gauss maps onto $z = 1$ plane, and label them as G and G' , respectively. G and G' correspond to convex polygons in 2D.
3. Compute the intersection between G and G' using a linear time algorithm such as [44]. The result is a convex polygon and let u_i be a vertex of the intersection set. If u_i is an original vertex of G or G' , it corresponds to the VF antipodal pair in object space. Otherwise, it corresponds to an EE antipodal pair.
4. In object space, determine which u_i corresponds to the best local improvement in PD, and set an adjacent vertex pair (adjacent to u_i) to $v_2 v'_2$.

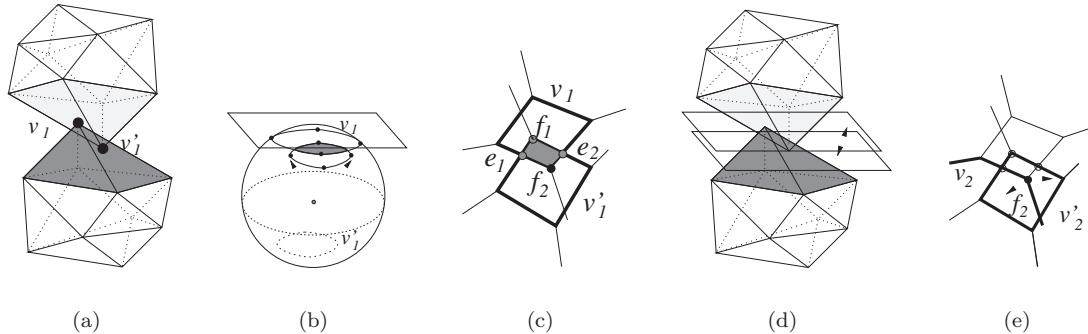

FIGURE 57.4 Iterative optimization for incremental PD computation: (a) The current VV pair is $v_1v'_1$ and a shaded region represents edges and faces incident to $v_1v'_1$. (b) shows local Gauss maps and their overlay for $v_1v'_1$. (c) shows the result of the overlay after central projection onto a plane. Here, f_1, e_1, f_2 and e_2 comprise vertices (candidate PD features) of the overlay. (d) illustrates how to compute the PD for the candidate PD features in object space. (e) f_2 is chosen as the next PD feature, thus $v_2v'_2$ is determined as the next vertex hub pair.

This iteration is repeated until either there is no more improvement in the PD value or number of iterations reach some maximum value. At step 4 of the iteration, the next vertex hub pair is selected in the following manner. If u_i corresponds to VF, then the algorithm chooses one of the two vertices adjacent to F assuming that the model is triangulated. The same reasoning is also applied to when u_i corresponds to EE. As a result, the algorithm needs to perform one more iteration in order to actually decide which vertex hub pair should be selected. A snapshot of a typical step during the iteration is illustrated in Figure 57.4. Eventually the algorithm computes a local minima.

57.4.2.3 Implementation and Application

The incremental algorithm is implemented as part of DEEP [12]. It works quite well in practice and is also able to compute the global penetration depth in most cases. It has been used for 6-DOF haptic rendering (force and torque display), dynamic simulation and virtual prototyping.

57.4.3 Non-Convex Models

Algorithms for penetration depth estimation between general polygonal models are based on discretization of the object space containing the objects or use of digital geometric algorithms that perform computations on a finite resolution grid. Fisher and Lin [45] have presented a PD estimation algorithm based on the distance field computation using the fast marching level-set method. It is applicable to all polyhedral objects as well as deformable models, and it can also check for self-penetration. Hoff et al. [46,47] have proposed an approach based on performing discretized computations on the graphics rasterization hardware. It uses multi-pass rendering techniques for different proximity queries between general rigid and deformable models, including penetration depth estimation. Kim et al. [43] have presented a fast approximation algorithm for general polyhedral models using a combination of object-space as well discretized computations. Given the global nature of the PD problem, it decomposes the boundary of each polyhedron into convex pieces, computes the pairwise Minkowski sums of the resulting convex polytopes and uses graphics rasterization hardware to perform the closest point query up to a given discretized resolution. The results obtained are refined using a local walking algorithm. To further speed up this computation and improve the estimate, the algorithm uses a hierarchical refinement technique that takes advantage of geometry culling, model simplification, accelerated ray-shooting, and local refinement with greedy walking. The overall approach combines discretized closest point queries with geometry culling and refinement at each level of the hierarchy. Its accuracy can vary as a function of the discretization error. It has been applied to haptic rendering and dynamic simulation.

57.5 Large Environments

Large environments are composed of multiple moving objects. Different methods have been proposed to overcome the computational bottleneck of $O(n^2)$ pairwise tests in an environment composed of n objects. The problem of performing proximity queries in large environments, is typically divided into two parts [3,23]: the *broad phase*, in which we identify the pair of objects on which we need to perform different proximity queries, and the *narrow phase*, in which we perform the exact pairwise queries. In this section, we present a brief overview of algorithms used in the broad phase.

Architecture for Multi-body Collision Detection

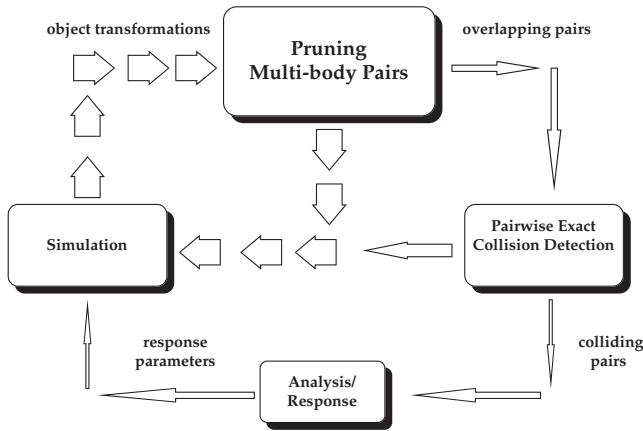

FIGURE 57.5 Architecture for multiple body collision detection algorithm.

The simplest algorithms for large environments are based on spatial subdivisions. The space is divided into cells of equal volume, and at each instance the objects are assigned to one or more cells. Collisions are checked between all object pairs belonging to each cell. In fact, Overmars has presented an efficient algorithm based on hash table to efficiently perform point location queries in fat subdivisions [48]. This approach works well for sparse environments in which the objects are uniformly distributed through the space. Another approach operates directly on four-dimensional volumes swept out by object motion over time [49].

57.5.1 Multiple-Object Collision Detection

Large-scale environments consist of stationary as well as moving objects. Let there be N moving objects and M stationary objects. Each of the N moving objects can collide with the other moving objects, as well as with the stationary ones. Keeping track of $(N^2) + NM$ pairs of objects at every time step can become time consuming as N and M get large. To achieve interactive rates, we must reduce this number before performing pairwise collision tests. In this section, we give an overview of sweep-and-prune algorithm used to perform multiple-object collision detection [3]. The overall architecture of the multiple object collision detection algorithm is shown in Figure 57.5.

The algorithm uses sorting to prune the number of pairs. Each object is surrounded by a 3-dimensional bounding volume. These bounding volumes are sorted in 3-space to determine which pairs are overlapping. The algorithm only needs to perform exact pairwise collision tests on these remaining pairs.

However, it is not intuitively obvious how to sort objects in 3-space. The algorithm uses a *dimension reduction* approach. If two bodies collide in a 3-dimensional space, their orthogonal projections onto the xy , yz , and xz -planes and x , y , and z -axes must overlap. Based on this observation, the algorithm uses axis-aligned bounding boxes and efficiently project them onto a lower dimension, and perform sorting on these lower-dimensional structures.

The algorithm computes a rectangular bounding box to be the tightest axis-aligned box containing each object at a particular orientation. It is defined by its minimum and maximum x , y , and z -coordinates. As an object moves, the algorithm recomputes its minima and maxima, taking into account the object's orientation.

As a precomputation, the algorithm computes each object's initial minima and maxima along each axis. It is assumed that the objects are convex. For non-convex polyhedral models, the following algorithm is applied to their convex hulls. As an object moves, its minima and maxima are recomputed in the following manner:

1. Check to see if the current minimum (or maximum) vertex for the x , y , or z -coordinate still has the smallest (or largest) value in comparison to its neighboring vertices. If so the algorithm terminates.
2. Update the vertex for that extreme direction by replacing it with the neighboring vertex with the smallest (or largest) value of all neighboring vertices. Repeat the entire process as necessary.

This algorithm recomputes the bounding boxes at an expected constant rate. It exploits the temporal and geometric coherence.

The algorithm does not transform all the vertices as the objects undergo motion. As it is updating the bounding boxes, new positions are computed for current vertices using matrix-vector multiplications. This approach is optimized based on the fact that

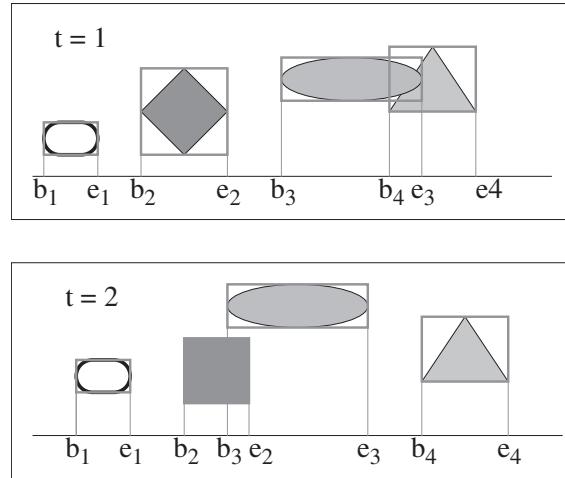

FIGURE 57.6 Bounding box behavior between successive instances. Notice the coherence between the 1D list obtained after projection onto the X-axis.

the algorithm is interested in *one* coordinate value of each extremal vertex, say the x coordinate while updating the minimum or maximum value along the x -axis. Therefore, there is no need to transform the other coordinates in order to compare neighboring vertices. This reduces the number of arithmetic operations by two-thirds, as we only compute a dot-product of two vectors and do not perform matrix-vector multiplication.

57.5.1.1 One-Dimensional Sweep and Prune

The one-dimensional sweep and prune algorithm begins by projecting each three-dimensional bounding box onto the x , y , and z axes. Because the bounding boxes are axis-aligned, projecting them onto the coordinate axes results in intervals (see Figure 57.6). The goal is to compute the overlaps among these intervals, because a pair of bounding boxes can overlap if and only if their intervals overlap in all three dimensions.

The algorithm constructs three lists, one for each dimension. Each list contains the values of the endpoints of the intervals corresponding to that dimension. By sorting these lists, it determines which intervals overlap. In the general case, such a sort would take $O(n \log n)$ time, where n is the number of objects. This time bound is reduced by keeping the sorted lists from the previous frame, changing only the values of the interval endpoints. In environments where the objects make relatively small movements between frames, the lists will be nearly sorted, so we can sort in expected $O(n)$ time, as shown in References 50,51. In practice, insertion sort works well for almost sorted lists.

In addition to sorting, the algorithm keeps track of changes in the overlap status of interval pairs (i.e., from overlapping in the last time step to non-overlapping in the current time step, and vice-versa). This can be done in $O(n + e_x + e_y + e_z)$ time, where e_x , e_y , and e_z are the number of exchanges along the x , y , and z -axes. This also runs in expected linear time due to coherence, but in the worst case e_x , e_y , and e_z can each be $O(n^2)$ with an extremely small constant.

This algorithm is suitable for dynamic environments where coherence between successive static queries is preserved. In computational geometry literature several algorithms exist that solve the static version of determining 3-D bounding box overlaps in $O(n \log^2 n + s)$ time, where s is the number of pairwise overlaps [52,53]. It has been reduced to $O(n + s)$ by exploiting coherence.

57.5.1.2 Implementation and Application

The sweep-and-prune has been used in some of the widely uses collision detection systems, including I-COLLIDE, V-COLLIDE, SWIFT and SWIFT++ [12]. It has been used for multi-body simulations and interactive walkthroughs of complex environments.

57.5.2 Two-Dimensional Intersection Tests

The two-dimensional intersection algorithm begins by projecting each three-dimensional axis-aligned bounding box onto any two of the x - y , x - z , and y - z planes. Each of these projections is a rectangle in 2-space. Typically there are fewer overlaps of these 2-D rectangles than of the 1-D intervals used by the sweep and prune technique. This results in fewer swaps as the objects move.

In situations where the projections onto one-dimension result in densely clustered intervals, the two-dimensional technique is more efficient. The interval tree is a common data structure for performing such two-dimensional range queries [54].

Each query of an interval intersection takes $O(\log n + k)$ time where k is the number of reported intersections and n is the number of intervals. Therefore, reporting intersections among n rectangles can be done in $O(n \log n + K)$ where K is the total number of intersecting rectangles [55].

58.1 Introduction

Image has been an integral part of our communication. Visual information aids us in understanding our surroundings better. Image processing, the science of manipulating digital images, is one of the methods used for digitally interpreting images. Image processing generally comprises three main steps:

1. Image acquisition: Obtaining the image by scanning it or by capturing it through some sensors.
2. Image manipulation/analysis: Enhancing and/or compressing the image for its transfer or storage.
3. Display of the processed image.

Image processing has been classified into two levels: low-level image processing and high-level image processing. Low-level image processing needs little information about the content or the semantics of the image. It is mainly concerned with retrieving low-level descriptions of the image and processing them. Low-level data include matrix representation of the actual image. Image calibration and image enhancement are examples of low-level image processing.

High-level image processing is basically concerned with segmenting an image into objects or regions. It makes decisions according to the information contained in the image. High-level data are represented in symbolic form. The data include features of the image such as object size, shape and its relation with other objects in the image. These image-processing techniques depend significantly on the underlying image data structure. Efficient data structures for region representation are important for use in manipulating pictorial information.

Many techniques have been developed for representing pictorial information in image processing [1]. These techniques include data structures such as quadtrees, linear quadtrees, Forest of Quadtrees, and Translation Invariant Data structure (TID). We will discuss these data structures in the following sections. Research on quadtrees has produced several interesting results in different areas of image processing [2–7]. In 1981, Jones and Iyengar [8] proposed methods of refining quadtrees. A good tracing of the history of the evolution of quadtrees is provided by Klinger and Dyer [9]. See also [Chapter 20](#) of this handbook.

58.2 What is Image Data?

An image is a visual reproduction of an object using an optical or electronic device. Image data include pictures taken by satellites, scanned images, aerial photographs and other digital photographs. In the computer, image is represented as a data file that consists of a rectangular array of picture elements called pixels. This rectangular array of pixels is also called a raster image. The pixels are the smallest programmable visual unit. The size of the pixel depends on the resolution of the monitor. The resolution can be defined as the number of pixels present on the horizontal axis and vertical axis of a display monitor. When the resolution is set to maximum the pixel size is equal to a dot on the monitor. The pixel size increases with the decrease of the resolution. [Figure 58.1](#) shows an example of an image.

In a monochrome image each pixel has its own brightness value ranging from 0 (black) to 255 (white). For a color image each pixel has a brightness value and a RGB color value. RGB is an additive color state that has separate values for red, green, and blue. Hence each pixel has independent values (0–255) for red, green, and blue colors. If the values for red, green, and blue components of the pixel are the same then the resulting pixel color is gray. Different shades of gray pixels constitute a gray-scale image. If pixels of an image have only two states, black or white, then the image is called a binary image.

Image data can be classified into raster graphics and vector graphics. Raster graphics, also known as bitmap graphics, represents an image using x and y coordinates (for 2d-images) of display space; this grid of x and y coordinates is called the raster. [Figure 58.2](#) shows how a circle will appear in raster graphics. In raster graphics an image is divided up in raster. All raster dots that are more than half full are displayed as black dots and the rest as white dots. This results in step like edges as shown in the figure. The appearance of jagged edges can be minimized by reducing the size of the raster dots. Reducing the size of the dots will increase the number of pixels needed but increases the size of the storage space.

Vector graphics uses mathematical formulas to define the image in a two-dimensional or three-dimensional space. In a vector graphics file an image is represented as a sequence of vector statements instead of bits, as in bitmap files. Thus it needs just minimal amount of information to draw shapes and therefore the files are smaller in size compared to raster graphics files.

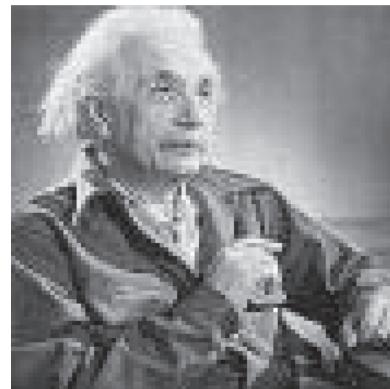

FIGURE 58.1 Example of an image.

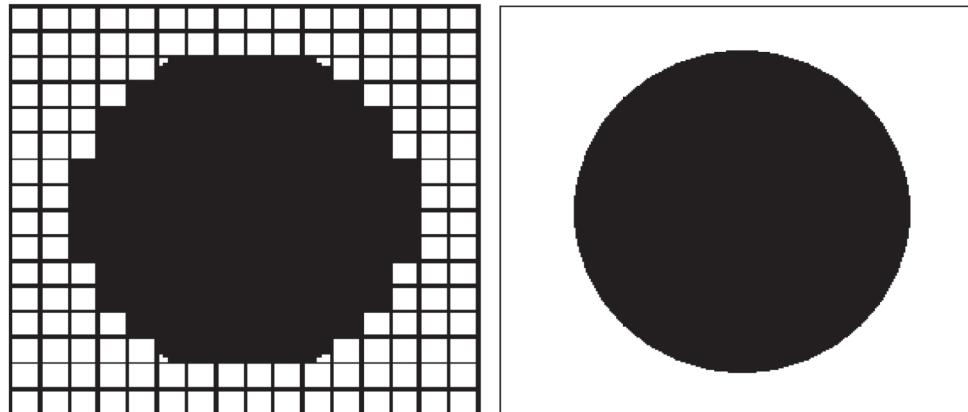

FIGURE 58.2 A circle in raster graphics.

Vector graphics does not consist of black and white pixels but is made of objects like line, circle, and rectangle. The other advantage of vector graphics is that it is flexible, so it can be resized without loss of information. Vector graphics is typically used for simple shapes. CorelDraw images, PDF, and PostScript are all in vector image format. The main drawbacks of vector graphics is that it needs longer computational time and has very limited choice of shapes compared to raster graphics.

Raster file, on the other hand, is usually larger than vector graphics file and is difficult to modify without loss of information. Scaling a raster file will result in loss of quality whereas vector graphics can be scaled to the quality of the device on which it is rendered. Raster graphics is used for representing continuous numeric values unlike vector graphics, which is used for discrete features. Examples of raster graphic formats are GIF, JPEG, and PNG.

58.3 Quadtrees

Considerable research on quadtrees has produced several interesting results in different areas of image processing. The basic relationship between a region and its quadtree representation is presented in [3]. In 1981, Jones and Iyengar [8] proposed methods for refining quadtrees. The new refinements were called virtual quadtrees, which include compact quadtrees and forests of quadtrees. We will discuss virtual quadtrees in a later section of this chapter. Much work has been done on the quadtree properties and algorithms for manipulations and translations have been developed by Samet [10,11], Dyer [2] and others [3,5,12].

58.3.1 What is a Quadtree?

A quadtree is a class of hierarchical data structures used for image representation. The fundamental principle of quadtrees is based on successive regular decomposition of the image data until each part contains data that is sufficiently simple so that it can be represented by some other simpler data structure. A quadtree is formed by dividing an image into four quadrants, each quadrant may further be divided into four sub quadrants and so on until the whole image has been broken down to small sections of uniform color.

In a quadtree the root represents the whole image and the non-root nodes represent sub quadrants of the image. Each node of the quadtree represents a distinct section of the image; no two nodes can represent the same part of the image. In other words, the sub quadrants of the image do not overlap. The node without any child is called a leaf node and it represents a region with uniform color. Each non-leaf node in the tree has four children, each of which represents one of the four sub regions, referred to as NW, NE, SW, and SE, that the region represented by the parent node is divided into.

The leaf node of a quadtree has the color of the pixel (black or white) it is representing. The nodes with uniform colored children have the color of their children and all their child nodes are removed from the tree. All the other nodes with non-uniform colored children have the gray color. [Figure 58.3](#) shows the concept of quadtrees.

The image can be retrieved from the quadtree by using a recursive procedure that visits each leaf node of the tree and displays its color at an appropriate position. The procedure starts with visiting the root node. In general, if the visited node is not a leaf then the procedure is recursively called for each child of the node, in order from left to right.

The main advantage of the quadtree data structure is that images can be compactly represented by it. The data structure combines data having similar values and hence reduces storage size. An image having large areas of uniform color will have very small storage size. The quadtree can be used to compress bitmap images, by dividing the image until each section has the same color. It can also be used to quickly locate any object of interest.

The drawback of the quadtree is that it can have totally different representation for images that differ only in rotation or translation. Though the quadtree has better storage efficiency compared to other data structures such as the array, it also has considerable storage overheads. For a given image it stores many white leaf nodes and intermediate gray nodes, which are not required information.

58.3.2 Variants of Quadtrees

The numerous quadtree variants that have been developed so far can be differentiated by the type of data they are designed to represent [13]. The many variants of the quadtree include region quadtrees, point quadtrees, line quadtrees, and edge quadtrees. Region quadtrees are meant for representing regions in images, while point quadtrees, edge quadtrees, and line quadtrees are used to represent point features, edge features, and line features, respectively. Thus there is no single quadtree data structure which is capable of representing a mixture of features of images like regions and lines.

58.3.2.1 Region Quadtrees

In the region quadtree, a region in a binary image is a subimage that contains either all 1's or all 0's. If the given region does not consist entirely of 1's or 0's, then the region is divided into four quadrants. This process is continued until each divided section

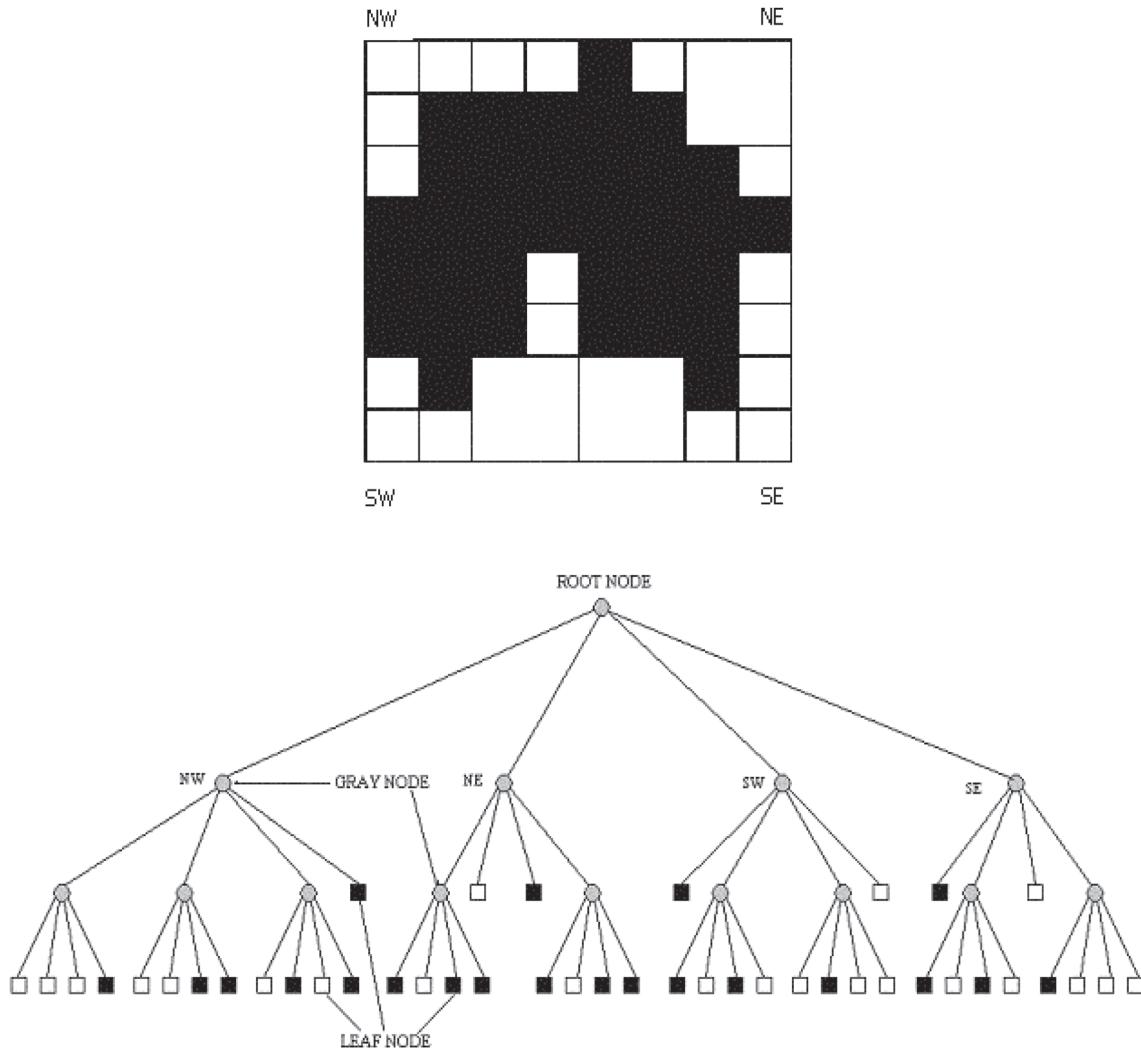

FIGURE 58.3 The concept of quadtrees.

consists entirely of 1's or 0's; such regions are called final regions. The final regions (either black or white) are represented by leaf nodes. The intermediate nodes are called gray nodes. A region quadtree is space efficient for images containing square-like regions. It is very inefficient for regions that are elongated or for representing line features.

58.3.2.2 Line Quadtrees

The line quadtree proposed by Samet [14] is used for representing the boundaries of a region. The given region is represented as in the region quadtree with additional information associated with nodes representing the boundary of the region. The data structure is used for representing curves that are closed. The boundary following algorithm using the line quadtree data structure is at least twice as good as the one using the region quadtree in terms of execution time; the map superposition algorithm has execution time proportional to number of nodes in the line quadtree [13]. The main disadvantage of the line quadtree is that it cannot represent independent linear features.

58.3.2.3 Edge Quadtrees

Shneier [15] formulated the edge quadtree data structure for storing linear features. The main principle used in the data structure is to approximate the curve being represented by a number of straight line segments. The edge quadtree is constructed using a recursive procedure. If the sub quadrant represented by a node does not contain any edge or line, it is not further subdivided and is represented by a leaf. If it does contain one then an approximate equation is fitted to the line. The error caused by approximation is calculated using a measure such as least squares. When the error is less than the predetermined value, the node becomes a leaf;

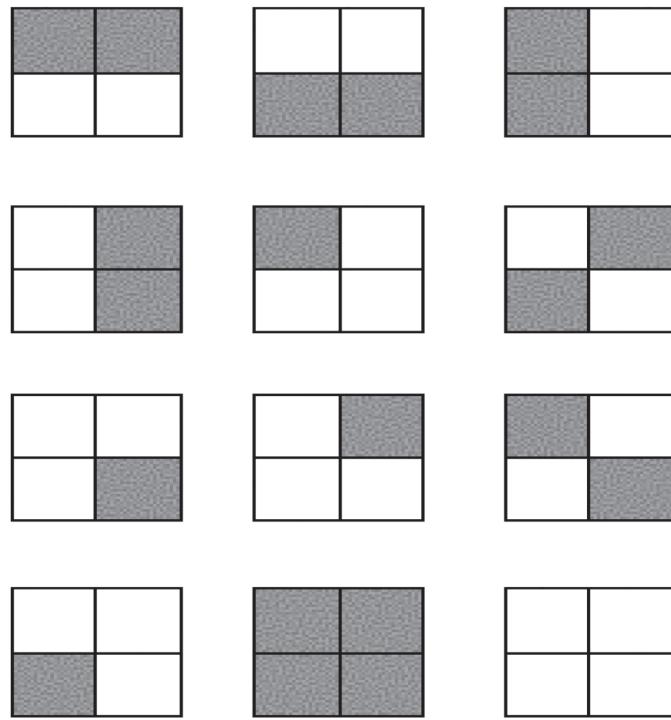

FIGURE 58.4 Template sets.

otherwise the region represented by the node is further subdivided. If an edge terminates (within the region represented by) a node then a special flag is set. Each node contains magnitude, direction, intercept, and error information about the edge passing through the node. The main drawback of the edge quadtree is that it cannot efficiently handle two or more intersecting lines.

58.3.2.4 Template quadtrees

An image can have regions and line features together. The above quadtree representational schemas are not efficient for representing such an image in one quadtree data structure. The template quadtree is an attempt toward development of such a quadtree data structure. It was proposed by Manohar, Rao, and Iyengar [13] to represent regions and curvilinear data present in images.

A template is a $2^k \times 2^k$ sub image, which contains either a region of uniform color or straight run of black pixels in horizontal, vertical, left diagonal, or right diagonal directions spanning the entire sub image. All the possible templates for a 2×2 sub image are shown in [Figure 58.4](#).

A template quadtree can be constructed by comparing a quadrant with any one of the templates, if they match then the quadrant is represented by a node with the information about the type of template it matches. Otherwise the quadrant is further divided into four sub quadrants and each one of them is compared with any of the templates of the next lower size. This process is recursively followed until the entire image is broken down into maximal blocks corresponding to the templates. The template quadtree representation of an image is shown in [Figure 58.5](#).

Here the leaf is defined as a template of variable size, therefore it does not need any approximation for representing curves present in the images. The advantage of template quadtree is that it is very accurate and has the capabilities for representing features like regions and curves. The main drawback is that it needs more space compared to edge quadtrees. For more information on template quadtrees see Reference 13.

58.4 Virtual Quadtrees

The quadtree has become a major data structure in image processing. Though the quadtree has better storage efficiency compared to other data structures such as the array, it also has considerable storage overhead. Jones and Iyengar [16] have proposed two ways in which quadtrees may be efficiently stored: as “forest of quadtrees” and as “compact quadtrees.” They called these new data structures virtual quadtrees because the basic operations performed in quadtrees can also be performed on the new

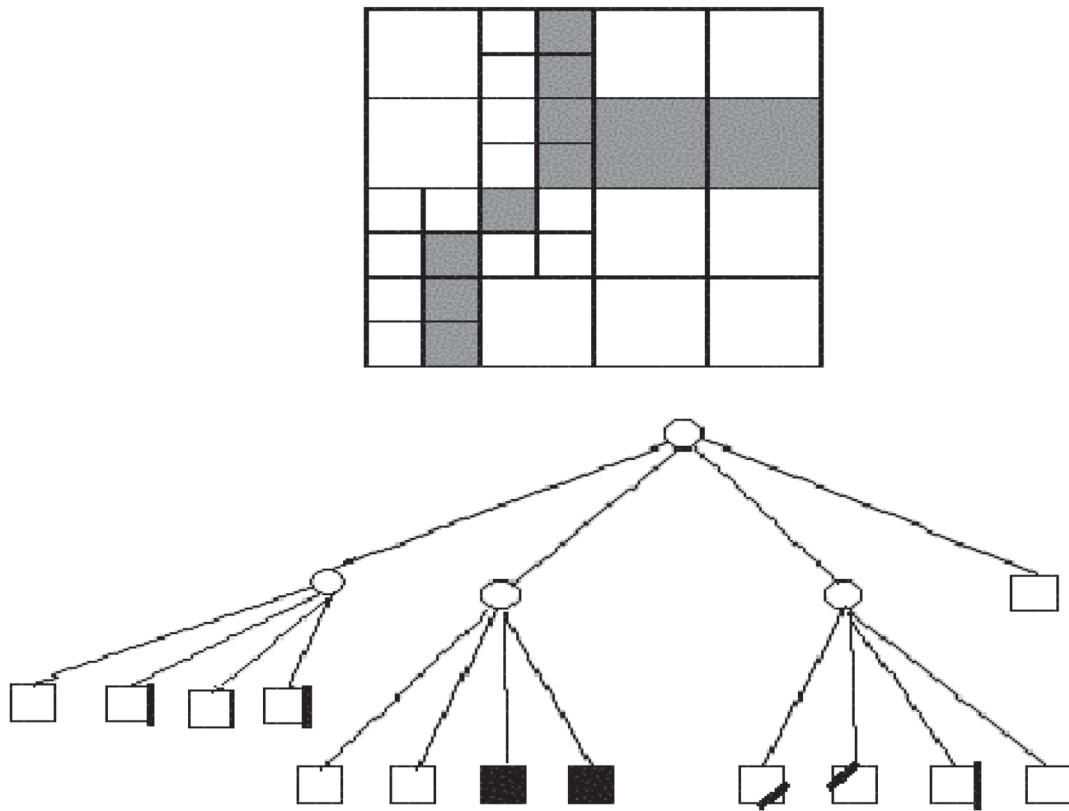

FIGURE 58.5 Template quadtree representation.

representations. The virtual quadtree is a space-efficient way of representing a quadtree. It is a structure that simulates quadtrees in such a way that we can,

1. Determine the color of any node in the quadtree.
2. Find the child node of any node, in any direction in the quadtree.
3. Find the parent node of any node in the quadtree.

The two types of virtual quadtrees, which we are going to discuss, are the compact quadtree and the forest of quadtrees.

58.4.1 Compact Quadtrees

The compact quadtree has all the information contained in a quadtree but needs less space. It is represented as $C(T)$, where T is the quadtree it is associated with. Each set of four sibling nodes in the quadtree is represented as a single node called metanode in the corresponding compact quadtree.

The metanode M has four fields, which are explained as follows:

- $MCOLOR(M, D)$ —The colors of the nodes included in M . Where $D \in \{NW, NE, SW, SE\}$.
- $MSONS(M)$ —Points to the first metanode that represents offsprings of a node represented in M ; NIL if no offspring exists.
- $MFATHER(M)$ —Points to the metanode that holds the representation of the parent of the nodes that M represents.
- $MCHAIN(M)$ —If there are more than one metanode that represent offspring of nodes represented by a given metanode M , then these are linked by $MCHAIN$ field.

The compact quadtree for the quadtree shown in the [Figure 58.6](#) is given in [Figure 58.7](#). In [Figure 58.7](#) downward links are $MSON$ links, horizontal links are $MCHAIN$ links and upward links are $MFATHER$ links.

The compact quadtree uses the same amount of space for the storage of color but it uses very less space for storage of pointers. In [Figure 58.7](#), the compact quadtree has 10 metanodes, whereas the quadtree has 41 nodes. Thus it saves about 85% of the storage space. Since the number of nodes in a compact quadtree is less a simple recursive tree traversal can be done more efficiently.

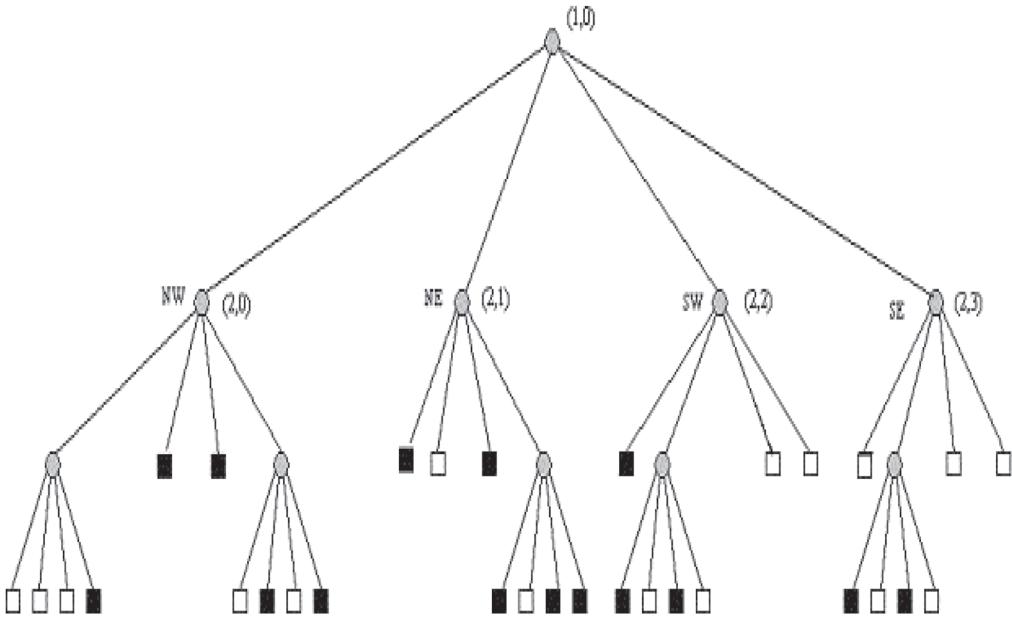

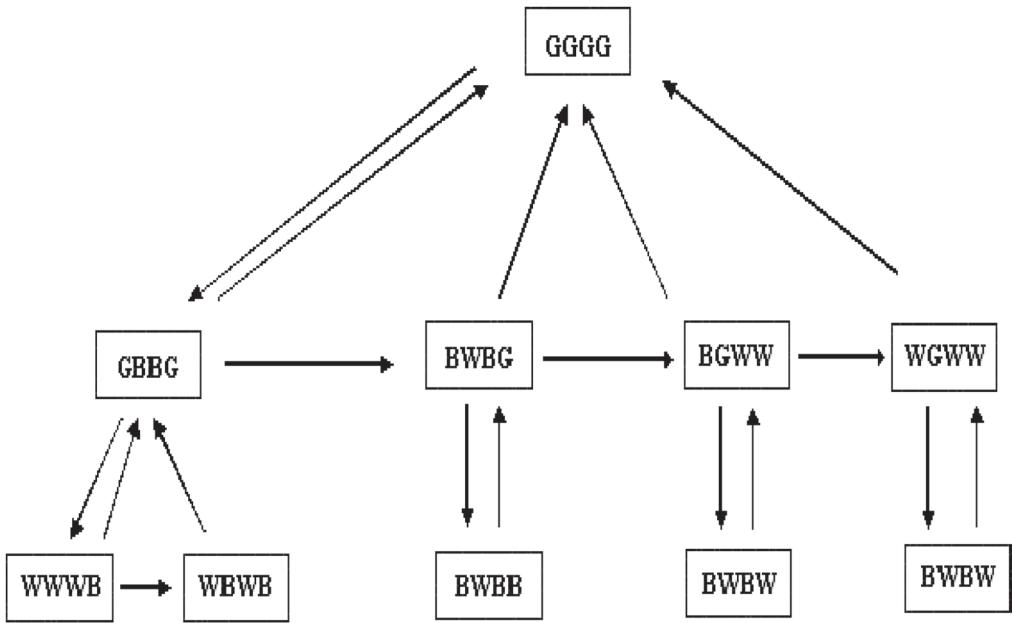

FIGURE 58.6 Quadtree with coordinates.

FIGURE 58.7 Compact quadtree $C(T)$.

58.4.2 Forest of Quadtrees (FQT)

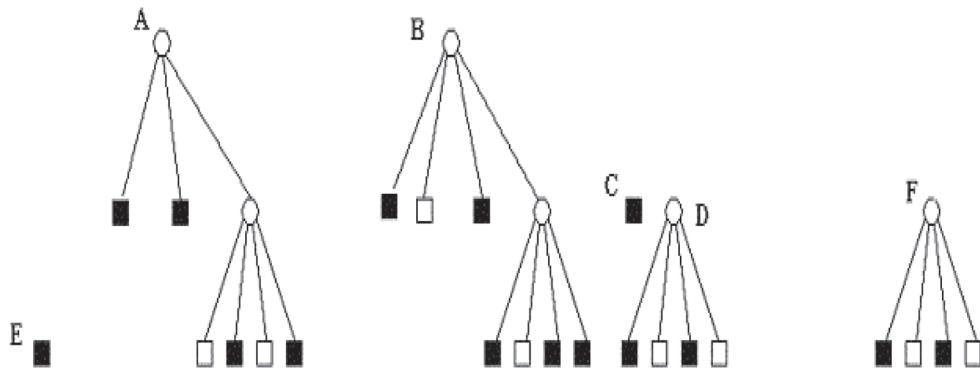

Jones and Iyengar [8] proposed a variant of quadtrees called forest of quadtrees to improve the space efficiency of quadtrees. A forest of quadtrees is represented by $F(T)$ where T is the quadtree it represents. A forest of quadtrees, $F(T)$ that represents T consists of a table of triples of the form (L, K, P) , and a collection of quadtrees where,

1. Each triple (L, K, P) consists of the coordinates, (L, K) , of a node in T , and a pointer, P , to a quadtree that is identical to the subtree rooted at position (L, K) in T .
2. If (L, K) and (M, N) are coordinates of nodes recorded in $F(T)$, then neither node is a descendant of the other.
3. Every black leaf in T is represented by a black leaf in $F(T)$.

Table in the FQT

2	0	Pointer to A
2	1	Pointer to B
3	8	Pointer to C
3	9	Pointer to D
4	3	Pointer to E
3	13	Pointer to F

Trees in the FQT

FIGURE 58.8 Forest of quadtrees $F(T)$.

To obtain the corresponding forest of quadtrees, the nodes in a quadtree need to be classified as good and bad nodes. A leaf node with black color or an intermediate node that has two or more black child nodes are called good nodes, the rest are called bad nodes. Only the good nodes are stored in the forest of quadtrees thereby saving lot of storage space. Figure 58.8 contains a forest of quadtrees that represents the quadtree shown in Figure 58.6.

To reduce a quadtree to a forest of quadtrees, we first need to identify the good nodes and the bad nodes. We then break down the quadtree into smaller quadtrees in such a way that each of them has a good root node and none of them is a subtree of another and the bad nodes encountered by forest are freed. This collection of quadtrees is called as forest of quadtrees. The time required for the execution of the conversion is obviously linear in the number of nodes in the quadtree [16].

Theorem:

The maximum number of trees in a forest of quadtrees derived from a quadtree that represents a square of dimension $2^k \times 2^k$ is 4^{k-1} , that is, one-fourth the area of the square. For proof see Reference 16.

The corresponding quadtree can be easily reconstructed from a forest of quadtrees F . The reconstructed quadtree $R(F)$ consists of real nodes and virtual nodes (nodes corresponding to the bad nodes that are deleted while creating the forest). Since the virtual nodes require no storage they are located by giving their coordinates. The virtual nodes are represented as $v(L, K)$.

58.5 Quadtrees and R-trees

Quadtrees and R-trees [17] are two commonly used spatial data structures to locate or organize objects in a given image. Both quadtrees and R-trees use bounding boxes to depict the outline of the objects. Therefore, the data structure only needs to keep

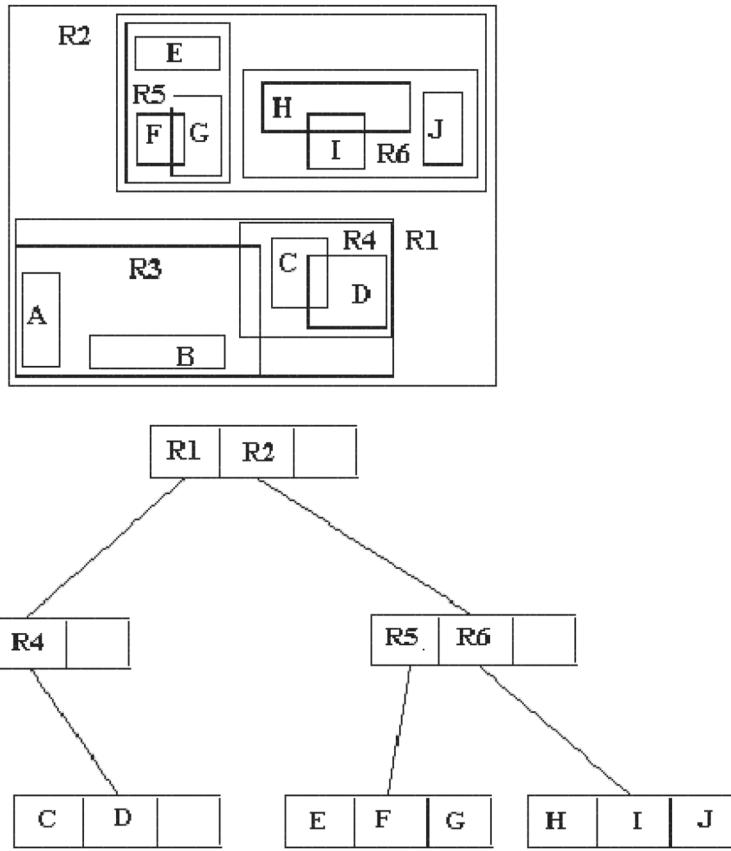

FIGURE 58.9 The concept of R-tree.

track of the boundaries instead of the actual shape and size of the objects in the image. The size of the bounding boxes usually depends on the size of the object we are trying to locate.

The R-tree (see also [Chapter 22](#)) is a hierarchical, height balanced data structure, similar to the B^+ -tree that aggregates objects based on their spatial proximity. It is a multidimensional generalization of the B^+ -tree. The R-tree indexes multidimensional data objects by enclosing data objects in bounding rectangles, which may further be enclosed in bounding rectangles; these bounding rectangles can overlap each other. Each node except the leaf node has a pointer and the corresponding bounding rectangle. The pointer points to the subtree with all the objects enclosed in its corresponding rectangle. The leaf node has a bounding rectangle and the pointer pointing to the actual data object. The root node has a minimum of two children unless it is a leaf node and all the leaf nodes appear at the same level. [Figure 58.9](#) Shows the R-tree representation of an image.

The main difference between quadtrees and R-trees is that unlike R-trees the bounding rectangle of quadtrees do not overlap. In real world objects overlap; in such cases more than one node in a quadtree can point to the same object. This is a serious disadvantage for the quadtree. [Figure 58.10](#) shows the quadtree representation of the image in [Figure 58.9](#).

As you can see from the [Figure 58.10](#) objects like “C” and “D” are represented by more than one node. This makes it difficult to find the origin of the quadtree.

The R-tree is a dynamic structure, so its contents can be modified without having to reconstruct the entire tree. It can be used to determine which objects intersect a given query region. The R-tree representation of an image is not unique; size and placement of rectangles in the tree depends on the sequence of insertions and deletions resulting in the tree starting from the empty R-tree.

58.6 Octrees

Octrees are 3D equivalent of quadtrees and are used for representing 3D images. An octree is formed by dividing a 3D space into 8 sub-cubes called cells. This process of dividing the cube into cells is carried on until the (image) objects lie entirely inside or outside the cells. The root node of an octree represents a cube, which encompasses the objects of interest.

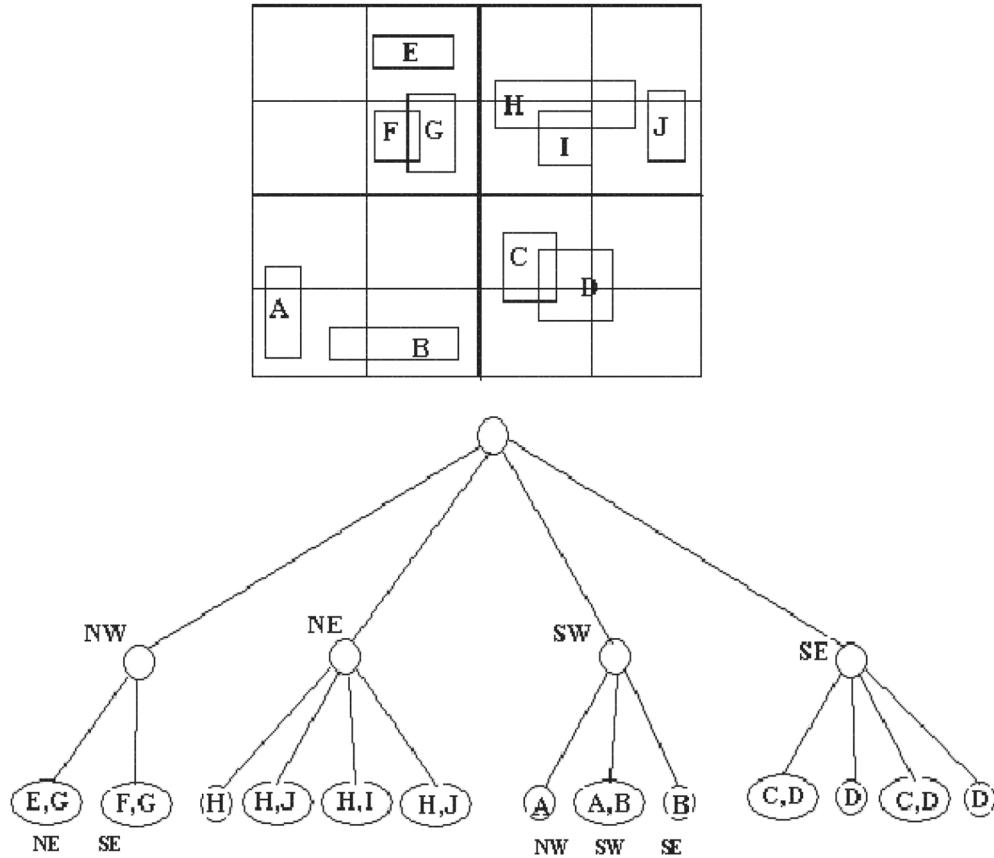

FIGURE 58.10 Quadtree representation of the image in Figure 58.9.

In the octree each node except the leaf node has eight child nodes, which represent the sub-cubes of the parent node. The node stores information like pointer to the child nodes, pointer to the parent node, and pointers to the contents of the cube. An example of an octree representation is shown in Figure 58.11.

The Octree become very ineffective if the objects in the image that it is representing are not uniformly distributed, as in that case many nodes in the octree will not contain any objects. Such an octree is also very costly to compute as a large amount of data has to be examined.

58.7 Translation Invariant Data Structure (TID)

Methods for the region representation using quadtrees exist in the literature [2,10,18]. Much work has been done on quadtree properties, and algorithms for translations and manipulations have been derived by Dyer [2], Samet [11,19], Shneier [20] and others.

Various improvements to quadtrees have been suggested including forests of quadtrees, hybrid quadtrees, linear quadtrees, and optimal quadtrees for image segments. All of these methods try to optimize quadtrees by removing some or all of the gray and white nodes. All of them maintain the same number of black nodes.

All these methods are sensitive to the placement of the origin. An image, which has been translated from its original position, can have a very different looking structure [21]. We explain this phenomenon by using the example given in Figure 58.12. In Example 1, the black square is in the upper left corner. In Example 2, it is translated down and right by one pixel. Figure 58.13 gives the quadtree representation for these two examples.

The shift sensitivity of the image data structure derives from the fact that the positions of the maximal blocks represented by leaf nodes are not explicitly represented in the data structure. Instead, these positions are determined by the paths leading to them from the root of the tree. Thus, when the image is shifted, the maximal blocks are formed in a different way.

For this reason Scott and Iyengar [21] have introduced a new data structure called Translation Invariant Data structure (TID), which is not sensitive to the placement of the region and is translation invariant.

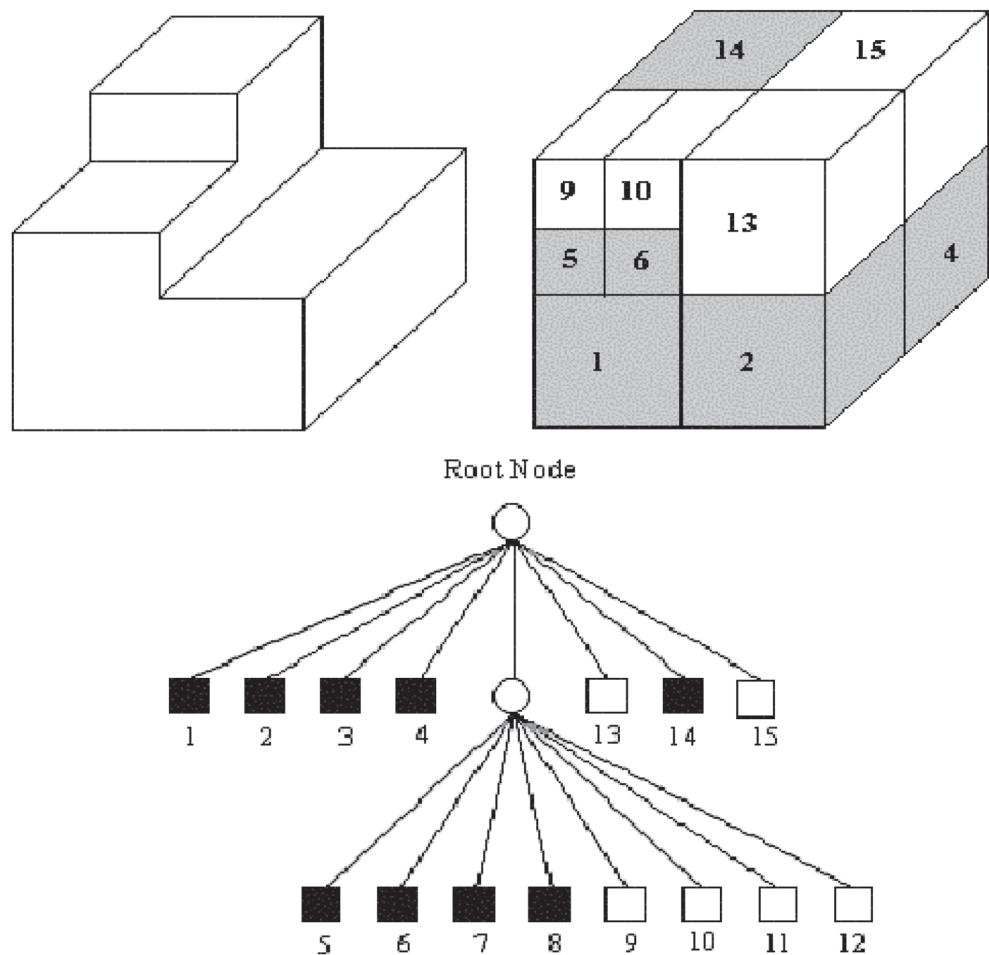

FIGURE 58.11 Octree representation.

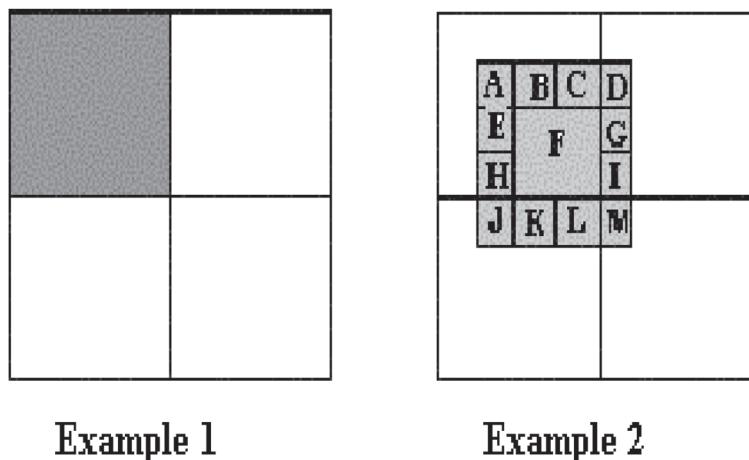

FIGURE 58.12 Sample Regions.

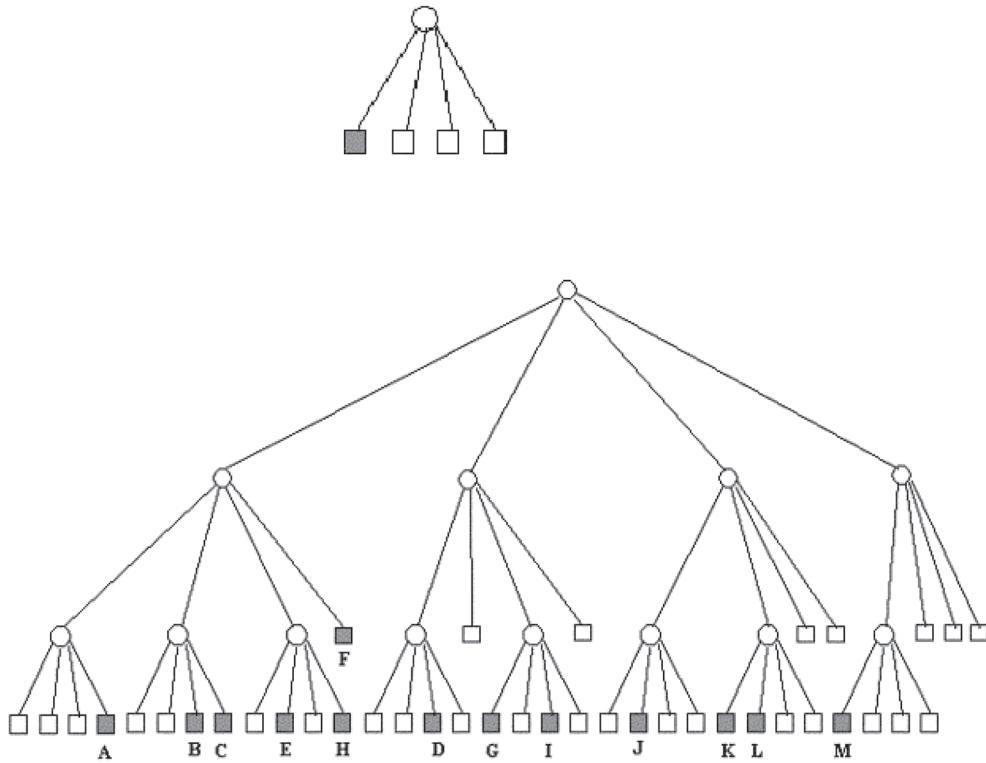

FIGURE 58.13 Quadtrees for Example 1 and 2 of [Figure 58.12](#).

A maximal square is a black square of pixels that is not included in any large square of black pixels. TID is made of such maximal squares, which are represented as (i, j, s) where (i, j) is the coordinates of the northwest vertex of the square and “ s ” is the length of the square. Translation made to any image can be represented as a function of these triples. For example consider a triple (i, j, s) , translating it x units to the right and y units up yields $(i+x, j+y, s)$ [21].

The rotation of the square by $\pi/2$ is only slightly more complicated due to the fact that the NW corner of the square changes upon rotation. The $\pi/2$ rotation around the origin gives $(-j, i+s, s)$.

58.8 Content-Based Image Retrieval System

Images have always been a part of human communication. Due to the increase in the use of Internet the interest in the potential of digital images has increased greatly. Therefore we need to store and retrieve images in an efficient way. Locating and retrieving a desired image from a large database can be a very tedious process and is still an active area of research. This problem can be reduced greatly by using Content-Based Image Retrieval (CBIR) systems, which retrieves images based only on the content of the image. This technique retrieves images on the basis of automatically-derived features such as color, texture, and shape.

58.8.1 What is CBIR?

Content-Based Image Retrieval is a process of retrieving desired images from a large database based on the internal features that can be obtained automatically from the images themselves. CBIR techniques are used to index and retrieve images from databases based on their pictorial content, typically defined by a set of features extracted from an image that describe the color, texture, and/or shape of the entire image or of specific objects in the image. This feature description is used to index a database through various means such as distance-based techniques, rule-based decision-making, and fuzzy inferencing [22–24]. Images can be matched in two ways. Firstly, an image can be compared with another image to check for similarity. Secondly, images similar to the given image can be retrieved by searching a large image database. The latter process is called content-based image retrieval.

58.8.1.1 General Structure of CBIR Systems

The general computational framework of a CBIR system as shown in [Figure 58.14](#) was proposed in Reference 25.

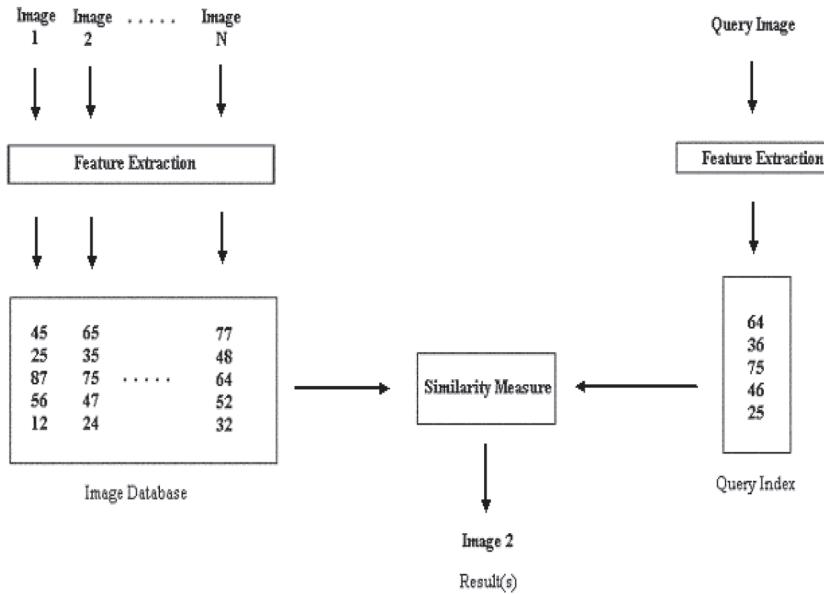

FIGURE 58.14 Computational framework of CBIR systems.

At first, the image database is created, which stores the images as numerical values supplied by the feature extraction algorithms. These values are used to locate an image similar to the query image. The query image is processed by the same feature extraction algorithm that is applied to the images stored in the database.

The similarity between the query image and the images stored in the database can be verified with the help of the similarity measure algorithm, which compares the results obtained from the feature extraction algorithms for both the query image and the images in the database. Thus after comparing the query image with all the images in the database the similarity measure algorithm gives a set as the result, which has all the images from the database that are similar to the query image.

58.8.2 An Example of CBIR System

An example of Content-Based Image Retrieval System is BlobWorld. The BlobWorld system, developed at the University of California, Berkeley, supports color, shape, spatial, and texture matching features. Blobworld is based on finding coherent image regions that roughly correspond to objects. The system automatically separates each image into homogeneous regions in order to improve content-based image retrieval. Querying is based on the user specifying attributes of one or two regions of interest, rather than a description of the entire image. For more information on Blobworld see Reference 26.

CBIR techniques are likely to be of most use in restricted subject areas, where merging with other types of data like text and sound can be achieved. Content-based image retrieval provides an efficient solution to the restrictions and the problems caused by the traditional information retrieval technique. The number of active research systems is increasing, which reflects the increasing interest in the field of content-based image retrieval.

58.9 Summary

In this chapter we have explained what an image data is and how it is stored in raster graphics and vector graphics. We then discussed some of the image representation techniques like quadtrees, virtual quadtrees, octrees, R-trees and translation invariant data structures. Finally, we have given a brief introduction to Content-Based Image Retrieval (CBIR) systems. For more information on image retrieval concepts see References 22–25.

59.1 Introduction

In the last 20 years, biological sequence data have been accumulating at exponential rate under continuous improvement of sequencing technology, progress in computer science, and steady increase of funding. Molecular sequence databases (e.g., EMBL, Genbank, DDJB, Entrez, Swissprot, etc.) currently collect hundreds of thousands of sequences of nucleotides and amino acids from biological laboratories all over the world, reaching into the hundreds of terabytes. Such an exponential growth makes it increasingly important to have fast and automatic methods to process, analyze, and visualize massive amounts of data.

The exploration of many computational problems arising in contemporary molecular biology has now grown to become a mature field of computer science. A coarse selection would include sequence homology and alignment, physical and genetic mapping, protein folding and structure prediction, gene-expression analysis, evolutionary tree construction, gene finding, assembly for shotgun sequencing, gene rearrangements and pattern discovery, among others.

In this chapter, we focus the attention on the applications of suffix trees and suffix arrays to computational biology. In fact, suffix trees, suffix arrays, and their variants are among the most used (and useful) data structures in computational biology. (See [Chapters 30](#) and [31](#) for more on suffix trees and DAWGs.)

This chapter is divided into three sections. In Sections 59.2 and 59.3, we describe two distinct applications of suffix trees to computational biology. In the first application, the use of suffix trees and DAWGs is essential in developing a linear-time algorithm for solving a pattern discovery problem. In the second application, suffix trees are used to solve a challenging algorithmic problem: the alignment of two or more complete genomes.

In Section 59.4, we describe the FM-index which is a sort of “compressed” suffix array based on a fascinating mathematical transformation called the Burrows–Wheeler transform. Because of its reduced space occupancy, the FM-index for a mammalian genome can be stored entirely in primary memory. Due to its memory efficiency, this data structure is a cornerstone of the majority of alignment tools, as well some assembly tools.

59.2 Discovering Unusual Words

In the context of computational biology, “pattern discovery” refers to the automatic identification of biologically significant patterns (or *motifs*) by statistical methods. These methods originated from the work of R. Staden [\[1\]](#) and have been recently expanded in a subfield of data mining. The underlying assumption is that biologically significant words show distinctive distributional patterns within the genomes of various organisms, and therefore they can be distinguished from the others. The reality is not too far from this hypothesis [\[2–10\]](#), because during the evolutionary process, living organisms have accumulated certain biases toward or against some specific motifs in their genomes. For instance, highly recurring oligonucleotides are often found in correspondence to regulatory regions or protein binding sites of genes [\[11–14\]](#). Vice versa, rare oligonucleotide motifs may be discriminated against due to structural constraints of genomes or specific reservations for global transcription controls [\[9,15\]](#). In some

prokaryotes, rare motifs can also correspond to restriction enzyme sites—bacteria have evolved to avoid those motifs to protect themselves.

From a statistical viewpoint, over- and underrepresented words have been studied quite rigorously (see, e.g., Reference 16 for a review). A substantial corpus of works has been also produced by the scientific community which studies combinatorics on words (see, e.g., References 17 and 18, and references therein). In the application domain, however, the “success story” of pattern discovery has been its ability to find previously unknown regulatory elements in *DNA* sequences [13,19]. Regulatory elements control the expression (i.e., the amount of *mRNA* produced) of the genes over time, as the result of different external stimuli to the cell and other metabolic processes that take place internally in the cell. These regulatory elements are typically, but not always, found in the *upstream* sequence of a gene. The upstream sequence is defined as a portion of *DNA* of 1–2 k bases of length, located upstream of the site that controls the start of transcription. The regulatory elements correspond to binding sites for the factors involved in the transcriptional process. The complete characterization of these elements is a critical step in understanding the function of different genes and the complex network of interaction between them.

The use of pattern discovery to find regulatory elements relies on a conceptual hypothesis that genes which exhibit similar expression patterns are assumed to be involved in the same biological process or functions. Although many believe that this assumption is an oversimplification, it is still a good working hypothesis. Co-expressed genes are therefore expected to share common regulatory domains in the upstream regions for the coordinated control of gene expression. In order to elucidate genes which are co-expressed as a result of a specific stress or condition, a *DNA* microarray experiment is typically designed. After collecting data from the microarray, co-expressed genes are usually obtained by clustering the time series corresponding to their expression profiles.

As said, words that occur unexpectedly often or rarely in genetic sequences have been variously linked to biological meanings and functions. With increasing availability of whole genomes, exhaustive statistical tables and global detectors of unusual words on a scale of millions, even billions of bases become conceivable. It is natural to ask how large such tables may grow with increasing length of the input sequence, and how fast they can be computed. These problems need to be regarded not only from the conventional perspective of asymptotic space and time complexities, but also in terms of the volumes of data produced and ultimately, of practical accessibility and usefulness. Tables that are too large at the outset saturate the perceptual bandwidth of the user and might suggest approaches that sacrifice some modeling accuracy in exchange for an increased throughput.

The number of distinct substrings in a string is at worst quadratic in the length of that string. The situation does not improve if one only computes and displays the most *unusual* words in a given sequence. This presupposes comparing the frequency of occurrence of every word in that sequence with its expectation: a word that departs from expectation beyond some preset *threshold* will be labeled as *unusual* or *surprising*. Departure from expectation is assessed by a distance measure often called a *score* function. The typical format for a *z-score* is that of a difference between observed and expected counts, usually normalized to some suitable moment. For most *a priori* models of a source, it is not difficult to come up with extremal examples of *observed* sequences in which the number of, say, overrepresented substrings grows itself with the square of the sequence length.

An extensive study of probabilistic models and scores for which the population of potentially unusual words in a sequence can be described by tables of size at worst linear in the length of that sequence was carried out in Reference 20. That study not only leads to more palatable representations for those tables but also supports (nontrivial) linear time and space algorithms for their constructions, as described in what follows. These results do not mean that the number of unusual words must be linear in the input, but just that their representation and detection can be made such. Specifically, it is seen that it suffices to consider as candidate surprising words only the members of an *a priori* well-identified set of “representative” words, where the cardinality of that set is linear in the text length. By the representatives being identifiable *a priori*, we mean that they can be known before any score is computed. By neglecting the words other than the representatives we are not ruling out that those words might be surprising. Rather, we maintain that any such word: (i) is embedded in one of the representatives and (ii) does not have a bigger score or degree of surprise than its representative (hence, it would add no information to compute and give its score explicitly).

59.2.1 Statistical Analysis of Words

For simplicity of exposition, assume that the source can be modeled by a Bernoulli distribution, that is, symbols are generated i.i.d., and that strings are ranked based on their number of occurrences (possibly overlapping). The results reported in the rest of this section can be extended to other models and counts [20].

We use standard concepts and notation about strings, for which we refer to References 21 and 22. For a substring y of a text x over an alphabet Σ , we denote by $f_x(y)$ the number of occurrences of y in x . We have $f_x(y) = |pos_x(y)| = |endpos_x(y)|$, where $pos_x(y)$ is the *start-set* of starting positions of y in x and $endpos_x(y)$ is the similarly defined *end-set*. Clearly, for any extension uyv of y , $f_x(uyv) \leq f_x(y)$.

Suppose now that string $x = x[0]x[1]\dots x[n-1]$ is a realization of a stationary ergodic random process and $y = y[0]y[1]\dots y[m-1] = y$ is an arbitrary but fixed pattern over Σ with $m < n$. We define Z_i , for all $i \in [0 \dots n-m]$, to be

1 if y occurs in x starting at position i , 0 otherwise, so that

$$Z_y = \sum_{i=0}^{n-m} Z_i$$

is the random variable for $f_x(y)$.

Expressions for the expectation and the variance for the number of occurrences in the Bernoulli model have been given by several authors [23–27]. Here we adopt derivations in References 21 and 22. Let p_a be the probability of symbol $a \in \Sigma$ and $\hat{p} = \prod_{i=0}^{m-1} p_{y[i]}$, we have

$$\begin{aligned} E(Z_y) &= (n - m + 1)\hat{p} \\ \text{Var}(Z_y) &= \begin{cases} (1 - \hat{p})E(Z_y) - \hat{p}^2(2n - 3m + 2)(m - 1) + 2\hat{p}B(y) & \text{if } m \leq (n + 1)/2 \\ (1 - \hat{p})E(Z_y) - \hat{p}^2(n - m + 1)(n - m) + 2\hat{p}B(y) & \text{otherwise} \end{cases} \end{aligned}$$

where

$$B(y) = \sum_{d \in \mathcal{P}(y)} (n - m + 1 - d) \prod_{j=m-d}^{m-1} p_{y[j]} \quad (59.1)$$

is the *autocorrelation factor* of y that depends on the set $\mathcal{P}(y)$ of the lengths of the periods* of y .

Given $f_x(y)$, $E(Z_y)$, and $\text{Var}(Z_y)$, a statistical significance score that measures the degree of “unusual-ness” of a substring y must be carefully chosen. Ideally, the score function should be independent of the structure and size of the word. That would allow one to make meaningful comparisons among substrings of various compositions and lengths based on the value of the score.

There is some general consensus that z -scores may be preferred over other types of score function [28]. For any word w , a standardized frequency called z -score can be defined by

$$z(y) = \frac{f_x(y) - E(Z_y)}{\sqrt{\text{Var}(Z_y)}}$$

If $E(Z_y)$ and $\text{Var}(Z_y)$ are known, then under rather general conditions, the statistics $z(y)$ is asymptotically normally distributed with zero mean and unit variance as n tends to infinity. In practice, $E(Z_y)$ and $\text{Var}(Z_y)$ are seldom known, but are estimated from the sequence under study.

59.2.2 Detecting Unusual Words

Consider now the problem of computing exhaustive tables reporting scores for all substrings of a sequence or perhaps at least for the most surprising among them. While the complexity of the problem ultimately depends on the probabilistic model and type of count, a table for all words of any size would require at least quadratic space in the size of the input, not to mention that such a table would take at least quadratic time to be filled.

As seen towards the end of the section, such a limitation can be overcome by partitioning the set of all words into equivalence classes with the property that it suffices to account for only one or two candidate surprising words in each class, while the number of classes is linear in the textstring size. More formally, given a score function z , a set of words C , and a real positive *threshold* T , we say that a word $w \in C$ is *T -overrepresented* in C (resp., *T -underrepresented*) if $z(w) > T$ (resp., $z(w) < -T$) and for all words $y \in C$ we have $z(w) \geq z(y)$ (resp., $z(w) \leq z(y)$). We say that a word w is *T -surprising* if $z(w) > T$ or $z(w) < -T$. We also call $\max(C)$ and $\min(C)$ respectively the longest and shortest words in C , when $\max(C)$ and $\min(C)$ are unique.

Let now x be a textstring and $\{C_1, C_2, \dots, C_l\}$ a partition of all its substrings, where $\max(C_i)$ and $\min(C_i)$ are uniquely determined for all $1 \leq i \leq l$. For a given score z and a real positive constant T , we call \mathcal{O}_z^T the set of T -overrepresented words of C_i , $1 \leq i \leq l$, with respect to that score function. Similarly, we call \mathcal{U}_z^T the set of T -underrepresented words of C_i , and \mathcal{S}_z^T the set of all T -surprising words, $1 \leq i \leq l$.

For strings u and $v = suz$, a (u, v) -path is a sequence of progressively longer words $\{w_0 = u, w_1, w_2, \dots, w_l = v\}$, $l \geq 0$, such that w_i is the extension of w_{i-1} ($1 \leq i \leq l$) with an additional symbol to its left or its right. In general, a (u, v) -path is not unique. If all $w \in C$ belong to some $(\min(C_i), \max(C_i))$ -path, we say that class C is *closed*.

A score function z is (u, v) -*increasing* (resp., *nondecreasing*) if given any two words w_1, w_2 belonging to a (u, v) -path, the condition $|w_1| < |w_2|$ implies $z(w_1) < z(w_2)$ (resp., $z(w_1) \leq z(w_2)$). The definitions of a (u, v) -*decreasing* and (u, v) -*nonincreasing* z -scores are symmetric. We also say that a score z is (u, v) -*monotone* when specifics are unneeded or understood. The following fact and its symmetric are immediate.

* String z has a *period* w if z is a nonempty prefix of w^k for some integer $k \geq 1$.

Fact 59.1

If the z -score under the chosen model is $(\min(C_i), \max(C_i))$ -increasing, and C_i is closed, $1 \leq i \leq l$, then

$$\mathcal{O}_z^T \subseteq \bigcup_{i=1}^l \{\max(C_i)\} \text{ and } \mathcal{U}_z^T \subseteq \bigcup_{i=1}^l \{\min(C_i)\}$$

In Reference 20, extensive results on the monotonicity of several scores for different probabilistic models and counts are reported. For the purpose of this chapter, we just need the following result.

Theorem 59.1

Let x be a text generated by a Bernoulli process, and p_{\max} be the probability of the most frequent symbol [20].

If $f_x(w) = f_x(wv)$ and $p_{\max} < \min\{1/\sqrt[3]{4m}, \sqrt{2} - 1\}$ then

$$\frac{f_x(wv) - E(Z_{wv})}{\sqrt{\text{Var}(Z_{wv})}} > \frac{f_x(w) - E(Z_w)}{\sqrt{\text{Var}(Z_w)}}$$

Here, we pursue substring partitions $\{C_1, C_2, \dots, C_l\}$ in forms which would enable us to restrict the computation of the scores to a constant number of candidates in each class C_i . Specifically, we require, (1) for all $1 \leq i \leq l$, $\max(C_i)$ and $\min(C_i)$ to be unique; (2) C_i to be closed, that is, all w in C_i belong to some $(\min(C_i), \max(C_i))$ path; (3) all w in C_i have the same count. Of course, the partition of all substrings of x into singleton classes fulfills those properties. In practice, l should be as small as possible.

We begin by recalling a few basic facts and constructs from, for example, Reference 29. We say that two strings y and w are *left-equivalent* on x if the set of starting positions of y in x matches the set of starting positions of w in x . We denote this equivalence relation by \equiv_l . It follows from the definition that if $y \equiv_l w$, then either y is a prefix of w , or vice versa. Therefore, each class has unique shortest and longest words. Also by definition, if $y \equiv_l w$ then $f_x(y) = f_x(w)$.

EXAMPLE 59.1

For instance, in the string ataatataataatataatag the set {ataaa, ataat, ataata} is a left-equivalent class (with position set {1, 6, 9, 14}) and so are {taa, taat, taata} and {aa, aat, aata}. There are 39 left-equivalent classes, much less than the total number of substrings, which is $22 \times 23/2 = 253$, and than the number of distinct substrings, in this case 61.

We similarly say that y and w are *right-equivalent* on x if the set of ending positions of y in x matches the set of ending positions of w in x . We denote this by \equiv_r . Finally, the equivalence relation \equiv_x is defined in terms of the *implication* of a substring of x [29,30]. Given a substring w of x , the implication $\text{imp}_x(w)$ of w in x is the longest string uvw such that every occurrence of w in x is preceded by u and followed by v . We write $y \equiv_x w$ iff $\text{imp}_x(y) = \text{imp}_x(w)$. It is not difficult to see that

Lemma 59.1

The equivalence relation \equiv_x is the transitive closure of $\equiv_l \cup \equiv_r$.

More importantly, the size l of the partition is linear in $|x| = n$ for all three equivalence relations considered. In particular, the smallest size is attained by \equiv_x , for which the number of equivalence classes is at most $n + 1$.

Each one of the equivalence classes discussed can be mapped to the nodes of a corresponding automaton or word graph, which becomes thereby the natural support for the statistical tables. The table takes linear space, since the number of classes is linear in $|x|$. The automata themselves are built by classical algorithms, for which we refer to, for example, References 21 and 29 with their quoted literature, or easy adaptations thereof. The graph for \equiv_l , for instance, is the compact subword tree T_x of x , whereas the graph for \equiv_r is the DAWG, or *Directed Acyclic Word Graph* D_x , for x . The graph for \equiv_x is the compact version of the DAWG.

These data structures are known to commute in simple ways, so that, say, an \equiv_x -class can be found on T_x as the union of some left-equivalent classes or, alternatively, as the union of some right-equivalent classes. Beginning with left-equivalent classes, that correspond one to one to the nodes of T_x , we can build some right-equivalent classes as follows. We use the elementary fact that whenever there is a branching node μ in T_x , corresponding to $w = ay$, $a \in \Sigma$, then there is also a node ν corresponding to y , and there is a special *suffix link* directed from ν to μ . Such auxiliary links induce another tree on the nodes of T_x , that we may call

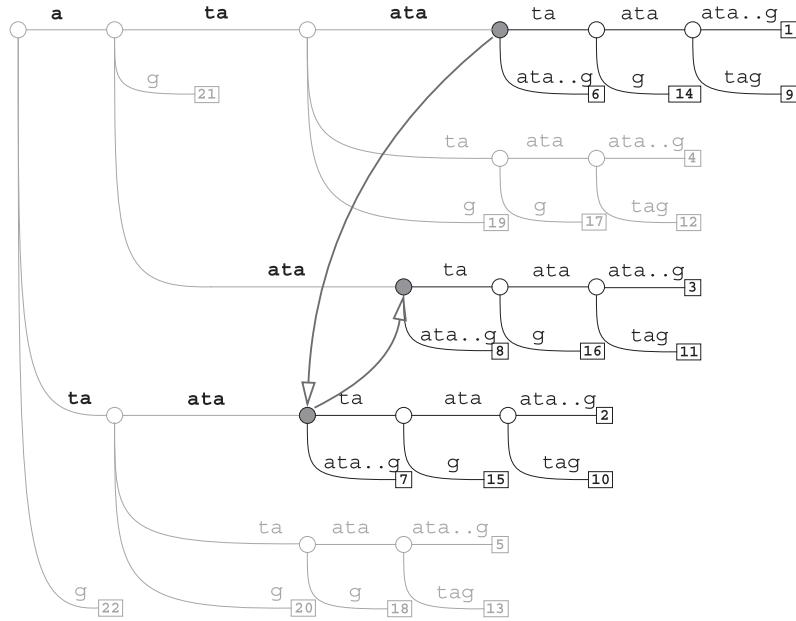

FIGURE 59.1 The tree T_x for $x = \text{ataatataataatataatataatag}$: subtrees rooted at solid gray nodes are isomorphic.

S_x . It is now easy to find a right-equivalent class with the help of suffix links. For this, traverse S_x bottom-up while grouping in a single class all strings such that their terminal nodes in T_x are roots of isomorphic subtrees of T_x . When a subtree that violates the isomorphism condition is encountered, we are at the end of one class and we start with a new one.

EXAMPLE 59.2

For example, the three subtrees rooted at the solid nodes in Figure 59.1 correspond to the end-sets of *ataata*, *taata*, and *aata*, which are the same, namely, $\{6, 11, 14, 19\}$. These three words define the right-equivalent class $\{\text{ataata}, \text{taata}, \text{aata}\}$. In fact, this class cannot be made larger because the two subtrees rooted at the end nodes of *ata* and *tataata* are not isomorphic to the subtree of the class. We leave it as an exercise for the reader to find *all* the right-equivalence classes on T_x . It turns out that there are 24 such classes in this example.

Subtree isomorphism can be checked by a classical linear-time algorithm by Aho et al. [31]. But on the suffix tree T_x this is done even more quickly once the f counts are available [32,33].

Lemma 59.2

Let T_1 and T_2 be two subtrees of T_x . T_1 and T_2 are isomorphic if and only if they have the same number of leaves and their roots are connected by a chain of suffix links.

If, during the bottom-up traversal of S_x , we collect in the same class strings such that their terminal arc leads to nodes with the same frequency counts f , then this would identify and produce the \equiv_x -classes, that is, the smallest substring partition.

EXAMPLE 59.3

For instance, starting from the right-equivalent class $C = \{\text{ataata}, \text{taata}, \text{aata}\}$, one can augment it with all words which are left-equivalent to the elements of C . The result is one \equiv_x -class composed by $\{\text{ataaa}, \text{ataat}, \text{ataata}, \text{taa}, \text{taat}, \text{taata}, \text{aa}, \text{aat}, \text{aata}\}$. Their respective *pos* sets are $\{1, 6, 9, 14\}$, $\{1, 6, 9, 14\}$, $\{1, 6, 9, 14\}$, $\{2, 7, 10, 15\}$, $\{2, 7, 10, 15\}$, $\{2, 7, 10, 15\}$, $\{3, 8, 11, 16\}$, $\{3, 8, 11, 16\}$, $\{3, 8, 11, 16\}$. Their respective *endpos* sets are $\{4, 9, 12, 17\}$, $\{5, 10, 13, 18\}$, $\{6, 11, 14, 19\}$, $\{4, 9, 12, 17\}$, $\{5, 10, 13, 18\}$, $\{6, 11, 14, 19\}$, $\{4, 9, 12, 17\}$, $\{5, 10, 13, 18\}$, $\{6, 11, 14, 19\}$. Because of Lemma 59.1, given two words y and w in the class, either they share the start set, or they share the end set, or they share the start set by transitivity with a third word

in the class, or they share the end set by transitivity with a third word in the class. It turns out that there are only seven \equiv_x -classes in this example.

Note that the longest string in this \equiv_x -class is unique (`ataata`) and that it contains all the others as substrings. The shortest string is unique as well (`aa`). As said, the number of occurrences for all the words in the same class is the same (4 in the example). Figure 59.2 illustrates the seven equivalence classes for the running example. The words in each class have been organized in a lattice, where edges correspond to extensions (or contractions) of a single symbol. In particular, horizontal edges correspond to right extensions and vertical edges to left extensions.

While the longest word in an \equiv_x -class is unique, there may be in general more than one shortest word. Consider, for example, the text $x = a^k g^k$, with $k > 0$. Choosing $k = 2$ yields a class which has three words of length two as minimal elements, namely, aa, gg, and ag. (In fact, $imp_x(aa) = imp_x(gg) = imp_x(ag) = aagg$.) Taking instead $k = 1$, all three substrings of $x = ag$ coalesce into a single class which has two shortest words.

Recall that by Lemma 59.1, each \equiv_x -class C can be expressed as the union of one or more left-equivalent classes. Alternatively, C can be also expressed as the union of one or more right-equivalent classes. The example above shows that there are cases in which left- or right-equivalent classes *cannot* be merged without violating the uniqueness of the shortest word. Thus we may use the \equiv_x -classes as the C_i 's in our partition only if we are interested in detecting overrepresented words. If underrepresented words are also wanted, then we must represent a same \equiv_x -class once for each distinct shortest word in it.

It is not difficult to accommodate this in the subtree merge procedure. Let $p(u)$ denote the parent of u in T_x . While traversing S_x bottom-up, merge two nodes u and v with the same f count if and only if both pairs (u, v) and $(p(u), p(v))$ are connected by a suffix link. This results in a substring partition slightly coarser than \equiv_x . It will be denoted by $\tilde{\equiv}_x$.

Fact 59.2

Let $\{C_1, C_2, \dots, C_l\}$ be the set of equivalence classes built on the equivalence relation $\tilde{\equiv}_x$ on the substrings of text x . Then, for all $1 \leq i \leq l$,

1. $\max(C_i)$ and $\min(C_i)$ are unique
 2. All $w \in C_i$ are on some $(\min(C_i), \max(C_i))$ -path
 3. All $w \in C_i$ have the same number of occurrences $f_x(w)$.

We are now ready to address the computational complexity of our constructions. In Reference 21, linear-time algorithms are given to compute and store expected value $E(Z_w)$ and variance $Var(Z_w)$ for the number of occurrences under Bernoulli model of

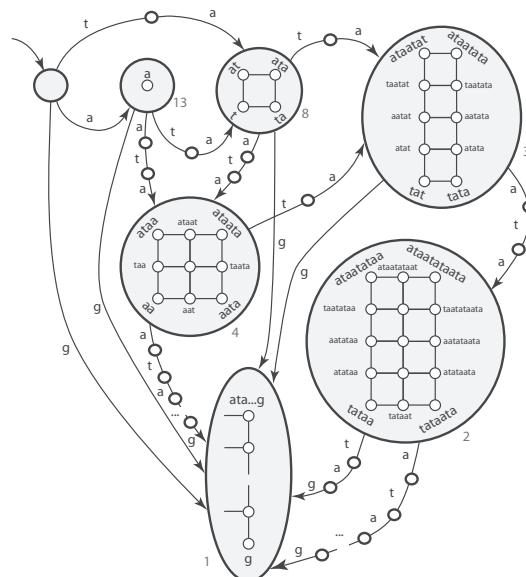

FIGURE 59.2 A representation of the seven \equiv_x -classes for $x = \text{ataatataataatataatag}$. The words in each class can be organized in a lattice. Numbers refer to the number of occurrences.

all prefixes of a given string. The crux of that construction rests on deriving an expression of the variance (see Expression 59.1) that can be cast within the classical linear time computation of the “failure function” or smallest periods for all prefixes of a string [31]. These computations are easily adapted to be carried out on the linked structure of graphs such as S_x or D_x , thereby yielding expectation and variance values at all nodes of T_x , D_x , or the compact variant of the latter. These constructions take time and space linear in the size of the graphs, hence linear in the length of x . Combined with the monotonicity results this yields immediately:

Theorem 59.2

Under the Bernoulli model [20], the sets \mathcal{O}_z^T and \mathcal{U}_z^T associated to the score

$$z(w) = \frac{f_x(w) - E(Z_w)}{\sqrt{\text{Var}(Z_w)}}$$

can be computed in linear time and space, provided that $p_{\max} < \min\{1/\sqrt[4]{4m}, \sqrt{2} - 1\}$.

59.3 Comparing Whole Genomes

As of writing this article (March 2015), Genbank contains “complete” genomes for more than 3900 virus, over 3200 bacterial, and about 180 eukaryote species. For many of these species, there are even several different genomes available. The abundance of complete genome sequences has given an enormous boost to comparative genomics. Association studies have become a powerful tool for the functional identification of genes and molecular genetics has in many cases revealed the biological basis of diversity. Comparing the genomes of related species gives new insights into the complex structure of organisms at the DNA level and protein level.

The first step when comparing genomes is to produce an alignment, that is, a collinear arrangement of sequence similarities. Alignment of nucleic or amino acid sequences has been one of the most important methods in sequence analysis, with much dedicated research and now many sophisticated algorithms available for aligning sequences with similar regions. These require defining a score for all possible alignments (typically, the sum of the similarity/identity values for each aligned symbol, minus a penalty for the introduction of gaps), along with a dynamic programming method to find optimal or near-optimal alignments according to this scoring scheme [34]. These dynamic programming methods run in time proportional to the product of the length of the sequences to be aligned. Hence they are not suitable for aligning entire genomes. In the last decade, a large number of genome alignment programs have been developed, most of which use an anchor-based method to compute an alignment (for an overview, see Reference 35). An *anchor* is an exact match of some minimum length occurring in all genomes to be aligned (see Figure 59.3). The anchor-based method can roughly be divided into the following three phases:

1. Computation of all potential anchors
2. Computation of an optimal collinear sequence of nonoverlapping potential anchors: these are the anchors that form the basis of the alignment (see Figure 59.4)
3. Closure of the gaps in between the anchors.

In the following, we will focus on phase 1 and describe two algorithms to compute potential anchors. The first algorithm allows one to align more than two genomes, while the second is limited to two genomes, but uses less space than the former. Both algorithms are based on suffix trees. For phase 2 of the anchor-based method, one uses methods from computational geometry.

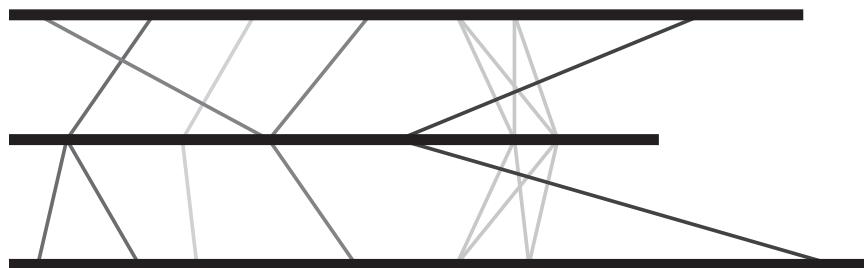

FIGURE 59.3 Three genomes represented as horizontal lines. Potential anchors of an alignment are connected by vertical lines. Each anchor is a sequence occurring at least once in all three genomes.

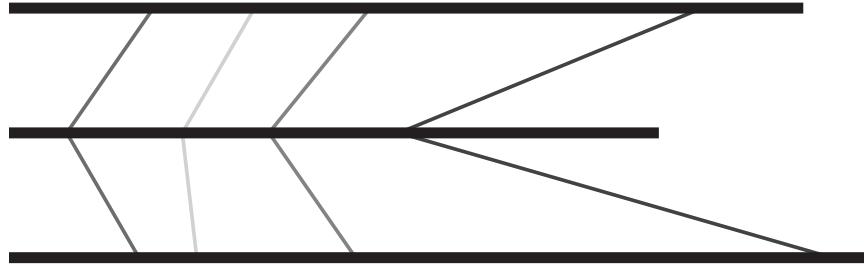

FIGURE 59.4 A collinear chain of nonoverlapping anchors.

The interested reader is referred to the algorithms described in References 36–39. In phase 3, one can apply any standard multiple or pairwise alignment methods, such as T-Coffee [40] or MAFFT [41]. Alternatively, one can even use the same anchor-based method with relaxed parameters, like it is possible in the CoCoNUT software [42].

59.3.1 Basic Definitions

We recall and extend the definition introduced in Section 59.2. A *sequence*, or a *string*, S of length n is written as $S = S[0]S[1] \dots S[n-1] = S[0 \dots n-1]$. A *prefix* of S is a sequence $S[0 \dots i]$ for some i , $0 \leq i \leq n-1$. A *suffix* of S is a sequence $S[i \dots n-1]$ for some i , $0 \leq i \leq n-1$. Consider a set $\{G_0, \dots, G_{k-1}\}$ of $k \geq 2$ sequences (the genomes) over some alphabet Σ . Let $n_q = |G_q|$ for $0 \leq q \leq k-1$. To simplify the handling of boundary cases, assume that $G_0[-1] = \$_{-1}$ and $G_{k-1}[n_{k-1}] = \$_{k-1}$ are unique symbols not occurring in Σ . A *multiple exact match* is a $(k+1)$ -tuple $(l, p_0, p_1, \dots, p_{k-1})$ such that $l > 0$, $0 \leq p_q \leq n_q - l$, and $G_q[p_q \dots p_q + l - 1] = G_{q'}[p_{q'} \dots p_{q'} + l - 1]$ for all q, q' , $0 \leq q, q' \leq k-1$. A multiple exact match is *left maximal* if for at least one pair (q, q') , $0 \leq q, q' \leq k-1$, we have $G_q[p_q - 1] \neq G_{q'}[p_{q'} - 1]$. A multiple exact match is *right maximal* if for at least one pair (q, q') , $0 \leq q, q' \leq k-1$, we have $G_q[p_q + l] \neq G_{q'}[p_{q'} + l]$. A multiple exact match is *maximal* if it is left maximal and right maximal. A maximal multiple exact match is also called *multiMEM*. Roughly speaking, a *multiMEM* is a sequence of length l that occurs in all sequences G_0, \dots, G_{k-1} (at positions p_0, \dots, p_{k-1}), and cannot simultaneously be extended to the left or to the right in every sequence. The ℓ -*multiMEM*-problem is to enumerate all *multiMEMs* of length at least ℓ for some given length threshold $\ell \geq 1$. For $k=2$, we use the notion *MEM* and ℓ -*MEM*-problem. The notions of matches defined here can be generalized in several ways. One important generalization is to require that for all q , the matching substring $G_q[p_q \dots p_q + l - 1]$ is allowed to occur at most r_q times in G_q for some user-defined parameter r_q . This allows to model, for example, maximal unique matches (by defining $r_q = 1$) or excludes repeats from being part of a *multiMEM* (by defining r_q as small constant). Methods to compute such rare multiple matches are described in Reference 74. Here we however restrict to solutions of the ℓ -*multiMEM*-problem.

Let $\$, \$_0, \dots, \$_{k-1}$ be pairwise different symbols not occurring in any G_q . These symbols are used to separate the sequences in the concatenation $S = G_0 \$_0 G_1 \$_1 \dots G_{k-2} \$_{k-2} G_{k-1} \$_{k-1}$. $\$_{k-1}$ will be used as a sentinel attached to the end of G_{k-1} . All these special symbols are collected in a set $Seps = \{\$, \$_0, \dots, \$_{k-2}, \$_{k-1}\}$.

Let $n = |S|$. For any i , $0 \leq i \leq n$, let $S_i = S[i \dots n-1] \$_{k-1}$ denote the i th nonempty suffix of $S \$_{k-1}$. Hence $S_n = \$_{k-1}$. For all q , $0 \leq q \leq k-1$ let t_q be the start position of G_q in S . For $0 \leq i \leq n-1$ such that $S[i] \notin Seps$, let

- $\sigma(i) = q$ iff position i occurs in the q th sequence in S and
- $\rho(i) = i - t_q$ denote the relative position of i in G_q .

We consider trees whose edges are labeled by nonempty sequences. For each symbol a , every node α in these trees has at most one a -edge $\xrightarrow{av} \beta$ for some sequence v and some node β . Let \mathcal{T} be a tree and α be a node in \mathcal{T} . A node α is denoted by w if and only if w is the concatenation of the edge labels on the path from the root of \mathcal{T} to α . A sequence w occurs in \mathcal{T} if and only if \mathcal{T} contains a node \overline{wv} , for some (possibly empty) sequence v . The *suffix tree* for S , denoted by $ST(S)$, is the tree \mathcal{T} with the following properties: (i) each node is either the root, a leaf or a branching node, and (ii) a sequence w occurs in \mathcal{T} if and only if w is a substring of $S \$_{k-1}$. For each branching node \overline{au} in $ST(S)$, where a is a symbol and u is a string, u is also a branching node, and there is a *suffix link* from \overline{au} to \overline{u} .

There is a one-to-one correspondence between the leaves of $ST(S)$ and the nonempty suffixes of $S \$_{k-1}$: leaf $\overline{S_i}$ corresponds to suffix S_i and vice versa.

For any node \overline{u} of $ST(S)$ (including the leaves), let $\mathcal{P}_{\overline{u}}$ be the set of positions i such that u is a prefix of S_i . In other words, $\mathcal{P}_{\overline{u}}$ is the set of positions in S where sequence u starts. $\mathcal{P}_{\overline{u}}$ is divided into disjoint and possibly empty position sets:

- For any q , $0 \leq q \leq k-1$, define $\mathcal{P}_{\overline{u}}(q) = \{i \in \mathcal{P}_{\overline{u}} \mid \sigma(i) = q\}$ that is, $\mathcal{P}_{\overline{u}}(q)$ is the set of positions i in S where u starts and i is a position in genome G_q .

- For any $a \in \Sigma \cup Seps$, define $\mathcal{P}_{\bar{u}}(a) = \{i \in \mathcal{P}_{\bar{u}} \mid S[i-1] = a\}$, that is, $\mathcal{P}_{\bar{u}}(a)$ is the set of positions i in S where u starts and the symbol to the left of this position is a . We also state that the left context of i is a .
- For any $q, 0 \leq q \leq k-1$ and any $a \in \Sigma \cup Seps$, define $\mathcal{P}_{\bar{u}}(q, a) = \mathcal{P}_{\bar{u}}(q) \cap \mathcal{P}_{\bar{u}}(a)$.

59.3.2 Computation of multiMEMs

We now describe an algorithm to compute all *multiMEMs*, using the suffix tree for S . The algorithm is part of the the multiple genome alignment software *MGA*. It improves on the method which was described in Reference 72.

The algorithm computes position sets $\mathcal{P}_{\bar{u}}(q, a)$ by processing the edges of the suffix tree in a bottom-up traversal. That is, the edge leading to node \bar{u} is processed only after all edges in the subtree below \bar{u} have been processed.

If \bar{u} is a leaf corresponding to, say suffix S_i , then compute $\mathcal{P}_{\bar{u}}(q, a) = \{i\}$ where $q = \sigma(i)$ and $a = S[i-1]$. For all $(q', a') \neq (q, a)$ compute $\mathcal{P}_{\bar{u}}(q', a') = \emptyset$. Now suppose that \bar{u} is a branching node with r outgoing edges. These are processed in any order. Consider an edge $\bar{u} \rightarrow \bar{w}$. Due to the bottom-up strategy, $\mathcal{P}_{\bar{w}}$ is already computed. However, only a subset of $\mathcal{P}_{\bar{u}}$ has been computed since only, say $j < r$, edges outgoing from \bar{u} have been processed. The corresponding subset of $\mathcal{P}_{\bar{u}}$ is denoted by $\mathcal{P}_{\bar{u}}^j$. The edge $\bar{u} \rightarrow \bar{w}$ is processed in the following way: at first, *multiMEMs* are output by combining the positions in $\mathcal{P}_{\bar{u}}^j$ and $\mathcal{P}_{\bar{w}}$. In particular, all $(k+1)$ -tuples $(l, p_0, p_1, \dots, p_{k-1})$ satisfying the following conditions are enumerated:

1. $l = |u|$
2. $p_q \in \mathcal{P}_{\bar{u}}^j(q) \cup \mathcal{P}_{\bar{w}}(q)$ for any $q, 0 \leq q \leq k-1$
3. $p_q \in \mathcal{P}_{\bar{u}}^j(q)$ for at least one $q, 0 \leq q \leq k-1$
4. $p_q \in \mathcal{P}_{\bar{w}}(q)$ for at least one $q, 0 \leq q \leq k-1$
5. $p_q \in \mathcal{P}_{\bar{w}}(q, a)$ and $p_{q'} \in \mathcal{P}_{\bar{w}}(q', b)$ for at least one pair $(q, q'), 0 \leq q, q' \leq k-1$ and different symbols a and b .

By definition of $\mathcal{P}_{\bar{u}}$, u occurs at positions p_0, p_1, \dots, p_{k-1} in S . Moreover, for all $q, 0 \leq q \leq k-1$, we define $\rho(p_q)$ as the relative position of u in G_q . Hence $(l, \rho(p_0), \rho(p_1), \dots, \rho(p_{k-1}))$ is a multiple exact match. Conditions 3 and 4 guarantee that not all positions are exclusively taken from $\mathcal{P}_{\bar{u}}^j(q)$ or from $\mathcal{P}_{\bar{w}}(q)$. In other words, at least two of the positions in $\{p_0, p_1, \dots, p_{k-1}\}$ are taken from different subtrees below \bar{u} . Suppose that $p_q \in \mathcal{P}_{\bar{u}}^j(q)$ and $p_{q'} \in \mathcal{P}_{\bar{w}}(q')$. Hence p_q comes from a subtree below \bar{u} that can be reached by one of the previous j edges processed so far. Let c be the first character of label of this edge. $p_{q'}$ comes from the subtree reached by $\bar{u} \rightarrow \bar{w}$ and the first character of the label of this edge is different from c . As a consequence $(l, \rho(p_0), \rho(p_1), \dots, \rho(p_{k-1}))$ is right maximal. Condition 5 means that at least two of the positions in $\{p_0, p_1, \dots, p_{k-1}\}$ have a different left context. This implies that $(l, \rho(p_0), \rho(p_1), \dots, \rho(p_{k-1}))$ is left maximal.

As soon as for the current edge $\bar{u} \rightarrow \bar{w}$ the *multiMEMs* are enumerated, the algorithm adds $\mathcal{P}_{\bar{w}}(q, a)$ to $\mathcal{P}_{\bar{u}}^j(q, a)$ to obtain position sets $\mathcal{P}_{\bar{u}}^{j+1}(q, a)$ for all $q, 0 \leq q \leq k-1$ and all $a \in \Sigma \cup Seps$. That is, the position sets are inherited from node \bar{w} to the parent node \bar{u} . Finally, $\mathcal{P}_{\bar{u}}(q, a)$ is obtained as soon as all edges outgoing from \bar{u} are processed.

The algorithm performs two operations on position sets, namely enumeration of multiple exact matches by combining position sets and accumulation of position sets. A position set $\mathcal{P}_{\bar{u}}(q, a)$ is the union of position sets from the subtrees below \bar{u} . Recall that we consider processing an edge $\bar{u} \rightarrow \bar{w}$. If the edges to the children of \bar{w} have been processed, the position sets of the children are obsolete. Hence it is not required to copy position sets. At any time of the algorithm, each position is included in exactly one position set. Thus the position sets require $O(n)$ space. For each branching node one maintains a table of $k(|\Sigma| + 1)$ references to possibly empty position sets. In particular, to achieve independence of the number of separator symbols, we store all positions from $\mathcal{P}_{\bar{u}}(q, a)$, $a \in Seps$, in a single set. Hence, the space requirement for the position sets is $O(|\Sigma|kn)$. The union operation for the position sets can be implemented in constant time using linked lists. For each node, there are $O(|\Sigma|k)$ union operations. Since there are $O(n)$ edges in the suffix tree, the union operations thus require $O(|\Sigma|kn)$ time.

Each combination of position sets requires to enumerate the following cartesian product:

$$\prod_{q=0}^{k-1} \left(\mathcal{P}_{\bar{u}}^j(q) \cup \mathcal{P}_{\bar{w}}(q) \right) \setminus \left(\left(\prod_{q=0}^{k-1} \mathcal{P}_{\bar{u}}^j(q) \right) \cup \left(\prod_{q=0}^{k-1} \mathcal{P}_{\bar{w}}(q) \right) \cup \left(\prod_{a \in \Sigma \cup Seps} (\mathcal{P}_{\bar{w}}(a) \cup \mathcal{P}_{\bar{u}}(a)) \right) \right) \quad (59.2)$$

The enumeration is done in three steps, as follows. In a first step one enumerates all possible k -tuples $(p_0, p_1, \dots, p_{k-1})$ of nonempty sets where each p_q is either $\mathcal{P}_{\bar{u}}^j(q)$ or $\mathcal{P}_{\bar{w}}(q)$. Such a k -tuple is called father/child choice, since it specifies to either choose a position from the father \bar{u} (a father choice) or from the child \bar{w} (a child choice). One rejects the two k -tuples specifying only father choices or only child choices and processes the remaining father/child choices further. In the second step, for a fixed father/child choice $(p_0, p_1, \dots, p_{k-1})$ one enumerates all possible k -tuples (a_0, \dots, a_{k-1}) (called symbol choices) such that $p_q(a_q) \neq \emptyset$. At most $|\Sigma|$ symbol choices consisting of k identical symbols (this can be decided in constant time) are rejected.

The remaining symbol choices are processed further. In the third step, for a fixed symbol choice (a_0, \dots, a_{k-1}) we enumerate all possible k -tuples (p_0, \dots, p_{k-1}) such that $p_q \in P_q(a_q)$ for $0 \leq q \leq k-1$. By construction, each of these k -tuples represents a *multiMEM* of length l . The cartesian product (59.2) thus can be enumerated in $O(k)$ space and in time proportional to its size.

The suffix tree construction and the bottom-up traversal (without handling of position sets) require $O(n)$ time. Thus the algorithm described here runs in $O(|\Sigma|kn)$ space and $O(|\Sigma|kn + z)$ time where z is the number of *multiMEMs*. It is still unclear if there is an algorithm which avoids the factors $|\Sigma|$ or k in the space or time requirement.

59.3.3 Space Efficient Computation of MEMs for Two Genomes

The previous algorithm, when applied to two genomes, requires to construct the suffix tree of the concatenation $S = G_0 \$_0 G_1$. The algorithm described next computes all *MEMs* of length at least ℓ by constructing the suffix tree of G_0 and matches G_1 against it. Thus, for genomes of similar sizes, the space requirement is roughly halved.

The matching process delivers substrings of G_1 represented by locations in the suffix tree, where a location is defined as follows: Suppose a string u occurs in $\text{ST}(G_0)$. If there is a branching node \bar{u} , then \bar{u} is the *location of* u . If \bar{v} is the branching node of maximal depth, such that $u = vw$ for some nonempty string w , then (\bar{v}, w) is the *location of* u . The location of u is denoted by $\text{loc}(u)$.

$\text{ST}(G_0)$ represents all suffixes $T_i = G_0[i \dots n_0 - 1] \$_0$ of $G_0 \$_0$. The algorithm processes G_1 suffix by suffix from longest to shortest. In the j th step, the algorithm processes suffix $R_j = G_1[j \dots n_1 - 1] \$_2$ and computes the locations of two prefixes p_{\min}^j and p_{\max}^j of R_j defined as follows:

- p_{\max}^j is the longest prefix of R_j that occurs in $\text{ST}(G_0)$.
- p_{\min}^j is the prefix of p_{\max}^j of length $\min\{\ell, |p_{\max}^j|\}$.

If $|p_{\min}^j| < \ell$, then $p_{\min}^j = p_{\max}^j$ and the longest prefix of R_j matching any substring of G_1 is not long enough. So in this case R_j is skipped. If $|p_{\min}^j| = \ell$, then at least one suffix represented in the subtree below $\text{loc}(p_{\min}^j)$ matches the first ℓ characters of R_j . To extract the *MEMs*, this subtree is traversed in a depth first order. The depth first traversal maintains for each visited branching node u the length of the longest common prefix of u and R_j . Each time a leaf \bar{T}_i is visited, one first checks if $G_0[i-1] \neq G_1[j-1]$. If this is the case, then $(\perp, \rho(i), \rho(j))$ is a left maximal exact match and one determines the length l of the longest common prefix of T_i and R_j . By construction, $l \geq \ell$ and $G_0[i+l] \neq G_1[j+l]$. Hence $(l, \rho(i), \rho(j))$ is an *MEM*. Now consider the different steps of the algorithm in more detail.

Computation of $\text{loc}(p_{\min}^j)$: For $j = 0$, one computes $\text{loc}(p_{\min}^j)$ by greedily matching $G_1[0 \dots \ell-1]$ against $\text{ST}(G_0)$. For all j , $1 \leq j \leq n_1 - 1$, one follows the suffix link of $\text{loc}(p_{\min}^{j-1})$, if this is a branching node, or of \bar{v} if $\text{loc}(p_{\min}^{j-1}) = (\bar{v}, w)$. This shortcut via the suffix link leads to a branching node on the path from the root to $\text{loc}(p_{\min}^j)$, from which one matches the next characters in G_1 . The method is similar to the matching statistics computation of Reference 43, and one can show that its overall running time for the computation of all $\text{loc}(p_{\min}^j)$, $0 \leq j \leq n_1 - 1$, is $O(n_1)$.

Computation of $\text{loc}(p_{\max}^j)$: Starting from $\text{loc}(p_{\min}^j)$ one computes $\text{loc}(p_{\max}^j)$ by greedily matching $G_1[|p_{\min}^j| \dots n_j - 1]$ against $\text{ST}(G_0)$. To facilitate the computation of longest common prefixes, one keeps track of the list of branching nodes on the path from $\text{loc}(p_{\min}^j)$ to $\text{loc}(p_{\max}^j)$. This list is called the *match path*. Since $|p_{\max}^{j-1}| \geq 1$ implies $|p_{\max}^j| \geq |p_{\max}^{j-1}| - 1$, we do not always have to match the edges of the suffix tree completely against the corresponding substring of G_1 . Instead, to reach $\text{loc}(p_{\max}^j)$, one rescans most of the edges by only looking at the first character of the edge label to determine the appropriate edge to follow. Thus the total time for this step is $O(n_1 + \alpha)$ where α is the total length of all match paths. α is upper bounded by the total size β of the subtrees below $\text{loc}(p_{\min}^j)$, $0 \leq j \leq n_1 - 1$. β is upper bounded by the number r of right maximal exact matches between G_0 and G_1 . Hence the running time for this step of the algorithm is $O(n_1 + r)$.

The depth first traversal: This maintains an *lcp*-stack which stores for each visited branching node, say \bar{u} , a pair of values $(\text{onmatchpath}, \text{lcpvalue})$, where the Boolean value *onmatchpath* is true, if and only \bar{u} is on the match path, and *lcpvalue* stores the length of the longest common prefix of u and R_j . Given the match path, the *lcp*-stack can be maintained in constant time for each branching node visited. For each leaf \bar{T}_i visited during the depth first traversal, the *lcp*-stack allows to determine in constant time the length of the longest common prefix of T_i and R_j . As a consequence, the depth first traversal requires time proportional to the size of the subtree. Thus the total time for all depth first traversals of the subtrees below $\text{loc}(p_{\min}^j)$, $0 \leq j \leq n_1 - 1$, is $O(r)$.

Altogether, the algorithm described here runs in $O(n_0 + n_1 + r)$ time and $O(n_0)$ space. It is implemented as part of the widely used *MUMmer* genome alignment software [44] which is available at <http://mummer.sourceforge.net/>.

59.4 The FM-index

In the last decade, next-generation sequencing (NGS) machines have become the main tool for genomic analysis. The widespread diffusion of NGS machines and their continuous increase in efficiency have posed new challenges to the bioinformatics

community. Usually, the first step in the analysis of NGS data is the alignment of millions of short (a few hundred bases) fragments to a reference genome. Such alignment is indeed an approximate matching problem since fragments can differ from the reference because of sequencing errors or individual differences. Because of the importance of the problem it is not surprising that many different alignment tools have been proposed in the literature [45,46]. Some of the most popular alignment tools, such as Bowtie2 [47], BWA-MEM [48], GEM [49], and Soap2 [50], solve the “inexact” alignment problem by first finding exact matches between substrings of the fragment and the reference genome. The FM-index has also been used in some genome assembly tools (e.g., SGA [51]).

Because of the size of the data involved, to find such exact matches these tools do not use the suffix array or suffix tree data structures introduced in Chapters 30 and 31. Instead, they use some variant of the more recent FM-index data structure described in this section. As we will see the FM-index is strictly related to the suffix array but it is much more compact and searches for exact matchings using a completely different, and somewhat surprising, strategy in which the problem of searching substrings is reduced to the easier problem of counting single characters.

Figure 59.5 shows the suffix array for the string $\text{agaatata} \text{taga\$}$, where, as usual, we have introduced a unique sentinel character $\$$ which is lexicographically smaller than all other symbols. On the right of the suffix array we show the matrix of characters obtained by transforming each suffix into a cyclic rotation of the input string. In the matrix we have highlighted the first (F) and last (L) columns. It is immediate to see that any column of this matrix, hence also F and L , is a permutation of the input string. Clearly column F contains the string characters alphabetically sorted, while the last column L has no apparent properties. The following result, due to Mike Burrows and David Wheeler, shows that indeed these two columns are related by the following nontrivial property.

Theorem 59.3

For any character α [52], the i th occurrence of α in L corresponds to the i th occurrence of α in F .

For example, in Figure 59.5 the second a in L and F are respectively $L[8]$ and $F[3]$; these two characters coincide in the sense that they are both the last a of the input string $\text{agaatata} \text{taga\$}$. In view of the above property, it is natural to define the *Last-to-First* column mapping LF , such that $LF(i)$ is the index in the first column F of the character corresponding to $L[i]$. For example since $L[8]$ corresponds to $F[3]$ we have $LF(8) = 3$. As another example $LF(2) = 9$ since $L[2]$, the second occurrence of g in L , corresponds to $F[9]$, the second occurrence of g in F ; indeed they are both the first g in $\text{agaatata} \text{taga\$}$.

Let C denote the array indexed by characters in Σ such that $C[\alpha]$ is the number of occurrences of text characters alphabetically smaller than α , and let $\text{Rank}_\alpha(L, k)$ denote the number of occurrences of the character α in the prefix $L[1, k]$. By Theorem 59.3, if $L[i] = \alpha$ then the character in column F corresponding to $L[i]$ is the $\text{Rank}_\alpha(L, i)$ -th occurrence of α in F . Since the characters in F are alphabetically sorted, this occurrence is in position $C[\alpha] + \text{Rank}_\alpha(L, i)$. Summing up, we have that the LF map can be computed as

$$LF(i) = C[L[i]] + \text{Rank}_{L[i]}(L, i) \quad (59.3)$$

Given the last column L and the LF map, it is possible to retrieve the original string s because of the following observation: since each row j is a cyclic rotation of s , character $L[j]$ immediately precedes $F[j]$ in s , and $L[LF(j)]$ immediately precedes $L(j) = F[LF(j)]$. Given L we can therefore retrieve s as follows: (i) compute F sorting the characters in L ; (ii) by construction, the special character $\$$ will be in $F[1]$, hence the last character of s is $s[n] = L[1]$; (iii) by the above observation we have $s[n-1] = L[LF(1)]$, $s[n-2] = L[LF(LF(1))]$, and by induction $s[n-i] = L[LF^i(1)]$, where $LF^i(\cdot) = LF(LF^{i-1}(\cdot))$.

The function mapping the string s to the last column L is therefore an invertible transformation, now called the Burrows–Wheeler Transform. In Reference 52, Burrows and Wheeler not only proved the reversibility of the transformation but also noted that column L is often easy to compress and thus originated the family of the so - called Burrows - - Wheeler compressors (for further reading, see Reference [53] and references therein).

In the context of computational biology, rather than in its compressibility, we are interested in another remarkable property of the Burrows–Wheeler Transform. As we now show, because of its relationship with the suffix array, column L can be used as a full - text index for the original string s . This property was first established in Reference 54 and it is based on the following result.

Theorem 59.4

Let $SA(s)$ denote the suffix array of the string s [54]. Assume that $[\text{begin}, \text{end}]$ denotes the range of rows of $SA(s)$ prefixed by a given pattern Q , where Q is a substring of s . Then, for any character α , the range of rows $[\text{begin}', \text{end}']$ prefixed by αQ is given by

$$\text{begin}' = C[\alpha] + \text{Rank}_\alpha(L, \text{begin} - 1) + 1 \quad \text{end}' = C[\alpha] + \text{Rank}_\alpha(L, \text{end}) \quad (59.4)$$

If $\text{begin}' > \text{end}'$ then no row in $SA(s)$ is prefixed by αQ , hence the pattern αQ does not appear inside s .

The above theorem follows from the observation that $[\text{begin}', \text{end}']$ are precisely the positions in column F corresponding, via the LF -map, to the occurrences of α in $L[\text{begin}, \text{end}]$. This means that $\text{begin}' = LF(i)$ (resp. $\text{end}' = LF(j)$), where i (resp. j) is the index of the first (resp. last) position in $L[\text{begin}, \text{end}]$ containing the character α . Note that Equation 59.4 computes begin' and end' without actually computing the two indices i and j . From Theorem 59.4, we immediately get the procedure `get_rows` in Figure 59.6 for determining the rows of $SA(s)$ prefixed by an arbitrary pattern P .

Note that Theorem 59.4 and Algorithm `get_rows` determine a range of rows in $SA(s)$ without using $SA(s)$. The algorithm relies only on the array C , which has size $|\Sigma|$, and the computation of the function $\text{Rank}_\alpha(L, \cdot)$. Indeed, the problem of searching substrings in s is reduced to the problem of counting single characters in L . The FM-index is loosely defined as a data structure taking $O(|s|)$ bits of space and supporting the `Rank` operation in constant time [55]; if the alphabet is not constant, both space and time can have an additional $O(\text{polylog}(|\Sigma|))$ factor.

Using algorithm `get_rows` an FM-index can report the number of occurrences of a pattern P in s in $O(|P|)$ time using $O(|s|)$ bits of space. The same problem can be solved by a suffix array in $O(|P| \log n)$ time, or in $O(|P| + \log n)$ time using also the LCP array (see Chapters 30 and 31). Given the simplicity of the binary search procedure, the suffix array is likely to be faster in practice. However, the suffix array uses $O(|s| \log |s|)$ bits of space that, both in theory and in practice, is significantly larger than the space usage of FM-index [56]. Indeed, a remarkable feature of the FM-index is that it can take advantage of the compressibility of the input string. Exploiting properties of the Burrows - Wheeler Transform, the FM-index can be stored in space asymptotically bounded by the k th-order entropy of the sequence s and still support the `Rank` operation in constant time [57–59]. The k th-order entropy is a natural lower bound for the compressibility of a sequence and it was somewhat surprising that in such a “minimal” space we can not only represent s but also search it.

Algorithm `get_rows`($P[1, p]$)

1. $i \leftarrow p$, $\alpha \leftarrow P[p]$, $\text{begin} \leftarrow C[\alpha] + 1$, $\text{end} \leftarrow C[\alpha + 1]$;
 2. **while** ($(\text{begin} \leq \text{end})$ **and** ($i \geq 1$)) **do**
 3. $\alpha \leftarrow P[i]$;
 4. $\text{begin} \leftarrow C[\alpha] + \text{Rank}_c(L, \text{begin} - 1) + 1$;
 5. $\text{end} \leftarrow C[\alpha] + \text{Rank}_c(L, \text{end})$;
 6. $i \leftarrow i - 1$;
 7. **if** ($\text{end} < \text{begin}$) **return** “no rows prefixed by $P[1, p]$ ” **else return** $[\text{begin}, \text{end}]$.
-

FIGURE 59.6 Algorithm `getrows` for finding the set of suffix array rows prefixed by $P[1, p]$. This procedure is known in the literature as “backward search” since the characters of P are considered right to left.

Algorithm get_position(*i*)

```

1.  $t \leftarrow 0$ ;
2. while row  $i$  is not marked do
3.    $i \leftarrow C[L[i]] + \text{Rank}_{L[i]}(L, i)$ ;
4.    $t \leftarrow t + 1$ ;
5. return  $\text{SA}[i] + t$ ;

```

FIGURE 59.7 Algorithm `get_position` for the computation of $\text{SA}[i]$ on an FM-index enriched with a sample of the suffix array. Note that the value computed at line 3 is $LF(i)$ (cf. Equation 59.3).

In some applications, we are interested not only in counting the occurrences but also in finding their positions within s . For this task, the speed of the suffix array is hard to beat: once the range of rows $[\text{begin}, \text{end}]$ is determined the positions are simply the values stored in $\text{SA}[\text{begin} \dots \text{end}]$. To efficiently solve the same problem on an FM-index it is necessary to enrich it with additional information. The common approach is to store along with the FM-index a sampling of the suffix array. For example, we can store the values $\text{SA}[i]$ which are multiples of a given value d . Then, using a hash table or a bit array (possibly compressed), we mark the rows containing the stored values.

In the example of Figure 59.5, if we take $d = 4$, we mark the rows $\{5, 7, 8\}$ since they contain the SA values $\{8, 4, 12\}$. To determine the position of the occurrences of the pattern `tag` we first use algorithm `get_rows` to find the SA rows prefixed by `tag`, which are the rows 11 and 12 of the suffix array. Then, we proceed determining the position in s of these two rows (or more precisely of the two suffixes prefixing these two rows). If we had the complete suffix array the desired values $\text{SA}[11] = 10$ and $\text{SA}[12] = 7$ would be immediately available, but we only have the SA values for the rows $\{5, 7, 8\}$. To determine for example $\text{SA}[11]$, we apply the LF -map (59.3) and compute the value $10 = LF(11)$ which is the entry in F corresponding to the character $L[11] = g$. By construction, we have that row 10 contains the suffix which is one character longer than the suffix in row 11, hence $\text{SA}[10] = \text{SA}[11] - 1$. Since row 10 is not marked, we still do not know the value $\text{SA}[10]$. We thus compute $LF(10) = 5$, which is the index of the row containing the suffix one character longer than the one in row 10. Reasoning as above we have

$$\text{SA}[5] = \text{SA}[10] - 1 = \text{SA}[11] - 2.$$

Now we find that row 5 is marked hence the value $\text{SA}[5] = 8$ is available, from which we correctly derive $\text{SA}[11] = 10$. The above procedure for retrieving the position of a single occurrence is formalized in Figure 59.7. The idea is to use the LF -map to move backward in the text until we reach a marked position for which the SA value is known. By construction we reach a marked position in at most $d - 1$ steps, so the cost of locating a single occurrence is bounded by d times the cost of a Rank operation. Since the cost of storing the SA values is $O(n \log n)/d$ bits, the parameter d offers a simple trade-off between memory usage and speed.

Although the above simple strategy works well in most cases, improvements or other approaches to the problem of locating the occurrences using an FM-index have been proposed in the literature. The reader should refer to References 60–62 and references therein for further information.

59.4.1 Fast Rank and Select Operations Using Wavelet Trees

Wavelet trees have been introduced in Reference 71 at roughly the same time as compressed indices and have quickly gained popularity as a very versatile data structure. They can be described as a data structure offering some degree of compression and supporting fast Rank/Select operations (see below), but over the years they have been used to provide elegant and efficient solutions for a myriad of problems in different algorithmic areas [63].

Consider again the string s of Figure 59.5 and let $s' = \text{ggt\$ttaaaagaa}$ denote its Burrows - - Wheeler transform, that is, column L of Figure 59.5. Figure 59.8 shows a wavelet tree for the string s' . The tree is a complete binary tree and each leaf corresponds to an alphabet character. To build the wavelet tree, we initially label the root with the string s' . Then at each internal node each character goes left or right depending on whether the leaf labeled with that character is on the left or the right subtree. So for example at the root \\$ and a both go left, while at the root's left child \\$ goes left and a goes right. Finally, we replace each string in the internal nodes with a binary string obtained replacing with 0 each character that goes left, and with 1 each character that goes right. The wavelet tree consists of the set of binary strings associated to the internal nodes; in our example the wavelet tree for $s' = \text{ggt\$ttaaaagaa}$ is represented by the binary strings $w_{\text{root}} = 110110000100$, $w_{\text{left}} = 0111111$, $w_{\text{right}} = 011110$ (we are assuming the shape of the tree and the correspondence from leaves to characters are established in advance so there is no need to encode them).

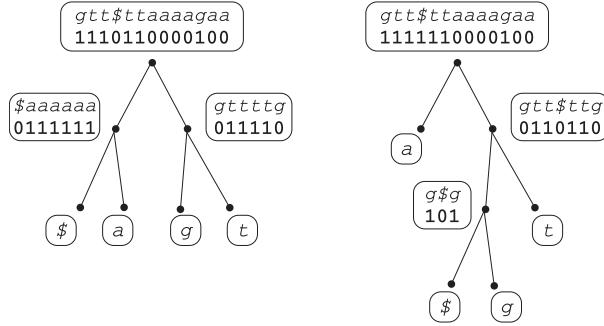

FIGURE 59.8 Two wavelet trees of different shapes for the string $s' = \text{ggt\$ttaaaagaa}$. The tree on the left is balanced and has all leaves at depth two. The tree on the right has the leaf associated to a at depth one: as a result it uses three less bits in the internal nodes.

Suppose now that we are given the wavelet tree and we want to retrieve the character $s'[6]$. Since $w_{root}[6] = 1$ we know that it is a character on the right subtree, so either g or t . To find out which, we count how many 1's there are in w_{root} up to position 6. Using the notation of the previous section this number is $\text{Rank}_1(w_{root}, 6) = 5$. Hence, $s'[6]$ corresponds to the fifth bit of w_{right} . Since $w_{right}[5] = 1$ and w_{right} 's right child is the leaf labeled t we have $s'[6] = t$. From the above decoding procedure, we can draw the following observations:

1. Each character in the input text is essentially encoded with one bit for each internal node in the path from the root to the corresponding leaf. Using a balanced tree each character requires at most $\lceil \log |\Sigma| \rceil$ bits so the total space usage will be similar to the space used for s' uncompressed. However, using a tree of different shape we can represent s' with less bits (see the tree on the right in Figure 59.8). For any input string, we can minimize the overall length of the internal node's binary strings using the shape of an optimal Huffman tree. Note that the resulting data structure would offer essentially the same compression as a Huffman code but it will also provide random access to the single characters, something which is not possible with Huffman codes. For further discussions on the compressibility of wavelet trees, see Reference 64 and references therein.
2. Assuming that the computation of Rank_1 on a binary string takes $O(r)$ time, decoding a single input character with the above procedure on a balanced wavelet tree takes $O(r \log |\Sigma|)$ time (notice that $\text{Rank}_0(w, k) = k - \text{Rank}_1(w, k)$). If the wavelet tree is skewed some characters could be more expensive to decode than others. For example, if we use a Huffman-shaped tree decoding will be faster for frequent characters and slower for those rarely occurring, a trade-off that could be appropriate in some situations. More in general, if we know the distribution of the accesses we can sacrifice space and choose the shape of the wavelet tree in order to minimize the average access time.

The above observations show that wavelet trees are interesting *per se*. However, their use for FM-indices is justified by another remarkable property. Recall that to efficiently search for patterns in s an FM-index need to support efficient Rank operations on s' . Consider again the example of Figures 59.5 and 59.8 and suppose we need to compute $\text{Rank}_a(s', 9)$, that is, count how many a 's are there in the first nine positions of s' . In the string w_{root} a is represented by 0, so by computing $\text{Rank}_0(w_{root}, 9) = 4$ we find that in the first nine positions of s' there are four occurrences of $\$$'s and a 's. To compute $\text{Rank}_a(s', 9)$, we need to count how many a 's are there among these four occurrences. This can be done looking at w_{left} : since there a is represented with a 1, we compute $\text{Rank}_1(w_{left}, 4) = 3$ and this is precisely the value $\text{Rank}_a(s', 9)$ that we were looking for. Summing up, Rank queries on s' for any character α can be resolved by $\text{Rank}_0/\text{Rank}_1$ queries on the nodes on the path from the root to the leaf associated to α . Note that, again, the wavelet tree shape influences the cost of the Rank queries on s' .

Putting all together, we have that combining FM-indices and wavelet trees the “difficult” problem of locating patterns in a reference text is reduced to the easier problem of computing Rank queries on binary strings (see Figure 59.9). Note that with an appropriate compressed representation of the binary strings and the use of compression boosting [65], the resulting data structure takes space close to the information theoretic lower bound given by the k th-order entropy of the indexed sequence [66].

Computing Rank queries on binary strings is by no means trivial if we want to compress the binary strings involved. However, if the space usage is not a major issue, there are simple data structures for this task that even first-year students can easily implement. For example, suppose we want to support Rank_1 operations on a binary string w (recall Rank_0 values can be obtained by difference). We split the content of w into blocks of 256 bits and we store each block into four 64-bit words. We interleave these blocks with additional 64-bit words storing the number of 1's in all the preceding blocks. These interleaved values are represented in gray in Figure 59.10.

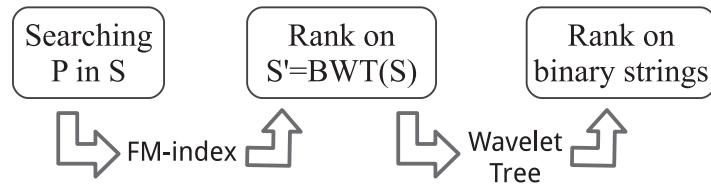

FIGURE 59.9 The problem of searching patterns in a string is reduced to the problem of counting 1's in binary strings thanks to the combined use of the FM-index and the wavelet tree data structure.

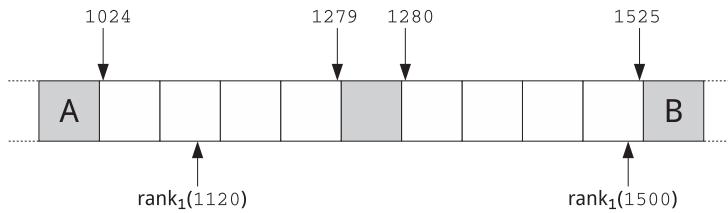

FIGURE 59.10 Simple scheme supporting Rank queries on a binary string described in Reference 67. Each cell represents a 64-bit word. Four consecutive white cells contain a 256-bit block from input string, each gray cell contains the number of 1's in the preceding blocks. The figure shows the 5th and 6th blocks of the input string containing bit ranges [1024, 1279] and [1280, 1525], respectively. Cell A stores the number of 1's in [0, 1023], cell B stores the number of 1's in [0, 1525].

To compute $\text{Rank}_1(w, k)$, we first locate the block containing $w[k]$. If $w[k]$ is in the first half of the block we sum the value in the immediately preceding gray cell with the number of 1's from said cell up to position k . Otherwise, if $w[k]$ is in the second half of a block, we subtract from the value stored in the immediately following gray cell the number of 1's from position $k + 1$ up to that cell. For example, in Figure 59.10 to compute $\text{Rank}_1(1120)$ we sum the value in A to the number of 1's in [1024, 1120], while to compute $\text{Rank}_1(1500)$ we subtract from the value in B the number of 1's in [1501, 1525].

Summing up, using the above data structure the computation of $\text{Rank}_1(w, k)$ only requires the access to up to three consecutive 64-bit words and counting the 1's in up to two of them. Since the latter operation is natively supported by modern Intel and AMD processors (under the name POPCNT), the whole procedure is extremely fast and simple to implement. This data structure uses one additional 64-bit word for each 256-bit block, so the total space usage in bits is $1.25|w|$. If we use this simple scheme for the binary strings of a wavelet tree, a representation of the Burrow–Wheeler Transform for the human genome (≈ 3 billion bases) would take less than 1 GB. Adding a sampling of the suffix array, say with $d = 20$, we get an FM-index of roughly 1.5 GB: this is almost 10 times smaller than the 12 GB used by the suffix array alone.

Together with the Rank operation many data structures support also its inverse, called Select. By definition $\text{Select}_\alpha(s', k)$ is the position in s' of the k th occurrence of character α , or some invalid value if α appears less than k times. As for the Rank operation, given a wavelet tree for s' , we can compute $\text{Select}_\alpha(s', k)$ performing $\text{Select}_0/\text{Select}_1$ operations on the binary strings associated to the nodes in the path from the leaf associated to α up to the tree root (i.e., for Select we traverse the tree upward rather than downward). Computing Select on $s' = \text{Bwt}(s)$ allows us to compute the inverse of the LF-map in an FM-index which is useful, for example, for extracting substrings of the indexed text s [59].

For a discussion of sophisticated schemes for Rank/Select queries offering a variety of time/space trade-offs the reader should refer to Reference 59 for the theoretical results, and to References 67–69 for implementations and extensive experiments. The SDSL library [70] offers efficient and ready to use implementations of succinct (compressed) data structures including FM-indices, Suffix trees, and Wavelet trees.

60.1 Introduction

Cheminformatics is an interdisciplinary science that exists at the interface between chemistry and computer and information sciences. Its goal is to design new molecules that meet societal needs. Among the many fields in which it is used, the design of new drugs (medicines) is an area that has seen the greatest application of cheminformatics. The goal of drug discovery is to find the optimal molecule that binds to a biological target, typically a protein. The number of theoretical molecules (known as *chemical space*) from which to find the optimal molecule is infinite. This chemical space can be reduced to a finite *druglike* chemical space (estimated to contain between 10^{12} and 10^{180} molecules) by eliminating molecules that are unlikely to be usable as drugs. The Chemical Abstracts Service (CAS) whose objective is “to find, collect, and organize all publicly disclosed substance information” currently (as of December 29, 2015) contains only approximately 105 million molecules, a small fraction of the druglike chemical space. In practice, the quest for a new molecule starts from lists of existing molecules. Cheminformatics techniques are used to filter these lists to generate a subset of molecules that are tested experimentally against the biological target using *high-throughput screening*. Molecules that bind to the target are said to be *hits*. From the list of hits, the filtering process identifies *leads* and from these, a candidate that enters preclinical development. Perhaps because of the strong connection with medicinal chemistry, cheminformatics is sometimes seen as being related to bioinformatics. However, a key distinction in the underlying algorithmic techniques is that bioinformatics focuses on sequence data (e.g., DNA sequences), whereas cheminformatics focuses on the structure of small molecules represented as graphs. Excellent introductions and surveys of the field include References 1–4.

The science of cheminformatics is largely based on a principle known as the *similar property principle*, which states that molecules with similar structures tend to have similar properties. This principle motivates a graph-theoretic approach to several problems. Graph-theoretic representations are often referred to as topological or 2D approaches in cheminformatics terminology. It should be noted that a molecule actually has 3D geometric structure and that this captures important information about the molecule not available in a 2D representation. In most cases, however, 2D techniques outperform 3D techniques, possibly because the former are a more mature computational technology than the latter. We will accordingly focus on 2D techniques in the remainder of this chapter.

Specific cheminformatics problems that require efficient data structures are listed below.

1. *Exact searches*: Given a query molecule q , is there a molecule d in database D such that $q = d$? This is discussed in Section 60.2.
2. *Similarity searches*: Given a query molecule q , identify molecules d in database D that are similar to q . This is discussed in Section 60.3.

60.2 Exact Searches

This section first describes a graph-theoretic representation of a molecule and then describes canonical representations that are used in the exact search problem.

60.2.1 Graph Theoretic Representations

A molecule can be represented mathematically as a chemical or molecular graph: an atom of the molecule corresponds naturally to a graph vertex while (covalent) bonds connecting atoms correspond naturally to edges between graph vertices. More precisely, a molecular graph is a labeled, undirected, connected multigraph.

1. Labels denote atom type (e.g., a carbon atom is represented by a graph vertex with a label “C”).
2. A pair of atoms may be connected by double- or triple bonds. This requires multiple edges between a pair of vertices in the graph making it a *multigraph*. (Recall that a simple graph permits at most one edge between a pair of vertices.)
3. If a molecular graph is not connected and consists of multiple connected components, each component is considered to be a separate molecule.

A molecular graph could be hydrogen-included (hydrogen atoms are explicitly included) or hydrogen-excluded (hydrogen atoms are excluded from the representation). In the latter, positions of the H atoms can be inferred from the valences and bonds of the remaining atoms. The valence of an atom is the maximum number of bonds incident on it and is determined by the number of electrons in the atom’s outermost shell and the octet rule. For example, carbon has a valence of 4. If a carbon atom in a hydrogen-excluded representation consists of (1) a double bond to a second carbon atom and (2) a single bond to a nitrogen atom, we can infer that it has a fourth implicit bond to a hydrogen atom. Other scenarios can also be accommodated within the graph representation.

- In conjugated systems such as benzene, bonds are not well defined and are represented by alternating single/double bonds or alternatively as bonds with a valency of 1.5.
- In a reduced graph model, each vertex represents a group of connected atoms.

Molecular graphs are typically represented using a variant of the well-known adjacency matrix. The adjacency matrix representation is known to be inefficient for sparse graphs (relative to adjacency lists), but the relatively small sizes of molecules make its use acceptable in this context.

60.2.2 Canonical Representations

Consider a data structure (database) that stores a set of molecules. A classical operation on such a data structure is to search for a particular query molecule. Underlying this is the need to solve the following problem: given two molecules M_1 and M_2 , are they the same molecule? This is usually a trivial question for most data. For example, two integers can be compared for equality in $O(1)$ time; or two strings can be compared in time proportional to their lengths by a simple character-by-character comparison. For graphs, however, this check for equality reduces to the graph isomorphism problem.

A graph G is said to be isomorphic to graph H if there exists a bijection $f : V(G) \rightarrow V(H)$ such that u and v in G are adjacent if and only if $f(u)$ and $f(v)$ are adjacent in H .

The status of the isomorphism problem is undetermined for general graphs: no polynomial-time algorithm has been discovered, nor has a proof of NP-completeness been found. However, polynomial-time algorithms have been found for special classes of graphs including planar graphs [5], interval graphs [6], and trees [7]. Just as efficient graph isomorphism algorithms have been discovered for other special classes of graphs, a theoretical polynomial-time solution has been proven to exist for graphs of bounded valence [8,9]. However, a practical, polynomial-time, graph isomorphism algorithm for graphs of bounded valence has not been implemented [10].

Faulon showed that a chemical graph can be converted to a bounded degree graph [10], implying that isomorphism can be solved in polynomial time for chemical graphs. However, the underlying algorithms are highly theoretical and are considered to be unimplementable and impractical.

For these and other reasons, the cheminformatics community has considered alternative approaches to implement exact searches. The main idea is to convert a molecular graph to a unique text string known as a canonical label. We denote the canonical label of a molecular graph M by $CL(M)$. The question of whether $M_1 == M_2$ is now reduced to the question $CL(M_1) == CL(M_2)$, which is easily resolved by a simple string comparison. Note that if the canonical labeling algorithm runs in polynomial time, this approach yields a polynomial time solution to the isomorphism problem for molecular graphs. Unfortunately existing canonical labeling algorithms suffer from one of two drawbacks.

1. They run in polynomial time, but do not result in unique labels; that is, two distinct molecular graphs get the same label.
2. They generate unique labels, but run in exponential time on some inputs.

These drawbacks are mitigated in that they do not arise often in practice. A theoretical analysis based on random chemical graphs [11] appears to confirm these observations.

60.2.3 Canonical Labeling Methods

A thorough treatment of all of the individual canonical labeling techniques is beyond the scope of this article. In the following, we describe three canonical labeling methods.

60.2.3.1 Morgan's Algorithm

The first attempt at creating a canonical name for molecules in systems came from the CAS [12]. This algorithm creates a name for a given compound based on the names, connectivity, and other properties of the atoms encountered during the traversal of its graphical representation. The key to Morgan's algorithm is the calculation of the graph's extended connectivity (EC):

1. Set the EC of all atoms to their degree.
2. Count the number of different EC values in the graph (let this be the cardinality C of the EC values).
3. Calculate a new EC value for each atom by summing the old values of its connected vertices (except if the EC is 1, do not change it).
4. Determine cardinality of the new EC values C_{new} and compare to the old value C_{old} ; if $C_{\text{new}} > C_{\text{old}}$, goto Step 3.
5. If $C_{\text{new}} < C_{\text{old}}$, use C_{old} .
6. If $C_{\text{new}} == C_{\text{old}}$, use C_{new} .

Many researchers have modified this algorithm to fit their particular needs or data sets. Chen et al. [13] describe a variant of Morgan's Algorithm in which each atom is assigned a code which consists of the atom's elemental symbol, its connectivity, and particle charge.

The example in Figure 60.1 (inspired by Chenet al. [13]) shows how the connectivity is calculated during each iteration of the algorithm.

Initially, there are three distinct connectivity values. After the next iteration, there are four. Since the next two iterations both produce six distinct values, the end condition is triggered and the current (last iteration) is used as the final values.

While this algorithm works for almost all chemical structures, it can fail when the graph is highly regular producing oscillatory behavior. Morgan's Algorithm has been adapted with approximation techniques to solve such problems [14]. As mentioned, many different versions of this algorithm have been produced. The variation from Chen et al. is $O(mn^2)$ where m is the number of starting points and n is the number of symmetry points [13].

60.2.3.2 Nauty

One of the fastest algorithms for isomorphism testing and canonical naming is Nauty (No AUTomorphism, Yes?) [15]. It is based on a method of finding the automorphism group for a graph [16]. An automorphism is a mapping of a graph onto itself. A graph may have many such mappings, which are collectively referred to as the automorphism group.

Given a graph $G(V, E)$, a partition of V is a set of disjoint subsets of V . The set of all partitions of V is denoted by $\Pi(V)$. The divisions of a particular partition π are called its cells. A partition with one cell is called a unit partition and a partition in which each cell contains only one vertex is called a discrete partition. Given two partitions π_1 and π_2 , π_1 is finer than π_2 (and

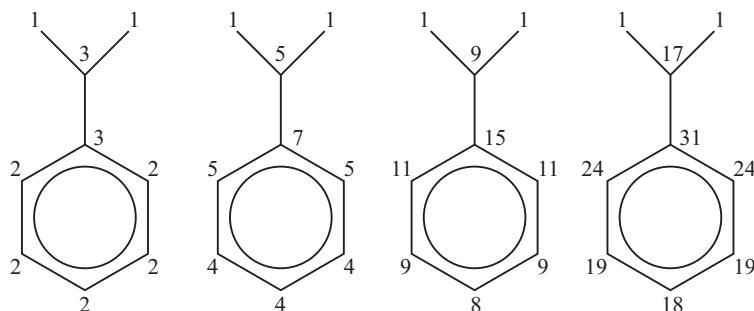

FIGURE 60.1 Connectivity graph of cumin.

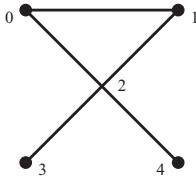

FIGURE 60.2 Graph for Nauty example.

π_2 is coarser than π_1 if every cell of π_1 is a subset of some cell in π_2 . The unit partition is the coarsest partition and the discrete partition is the finest. The key to the algorithm is producing *equitable* partitions. A partition π is said to be equitable if, given a partition π of V into n cells (where a cell W is a set of vertices): $\pi = W_1, W_2, \dots, W_n$, π is equitable if for every cell W_i there exists a d_i such that every vertex in cell W_i is adjacent to exactly d_i vertices in cell W_{i+1} . McKay [16] proves that every graph has a unique, coarsest equitable partition that is guaranteed to exist. The Nauty package implements a refinement process that takes any partition (usually a unit partition) as input and produces the unique equitable coarsest partition as output. The vertices are initially divided into cells by degree, sorted in increasing order. Each cell is then iteratively compared with subsequent cells by comparing the degrees in each cell. Whenever a discrepancy in degree is found, the cell is divided. If no discrepancies are found, the loop ends. Since a discrete partition cannot be further divided, it is also an end condition. Each cell in the partition is “colored” producing a unique name.

Given the graph in Figure 60.2, and the initial unit partition $\pi = [01234]$, the initial refinement process would create the partition $\pi = [34|01|2]$ which, for this simple example, is the coarsest equitable partition. Nodes 3 and 4 would be colored the same as would nodes 0 and 1.

The time complexity of Nauty was analyzed in Reference 17, where it is proven that the worst-case time complexity is exponential. In practice, when used on chemical graphs, Nauty appears to have a complexity that is linear.

60.2.3.3 Signature-Based Canonization

This naming algorithm produces a molecular descriptor called a signature which is based on extended valence sequences [10].

The algorithm first constructs a graph, which is similar in form to a tree, for each atom in the molecule. The graph is not formally a tree since vertices representing atoms may appear more than once in the graph. The root of the “tree” is the atom being considered. The next level is composed of nodes representing all of the atoms connected to the root atom. The next level contains all of the atoms connected to atoms in the previous level. This process continues until all bonds in the molecule have been considered. As previously mentioned, it is possible that a node representing an atom could appear multiple times in the graph. In fact, when these repeated nodes occur at the same level, entire subtree structures are repeated. For this reason, the space requirements of the algorithm are minimized by pointing to repeated subtrees, thus forming a directed acyclic graph (DAG).

Each node in the tree is then initialized with an integer invariant that is derived from the represented atom’s type. Then, starting from the level furthest from the root, the nodes are sorted based on their invariants. The invariants of the nodes at the next level closer to the root are then recalculated based on their invariants and those of their neighbors. This process continues until the root is reached. The purpose of this procedure is the production of a unique ordering of the edges of the graph based on the node invariants.

The graph is then traversed in a depth-first manner, producing a signature for the atom. This signature contains enough information to completely rebuild the molecule. In fact, the molecule can be reconstructed from the signature produced for any of the atoms in the graph. The lexicographically largest signature of all of the atom signatures is used to represent the molecule. Since all signatures contain all of the needed information, the other signatures can be discarded. Pseudocode for Signature-based canonization follows.

1. For each atom in the molecule:
 - a. Create the signature tree with the current atom at the root
 - b. Assign initial integer invariant values
 - c. For each level of the signature tree, from the leaves to the root:
 - i. Sort the nodes at the current level, based on invariant values
 - ii. Recalculate the invariant values for the nodes on the next level using the values of the neighboring nodes
 - d. Produce a signature string for the atom based on a depth-first search for every node in the tree
 - e. Associate the signature string with the current atom
2. Choose the lexicographically largest signature string to represent the molecule
3. Discard all other signature strings.

The worst-case time complexity of the Signature algorithm on pathological inputs is exponential.

60.3 Chemical Fingerprints and Similarity Search

Because of the difficulties associated with the graph isomorphism and subgraph isomorphism problems, molecules are encoded and stored in chemical databases as fingerprints. Chemical fingerprints are representations of 2D chemical structure and are used in chemical database substructure searching, similarity search, clustering, and classification. Several chemical fingerprinting schemes are described in the literature. One of these is the extended connectivity fingerprint (ECFP).

The ECFP is a circular fingerprint based on Morgan's algorithm. ECFPs are not designed for substructure searches, but are instead used for similarity searches, clustering, and virtual screening. They are generated in three steps: (1) an initial assignment stage, where each atom is assigned an integer identifier; (2) an iterative updating stage in which each atom's identifier is updated to include its neighbors; and (3) finally, a duplicate identifier removal stage. The ECFP set includes all of the identifiers generated in each iteration. For more details about ECFP and a comprehensive discussion of other fingerprint techniques, we refer the reader to Reference 18.

In the remainder of this chapter, we do not focus on a particular fingerprinting scheme, but on the underlying concept as illustrated in Figure 60.3.

60.3.1 Tanimoto Similarity

Given two sets a and b , the Tanimoto similarity $S(a, b)$ between them is defined as

$$\begin{aligned} S(a, b) &= \frac{|a \cap b|}{|a \cup b|} \\ &= \frac{|a \cap b|}{|a| + |b| - |a \cap b|} \end{aligned}$$

where $|a|$ denotes the cardinality of set a . The cardinality of a set is given by the number of “1”s in the corresponding fingerprint. The Tanimoto similarity is well defined as long as at least one set is nonempty. Note that $0 \leq S(a, b) \leq 1$, with $S(a, b) = 0$ when the intersection is empty and $S(a, b) = 1$ when the two sets are identical.

Tanimoto similarities are used to find all sets (represented by fingerprints) in a database that are similar to a query fingerprint as follows:

Given a database D of fingerprints and a query fingerprint q , return all fingerprints $d \in D$ such that $S(q, d) \geq t$, where t is a user-specified threshold.

Note that the time complexity of this operation is $O(|D|f)$, where f denotes the time needed to compute the Tanimoto similarity between a pair of fingerprints, which is proportional to the length of the fingerprint vector.

An alternative formulation for similarity searches does not require the user to specify an arbitrary t , but instead returns the top C hits:

Given a database D of fingerprints and a query fingerprint q , return C fingerprints $d \in D$ with the highest $S(q, d)$ values.

This approach requires the computation of all Tanimoto similarities as before $O(|D|f)$. A max-heap is used to keep track of the top C hits for an additional computation of $O(|D|(\log C))$. Given the large sizes of molecular databases, a linear search that

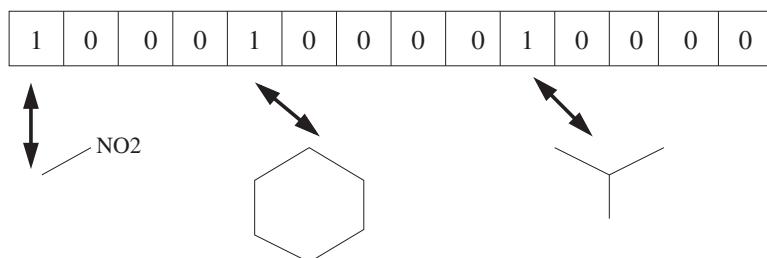

FIGURE 60.3 Illustration of fingerprints: the fingerprint vector is a bit string with each element in the vector denoting a particular molecular substructure. Examples of substructure features used in the fingerprint include all possible labeled paths or labeled trees (circular substructures) up to a certain length. A bit is set to “1” if and only if the corresponding substructure is present in the molecule. In some versions, each element of the vector is a count of the number of occurrences of the particular substructure.

compares a query fingerprint with each of the database fingerprints is unacceptably expensive. In the sections below, we describe several improvements to the linear search based on the use of innovative data structures.

60.3.2 Bitbound Algorithm

One strategy [19] to improve search times is to use information about the cardinalities of both sets to reduce the number of database fingerprints against whom similarities are computed. For a given fixed $|q|$ and $|d|$, $S(q, d)$ is maximized when $|q \cap d|$ is maximized and $|q \cup d|$ is minimized. This occurs when $q \subseteq d$ or $d \subseteq q$ and results in the following bound:

$$S(q, d) \leq \frac{\min(|q|, |d|)}{\max(|q|, |d|)}.$$

Consider an example of a similarity search where the size of the query fingerprint $|q| = 200$ and the user-defined similarity threshold $t = 0.8$.

Case 1 $|q| \leq |d|$: $S(q, d) \leq 200/|d|$. Any fingerprints $d \in D$ such that $|d| > 250$ result in $S(q, d) \leq 0.8$ and can be immediately discarded without further analysis.

Case 2 $|q| \geq |d|$: $S(q, d) \leq |d|/200$. Any fingerprints $d \in D$ such that $|d| < 160$ result in $S(q, d) \leq 0.8$ and can also be immediately discarded.

Only d with $160 \leq |d| \leq 250$ need to be evaluated further against query q . To exploit this observation, the database is preprocessed so that fingerprints are placed in bins indexed by size. Only bins corresponding to sizes in the range $[|q|t, |q|/t]$ need to be searched.

This organization of fingerprints by cardinality can also be used in the top C hits formulation. We compute the bound for each bin and sort the bins in decreasing order of bound. The fingerprints are explored (i.e., their Tanimoto similarity against q is computed) in this order. Once again, a max-heap is used to store the top C hits. The search is terminated when the smallest similarity value in the heap is greater than the highest bound remaining.

60.3.3 Fingerprint Compression

Fingerprints can be very long ($2^{15} - 2^{20}$ bits) and sparse. Recall that the computation time for similarity and top- C searches includes a factor f corresponding to fingerprint size. Compressing fingerprints not only reduces the size of the database but also improves computation time. Long fingerprints may be compressed by a factor of k by folding them using a simple modulo operation.

Compressed fingerprints can now be used instead of the original fingerprints for similarity searches as described earlier. This introduces an error that results in a systematic overestimate of Tanimoto similarity. (A given bit location in a pair of compressed fingerprints could both be 1 even though none of the corresponding k pairs of bits in the original fingerprints were both “1”s.) Molecules that would not meet the similarity threshold using the original fingerprints might meet them using compressed fingerprints. This overestimate results in a reduction in the quality of the similarity search. A mathematical correction of this overestimate is derived in Reference 20.

The folding scheme described above is *lossy* because it is not possible to recover the original fingerprint from the compressed fingerprint. An alternative *lossless* approach for reducing fingerprint size exploits the sparsity of fingerprints by storing the indices of “1” bits. In the example, (1 0 0 0 1 1 0 0 0 0 0 1 0 1) can be represented by (1 5 6 13 15). Another approach is to store the lengths of 0 runs: (0 3 6 1) in our example. These reduced vectors can be compressed optimally using Golomb-Rice or Elias Codes based on statistical assumptions [21].

60.3.4 Hashing Approaches for Improved Searches

Additional improvements over the bounds presented in Section 60.3.2 can be obtained by associating with each fingerprint a short integer signature vector of length M . When $M = 1$, the integer is simply the number of “1”s in the fingerprint, making the improvement of Section 60.3.2 a special case of this approach. The case when $M = 5$ is illustrated by a simple modification to the example in Figure 60.4: instead of taking the OR of corresponding bits, we add their values giving the vector (2 0 1 0 2).

In our explanation, we focus on the case where $M = 2$. The two integers in this case may be obtained by separately counting the number of “1”s in the first half and the second half, respectively. For fingerprint q , the two counts are denoted by q_1 and q_2 , respectively.

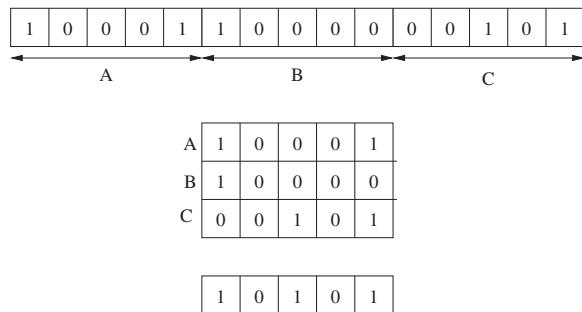

FIGURE 60.4 Illustration of folding: a long fingerprint consisting of 15 bits (1 0 0 0 1 1 0 0 0 0 0 1 0 1) is folded by a factor of 3 to give a fingerprint (1 0 1 0 1) of length 5. The original fingerprint is interpreted as having been subdivided into three segments of length 5 each. Bit j in the compressed fingerprint is the logical OR of bits j in the three segments.

We can now compute a bound on $S(q, d)$ as follows:

$$\begin{aligned} S(q, d) &\leq \frac{\min(q_1, d_1) + \min(q_2, d_2)}{\max(q_1, d_1) + \max(q_2, d_2)} \\ &= \frac{\min(q_1, d_1) + \min(q_2, d_2)}{|q| + |d| - \min(q_1, d_1) - \min(q_2, d_2)} \\ &\leq t. \end{aligned}$$

From, this we get $\min(q_1, d_1) + \min(q_2, d_2) \leq \frac{t}{t+1}(|q| + |d|)$. There are now four cases, depending on the outcome of the min operations:

1. $q_1 + q_2 \leq \frac{t}{t+1}(|q| + |d|)$
2. $d_1 + d_2 \leq \frac{t}{t+1}(|q| + |d|)$
3. $q_1 + d_2 \leq \frac{t}{t+1}(|q| + |d|)$
4. $d_1 + q_2 \leq \frac{t}{t+1}(|q| + |d|)$.

The first two cases give us $|q|t \leq |d| \leq |q|/t$, the inequalities corresponding to $M = 1$, identical to those obtained in Section 60.3.2. For a fixed value of $|d|$, cases 3 and 4 give us $-q_2 + t(|q| + |d|)/(t+1) < d_1 < |d| + q_1 - t(|q| + |d|)/(1+t)$. Consider an example with $|q| = 200$ and $t = 0.8$ as before. Recall that this already reduces the search to values of $|d|$ in [160, 250]. Suppose $q_1 = 125$ and $q_2 = 75$. Suppose also that we are considering database fingerprints with $|d| = 200$. Substituting, this gives $102 < d_1 < 147$. This allows us to further eliminate fingerprints in the $|d| = 200$ bin that do not meet this criteria. This computation is facilitated by a secondary sorting within each bin on d_1 . Recall that bins are already ordered by $|d|$.

60.3.5 Triangle Inequality and Improvements

Recall that Tanimoto similarity is guaranteed to be in the range $[0, 1]$ with a high value denoting a high similarity and vice versa. We can also define *Tanimoto distance* $D(a, b) = 1 - S(a, b)$. The Tanimoto distance is a distance metric and satisfies the triangle inequality; that is, given three fingerprints a , b , and c : $|D(b, a) - D(a, c)| \leq D(b, c) \leq D(b, a) + D(a, c)$. This inequality can be used to prune searches as follows: suppose $D(a, b)$ is small (say 0.1) and $D(a, c)$ is large (say 0.9). We have $0.8 \leq D(b, c) \leq 1.0$, which implies that $0 \leq S(b, c) \leq 0.2$. For $t > 0.2$, we are able to avoid computing $S(b, c)$. Notice that this computation does not utilize information about the precise bits that are common between a and c or a and b to compute a bound between b and c . A more sophisticated analysis that considers this information gives an *intersection bound* that is tighter than the distance bound that results in more efficient searches [22].

60.3.6 XOR Filter

Another strategy [23] for improving similarity searches is to augment the original fingerprint with a signature: a folded fingerprint based on the XOR operator unlike the example in Figure 60.4 which uses the OR operator. The XOR-based signature on the example is (0, 0, 1, 0, 0). The signature is used to prune the search space as described below.

First, note that the union and intersection used in the computation of Tanimoto's similarity can be expressed in terms of the XOR (\oplus) operator as follows. In set-theoretic terms, $|a \oplus b| = |a - b| + |b - a|$.

$$\begin{aligned}|a \cap b| &= \frac{1}{2}[|a| + |b| - |a \oplus b|] \\ |a \cup b| &= \frac{1}{2}[|a| + |b| + |a \oplus b|].\end{aligned}$$

Let the XOR-folded fingerprints of a and b be α and β , respectively. We then have $|a \oplus b| \geq |\alpha \oplus \beta|$, which gives.

$$\begin{aligned}|a \cap b| &\leq \frac{1}{2}[|a| + |b| - |\alpha \oplus \beta|] \\ |a \cup b| &\geq \frac{1}{2}[|a| + |b| + |\alpha \oplus \beta|]\end{aligned}$$

resulting in

$$S(a, b) \leq \frac{|a| + |b| - |\alpha \oplus \beta|}{|a| + |b| + |\alpha \oplus \beta|}.$$

If the quantity in the RHS is less than the similarity threshold t , we can discontinue the computation of $S(a, b)$. The XOR filter will sometimes result in better bounds than *BitBound* and can be used in addition to it.

60.3.7 Inverted Indices

Consider a database of $|D|$ molecules represented as f -bit binary fingerprints, with each bit i , $1 \leq i \leq f$, corresponding to the presence/absence of a feature. In an inverted index, a list of molecules is maintained for each of the f features. List i consists of all molecules whose i th bit is set to 1. Consider the fingerprint corresponding to a query molecule q . In order to compute its Tanimoto similarity with each fingerprint in the database, we only need to traverse the lists corresponding to features present in q . We maintain a counter for each molecule in D that is initialized to 0. When a molecule is encountered in one of the relevant lists, its counter is incremented. The final value of the counter for each molecule represents the size of its intersection with the query molecule, the numerator of the Tanimoto similarity formula.

Nasr et al. note that the similarity threshold problem can be reduced to the T occurrence problem in information retrieval (i.e., finding all fingerprints with an intersection of size at least T with the query), for which efficient solutions based on the inverted index exist. We have

$$\begin{aligned}S(a, b) &= \frac{|a \cap b|}{|a \cup b|} \\ &= \frac{|a \cap b|}{|a| + |b| - |a \cap b|} \\ &\geq t\end{aligned}$$

which gives

$$T = |a \cap b| \geq \frac{t(|a| + |b|)}{t + 1}.$$

The invertex index-based *DivideSkip* solution [24] to the T -occurrence problem is presented and applied in Reference 23.

60.3.8 LINGO

A set of LINGOs [25] is defined as all substrings of length q in the modified SMILES string for a molecule. A simplified SMILES string $S = c0cccc0L$ for $q = 4$ gives the multiset $\{c0cc, 0ccc, cccc, cccc, ccc0, cc0L\}$. The similarity between two molecules represented by their SMILES strings can be computed as the Tanimoto similarity between their LINGO multisets (LINGOsim). The LINGOsim computation is performed by representing the LINGOs of the query by a trie/finite state machine to improve the efficiency of the computation [26]. An alternative solution stores the database of molecules (with each molecule represented by a LINGO multiset) as an inverted index [27].

60.3.9 Trie-Based Approaches for Storing Fingerprints

A database of binary fingerprints can be stored in a binary tree. Starting with the root, the complete set of fingerprints is recursively split into two sets corresponding to its left and right subtrees. Each fingerprint is assigned to one of the two sets depending on the value of its first (leftmost) bit. If the value is 0 (1), it is assigned to the left (right) subtree. At level i of the tree, bit i of the fingerprint is used to determine the assignment of the fingerprint to the appropriate subtree. For an exact search for a fingerprint, the algorithm starts at the root and follows left or right pointers that spell out the fingerprint in time proportional to f .

For a threshold similarity search, a naive solution visits all of the leaves of the trie and computes the Tanimoto similarity. This search can be pruned by employing the Tanimoto lookahead condition [28] described later. Let

1. $B(n, d)$ denote the partial bit string spelled by the path from the root to node n at depth d .
2. $Q(d)$ denote the partial bit string formed from the first d bits of the query fingerprint.
3. $QL(d)$ denote the number of “1”s in the query bit string after position d .

The Running Union Count and Running Intersection Counts are defined respectively as $RUC(n, d) = |B(n, d) \cup Q(d)|$ and $RIC(n, d) = |B(n, d) \cap Q(d)|$. The maximum value of the Tanimoto similarity between query q and *any* molecule that is reached by traversing the bit tree through node n is given by

$$Smax(n, q) = \frac{RIC(n, d) + QL(d)}{RUC(n, d) + QL(d)}.$$

The search can be terminated at node n if this value computed at node n is less than the threshold t .

A more efficient organization of the tree splits the fingerprints into two sets using a bit of maximal entropy (i.e., one that yields two subsets as much as possible of equal size) rather than picking the next bit in left-to-right order. This is the *Singlebit* tree described in Reference 29. The equation for $Smax$ above applies to the modified tree, but requires that each tree node keep track of the bit used at that node as well as the bits used by its ancestors to split the fingerprint set.

60.3.10 Multibit and Union Tree

The Singlebit tree was found to be inefficient in experiments [29] because a relatively small tree depth was found to be enough to partition the fingerprints. This meant that the algorithm is only aware of a small fraction of bits, resulting in bounds that do not prune a large number of fingerprints.

The Multibit tree addresses this shortcoming by recording in each node the list of bits that have constant value 0 or 1 in all of the fingerprints stored in the node’s subtree. For example, consider a node whose subtree contains two fingerprints: 10, 101, and 10110. The node would store the three common bits as (1,1) (2,0) (3,1) where the first element denotes the position of the bit and the second is the common value. Using this information results in tighter bounds and greater pruning [29,30].

An alternative strategy (UnionBit Tree) has a node store the union of the fingerprint vectors in its leaves. In the example above, the node would store 10111. A query fingerprint’s intersection with the union vector has cardinality guaranteed to be greater than or equal to that of any of the individual fingerprints. The UnionBit tree uses less CPU time and memory relative to the MultiBit tree [31].

60.3.11 Combining Hashing and Trees

The *BitBound* algorithm (described in Section 60.3.2) organizes fingerprints by placing each fingerprint in a bin corresponding to its cardinality, the number of 1s in that fingerprint; that is, all fingerprints with 15 1s are placed in bin 15. The bins are sorted by cardinality; the BitBound algorithm searches bins in a specified range as described earlier. Improved solutions are obtained by storing the fingerprints in each bin using a multibit tree [30].

The most fundamental computation in numerical linear algebra is the factorization of a matrix as a product of two or more matrices with simpler structure. An important example is Gaussian elimination, in which a matrix is written as a product of a lower triangular matrix and an upper triangular matrix. The factorization is accomplished by elementary operations in which two or more rows (columns) are combined together to transform the matrix to the desired form. In Gaussian elimination, the desired form is an upper triangular matrix, in which nonzero elements below the diagonal have been transformed to be equal to zero. We say that the subdiagonal elements have been eliminated. (The transformations that accomplish the elimination yield a lower triangular matrix.)

The input matrix is usually sparse, that is, only a few of the matrix elements are nonzero to begin with; in this situation, row operations constructed to eliminate nonzero elements in some locations might create new nonzero elements, called fill, in other locations, as a side-effect. Data structures that predict fill from graph models of the numerical algorithm, and algorithms that attempt to minimize fill, are key ingredients of efficient sparse matrix algorithms.

This chapter surveys these data structures, known as *elimination structures*, and the algorithms that construct and use them. We begin with the *elimination tree*, a data structure associated with symmetric Gaussian elimination, and we then describe its most important applications. Next we describe other data structures associated with symmetric Gaussian elimination, the *clique tree*, the *clique cover*, and the *quotient graph*. We then consider data structures that are associated with asymmetric Gaussian elimination, the *column elimination tree* and the *elimination directed acyclic graph*.

This survey has been written with two purposes in mind. First, we introduce the algorithms community to these data structures and algorithms from combinatorial scientific computing; the initial subsections should be accessible to the non-expert. Second, we wish to briefly survey the current state of the art, and the subsections dealing with the advanced topics move rapidly. A collection of articles describing developments in the field circa 1991 may be found in [1]; Duff provides a survey as of 1996 in [2].

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

61.1 The Elimination Tree

61.1.1 The Elimination Game

Gaussian elimination of a symmetric positive definite matrix A , which factors the matrix A into the product of a lower triangular matrix L and its transpose L^T , $A = LL^T$, is one of the fundamental algorithms in scientific computing. It is also known as Cholesky factorization. We begin by considering the graph model of this computation performed on a symmetric matrix A that is sparse, that is, few of its matrix elements are nonzero. The number of nonzeros in L and the work needed to compute L depend strongly on the (symmetric) ordering of the rows and columns of A . The graph model of sparse Gaussian elimination was introduced by Parter [3], and has been called the *elimination game* by Tarjan [4]. The goal of the elimination game is to symmetrically order the rows and columns of A to minimize the number of nonzeros in the factor L .

We consider a sparse, symmetric positive definite matrix A with n rows and n columns, and its adjacency graph $G(A) = (V, E)$ on n vertices. Each vertex in $v \in V$ corresponds to the v th row of A (and by symmetry, the v th column); an edge $(v, w) \in E$ corresponds to the nonzero a_{vw} (and by symmetry, the nonzero a_{wv}). Since A is positive definite, its diagonal elements are positive; however, by convention, we do not explicitly represent a diagonal element a_{vv} by a loop (v, v) in the graph $G(A)$. (We use v, w, \dots to indicate unnumbered vertices, and i, j, k, \dots to indicate numbered vertices in a graph.)

We view the vertices of the graph $G(A)$ as being initially unnumbered, and number them from 1 to n , as a consequence of the elimination game. To number a vertex v with the next available number, add new *fill edges* to the current graph to make all currently unnumbered neighbors of v pairwise adjacent. (Note that the vertex v itself does not acquire any new neighbors in this step, and that v plays no further role in generating fill edges in future numbering steps.)

The graph that results at the end of the elimination game, which includes both the edges in the edge set E of the initial graph $G(A)$ and the set of fill edges, F , is called the filled graph. We denote it by $G^+(A) = (V, E \cup F)$. The numbering of the vertices is called an elimination ordering, and corresponds to the order in which the columns are factored. An example of a filled graph resulting from the elimination game on a graph is shown in Figure 61.1. We will use this graph to illustrate various concepts throughout this paper.

The goal of the elimination game is to number the vertices to minimize the fill since it would reduce the storage needed to perform the factorization, and also controls the work in the factorization. Unfortunately, this is an NP-hard problem [5]. However, for classes of graphs that have small separators, it is possible to establish upper bounds on the number of edges in the filled graph, when the graph is ordered by a nested dissection algorithm that recursively computes separators. Planar graphs, graphs of “well-shaped” finite element meshes (aspect ratios bounded away from small values), and overlap graphs possess elimination orderings with bounded fill. Conversely, the fill is large for graphs that do not have good separators.

Approximation algorithms that incur fill within a polylog factor of the optimum fill have been designed by Agrawal, Klein and Ravi [6]; but since it involves finding approximate concurrent flows with uniform capacities, it is an impractical approach for

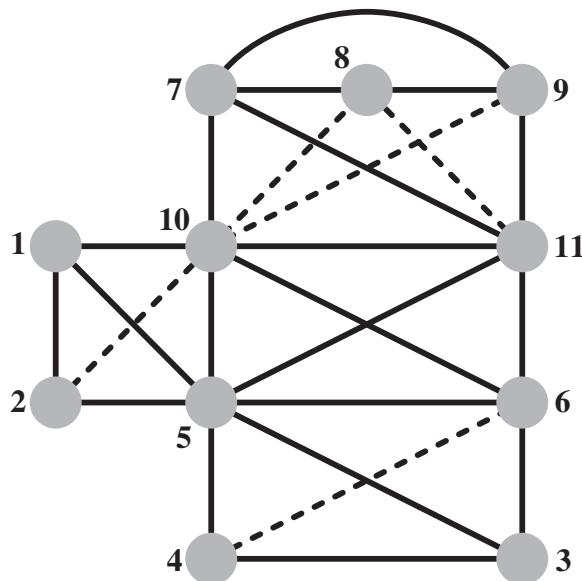

FIGURE 61.1 A filled graph $G^+(A)$ resulting from the elimination game on a graph $G(A)$. The solid edges belong to $G(A)$, and the broken edges are filled edges generated by the elimination game when vertices are eliminated in the order shown.

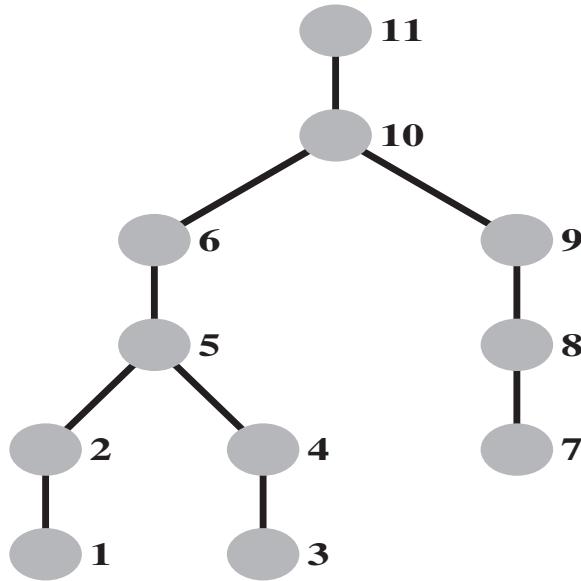

FIGURE 61.2 The elimination tree of the example graph.

large problems. A more recent approximation algorithm, due to Natanzon, Shamir and Sharan [7], limits fill to within the square of the optimal value; this approximation ratio is better than that of the former algorithm only for dense graphs.

The elimination game produces sets of cliques in the graph. Let $\text{hadj}^+(v)$ ($\text{ladj}^+(v)$) denote the higher-numbered (lower-numbered) neighbors of a vertex v in the graph $G^+(A)$; in the elimination game, $\text{hadj}^+(v)$ is the set of unnumbered neighbors of v immediately prior to the step in which v is numbered. When a vertex v is numbered, the set $\{v\} \cup \text{hadj}^+(v)$ becomes a clique by the rules of the elimination game. Future numbering steps and consequent fill edges added do not change the adjacency set (in the filled graph) of the vertex v . (We will use $\text{hadj}(v)$ and $\text{ladj}(v)$ to refer to higher and lower adjacency sets of a vertex v in the original graph $G(A)$.)

61.1.2 The Elimination Tree Data Structure

We define a forest from the filled graph by defining the parent of a vertex v to be the lowest numbered vertex in $\text{hadj}^+(v)$. It is clear that this definition of parent yields a forest since the parent of each vertex is numbered higher than itself. If the initial graph $G(A)$ is connected, then indeed we have a tree, the *elimination tree*; if not we have an *elimination forest*.

In terms of the Cholesky factor L , the elimination tree is obtained by looking down each column below the diagonal element, and choosing the row index of the first subdiagonal nonzero to be the parent of a column. It will turn out that we can compute the elimination tree corresponding to a matrix and a given ordering without first computing the filled graph or the Cholesky factor.

The elimination tree of the graph in Figure 61.1 with the elimination ordering given there is shown in Figure 61.2.

A *fill path* joining vertices i and j is a path in the original graph $G(A)$ between vertices i and j , all of whose interior vertices are numbered lower than both i and j . The following theorem offers a static characterization of what causes fill in the elimination game.

Theorem 61.1: ([8])

The edge (i, j) is an edge in the filled graph if and only if a fill path joins the vertices i and j in the original graph $G(A)$.

In the example graph in Figure 61.1, vertices 9 and 10 are joined a fill path consisting of the interior vertices 7 and 8; thus $(9, 10)$ is a fill edge. The next theorem shows that an edge in the filled graph represents a dependence relation between its end points.

Theorem 61.2: ([9])

If (i, j) is an edge in the filled graph and $i < j$, then j is an ancestor of the vertex i in the elimination tree $T(A)$.

This theorem suggests that the elimination tree represents the information flow in the elimination game (and hence sparse symmetric Gaussian elimination). Each vertex i influences only its higher numbered neighbors (the numerical values in the column i affect only those columns in $\text{hadj}^+(i)$). The elimination tree represents the information flow in a minimal way in that we need consider only how the information flows from i to its parent in the elimination tree. If j is the parent of i and ℓ is another higher neighbor of i , then since the higher neighbors of i form a clique, we have an edge (j, ℓ) that joins j and ℓ ; since by Theorem 61.2, ℓ is an ancestor of j , the information from i that affects ℓ can be viewed as being passed from i first to j , and then indirectly from j through its ancestors on the path in the elimination tree to ℓ .

An immediate consequence of the Theorem 61.2 is the following result.

Corollary 61.1

If vertices i and j belong to vertex-disjoint subtrees of the elimination tree, then no edge can join i and j in the filled graph.

Viewing the dependence relationships in sparse Cholesky factorization by means of the elimination tree, we see that any topological reordering of the elimination tree would be an elimination ordering with the same fill, since it would not violate the dependence relationships. Such reorderings would not change the fill or arithmetic operations needed in the factorization, but would change the schedule of operations in the factorization (i.e., when a specific operation is performed). This observation has been used in sparse matrix factorizations to schedule the computations for optimal performance on various computational platforms: multiprocessors, hierarchical memory machines, external memory algorithms, etc. A postordering of the elimination tree is typically used to improve the spatial and temporal data locality, and thereby the cache performance of sparse matrix factorizations.

There are two other perspectives from which we can view the elimination tree.

Consider directing each edge of the filled graph from its lower numbered endpoint to its higher numbered endpoint to obtain a directed acyclic graph (DAG). Now form the transitive reduction of the directed filled graph; that is, delete an edge (i, k) whenever there is a directed path from i to k that does not use the edge (i, k) (this path necessarily consists of at least two edges since we do not admit multiple edges in the elimination game). The minimal graph that remains when all such edges have been deleted is unique, and is the elimination tree.

One could also obtain the elimination tree by performing a depth-first search (DFS) in the filled graph with the vertex numbered n as the initial vertex for the DFS, and choosing the highest numbered vertex in $\text{hadj}^+(i)$ as the next vertex to search from a vertex i .

61.1.3 An Algorithm

We begin with a consequence of the repeated application of the following fact: If a vertex i is adjacent to a higher numbered neighbor k in the filled graph, and k is not the parent of i , p_i , in the elimination tree, then i is adjacent to both k and p_i in the filled graph; when i is eliminated, by the rules of the elimination game, a fill edge joins p_i and k .

Theorem 61.3

If (i, k) is an edge in the filled graph and $i < k$, then for every vertex j on an elimination tree path from i to k , (j, k) is also an edge in the filled graph.

This theorem leads to a characterization of $\text{hadj}^+(k)$, the set of lower numbered neighbors of a vertex k in the filled graph, which will be useful in designing an efficient algorithm for computing the elimination tree. The set $\text{hadj}^+(k)$ corresponds to the column indices of nonzeros in the k th row of the Cholesky factor L , and $\text{hadj}(k)$ corresponds to the column indices of nonzeros in the lower triangle of the k th row of the initial matrix A .

Theorem 61.4: ([10])

Every vertex in the set $\text{hadj}^+(k)$ is a vertex reachable by paths in the elimination tree from a set of leaves to k ; each leaf l corresponds to a vertex in the set $\text{hadj}(k)$ such that no proper descendant d of l in the elimination tree belongs to the set $\text{hadj}(k)$.

Theorem 61.4 characterizes the k th row of the Cholesky factor L as a *row subtree* $T_r(k)$ of the elimination subtree rooted at the vertex k , and pruned at each leaf l . The leaves of the pruned subtree are contained among $\text{hadj}(k)$, the column indices of the nonzeros in (the lower triangle of) the k th row of A . In the elimination tree in Figure 61.2, the pruned elimination subtree corresponding to row 11 has two leaves, vertices 5 and 7; it includes all vertices on the etree path from these leaves to the vertex 11.

FIGURE 61.3 An algorithm for computing an elimination tree. Initially each vertex is in a subtree with it as the root.

The observation above leads to an algorithm, shown in Figure 61.3, for computing the elimination tree from the row structures of A , due to Liu [10].

This algorithm can be implemented efficiently using the union-find data structure for disjoint sets. A height compressed version of the p . array, ancestor, makes it possible to compute the root fast; and union by rank in merging subtrees helps to keep the merged tree shallow. The time complexity of the algorithm is $O(e\alpha(e, n) + n)$, where n is the number of vertices and e is the number of edges in $G(A)$, and $\alpha(e, n)$ is a functional inverse of Ackermann's function. Liu [11] shows experimentally that path compression alone is more efficient than path compression and union by rank, although the asymptotic complexity of the former is higher. Zmijewski and Gilbert [12] have designed a parallel algorithm for computing the elimination tree on distributed memory multiprocessors.

The concept of the elimination tree was implicit in many papers before it was formally identified. The term elimination tree was first used by Duff [13], although he studied a slightly different data structure; Schreiber [9] first formally defined the elimination tree, and its properties were established and used in several articles by Liu. Liu [11] also wrote an influential survey that delineated its importance in sparse matrix computations; we refer the reader to this survey for a more detailed discussion of the elimination tree current as of 1990.

61.1.4 A Skeleton Graph

The filled graph represents a supergraph of the initial graph $G(A)$, and a skeleton graph represents a subgraph of the latter. Many sparse matrix algorithms can be made more efficient by implicitly identifying the edges of a skeleton graph $G^-(A)$ from the graph $G(A)$ and an elimination ordering, and performing computations only on these edges. A skeleton graph includes only the edges that correspond to the leaves in each row subtree in Theorem 61.4. The other edges in the initial graph $G(A)$ can be discarded, since they will be generated as fill edges during the elimination game. Since each leaf of a row subtree corresponds to an edge in $G(A)$, the skeleton graph $G^-(A)$ is indeed a subgraph of the former. The skeleton graph of the example graph is shown in Figure 61.4.

The leaves in a row subtree can be identified from the set $\text{adj}(j)$ when the elimination tree is numbered in a postordering. The subtree $T(i)$ is the subtree of the elimination tree rooted at a vertex i , and $|T(i)|$ is the number of vertices in that subtree. (It should not be confused with the row subtree $T_r(i)$, which is a pruned subtree of the elimination tree.)

Theorem 61.5: ([10])

Let $\text{adj}(j) = \{i_1 < i_2 < \dots < i_s\}$, and let the vertices of a filled graph be numbered in a postordering of its elimination tree T . Then vertex i_q is a leaf of the row subtree $T_r(j)$ if and only if either $q = 1$, or for $q \geq 2$, $i_{q-1} < i_q - |T(i_q)| + 1$.

61.1.5 Supernodes

A supernode is a subset of vertices S of the filled graph that form a clique and have the same higher neighbors outside S . Supernodes play an important role in numerical algorithms since loops corresponding to columns in a supernode can be blocked to obtain high performance on modern computer architectures. We now proceed to define a supernode formally.

A maximal clique in a graph is a set of vertices that induces a complete subgraph, but adding any other vertex to the set does not induce a complete subgraph. A supernode is a maximal clique $\{i_s, i_{s+1}, \dots, i_{s+t-1}\}$ in a filled graph $G^+(A)$ such that for each $1 \leq j \leq t-1$,

$$\text{hadj}^+(i_s) = \{i_{s+1}, \dots, i_{s+j}\} \cup \text{hadj}^+(i_{s+j}).$$

Let $\text{hd}^+(i_s) \equiv |\text{hadj}^+(i_s)|$; since $\text{hadj}^+(i_s) \subseteq \{i_{s+1}, \dots, i_{s+j}\} \cup \text{hadj}^+(i_{s+j})$, the relationship between the higher adjacency sets can be replaced by the equivalent test on higher degrees: $\text{hd}^+(i_s) = \text{hd}^+(i_{s+j}) + j$.

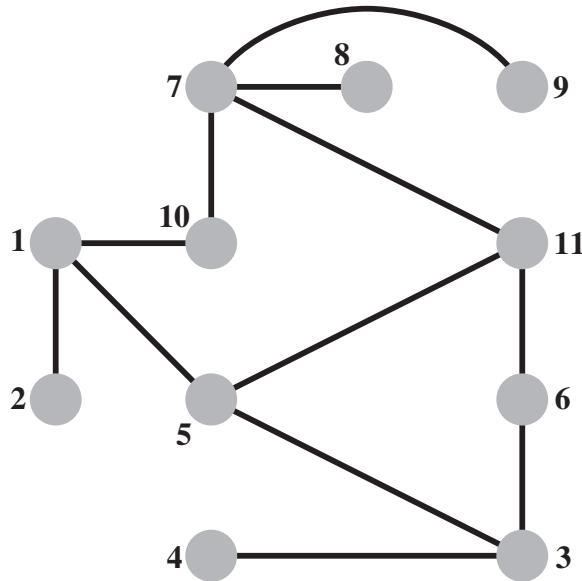

FIGURE 61.4 The skeleton graph $G^-(A)$ of the example graph.

In practice, *fundamental supernodes*, rather than the maximal supernodes defined above, are used, since the former are easier to work with in the numerical factorization. A fundamental supernode is a clique but not necessarily a maximal clique, and satisfies two additional conditions: (1) i_{s+j-1} is the only child of the vertex i_{s+j} in the elimination tree, for each $1 \leq j \leq t - 1$; (2) the vertices in a supernode are ordered consecutively, usually by post-ordering the elimination tree. Thus vertices in a fundamental supernode form a path in the elimination tree; each of the non-terminal vertices in this path has only one child, and the child belongs to the supernode.

The fundamental supernodes corresponding to the example graph are: $\{1, 2\}$; $\{3, 4\}$; $\{5, 6\}$; $\{7, 8, 9\}$; and $\{10, 11\}$.

Just as we could compute the elimination tree directly from $G(A)$ without first computing $G^+(A)$, we can compute fundamental supernodes without computing the latter graph, using the theorem given below. Once the elimination tree is computed, this algorithm can be implemented in $O(n + e)$ time, where $e \equiv |E|$ is the number of edges in the original graph $G(A)$.

Theorem 61.6: ([14])

A vertex i is the first node of a fundamental supernode if and only if i has two or more children in the elimination tree T , or i is a leaf of some row subtree of T .

61.2 Applications of Etrees

61.2.1 Efficient Symbolic Factorization

Symbolic factorization (or symbolic elimination) is a process that computes the nonzero structure of the factors of a matrix without computing the numerical values of the nonzeros.

The symbolic Cholesky factor of a matrix has several uses. It is used to allocate the data structure for the numeric factor and annotate it with all the row/column indices, which enables the removal of most of the non-numeric operations from the innermost loop of the subsequent numeric factorization [15,16]. It is also used to compute relaxed supernode (or amalgamated node) partitions, which group columns into supernodes even if they only have approximately the same structure [17,18]. Symbolic factors can also be used in algorithms that construct approximate Cholesky factors by dropping nonzeros from a matrix A and factoring the resulting, sparser matrix B [19,20]. In such algorithms, elements of A that are dropped from B but which appear in the symbolic factor of B can be added to the matrix B ; this improves the approximation without increasing the cost of factoring B . In all of these applications a supernodal symbolic factor (but not a relaxed one) is sufficient; there is no reason to explicitly represent columns that are known to be identical.

The following algorithm for symbolically factoring a symmetric matrix A is due to George and Liu [21] (and in a more graph-oriented form due to [8]; see also [16, Section 5.4.3] and [11, Section 8]).

The algorithm uses the elimination tree implicitly, but does not require it as input; the algorithm can actually compute the elimination tree on the fly. The algorithm uses the observation that

$$\text{hadj}^+(j) = \text{hadj}(j) \bigcup_{i, p_i=j} \text{hadj}^+(i).$$

That is, the structure of a column of L is the union of the structure of its children in the elimination tree and the structure of the same column in the lower triangular part of A . Identifying the children can be done using a given elimination tree, or the elimination tree can be constructed on the fly by adding column i to the list of children of p_i when the structure of i is computed (p_i is the row index of the first subdiagonal nonzero in column i of L). The union of a set of column structures is computed using a boolean array \mathbb{P} of size n (whose elements are all initialized to false), and an integer stack to hold the newly created structure. A row index k from a child column or from the column of A is added to the stack only if $\mathbb{P}[k] = \text{false}$. When row index k is added to the stack, $\mathbb{P}[k]$ is set to true to signal that k is already in the stack. When the computation of $\text{hadj}^+(j)$ is completed, the stack is used to clear \mathbb{P} so that it is ready for the next union operation. The total work in the algorithm is $\Theta(|L|)$, since each nonzero requires constant work to create and constant work to merge into the parent column, if there is a parent. (Here $|L|$ denotes the number of nonzeros in L , or equivalently the number of edges in the filled graph $G^+(A)$; similarly $|A|$ denotes the number of nonzeros in A , or the number of edges in the initial graph $G(A)$.)

The symbolic structure of the factor can usually be represented more compactly and computed more quickly by exploiting supernodes, since we essentially only need to represent the identity of each supernode (the constituent columns) and the structure of the first (lowest numbered) column in each supernode. The structure of any column can be computed from this information in time proportional to the size of the column. The George-Liu column-merge algorithm presented above can compute a supernodal symbolic factorization if it is given as input a supernodal elimination tree; such a tree can be computed in $O(|A|)$ time by the Liu-Ng-Peyton algorithm [14]. In practice, this approach saves a significant amount of work and storage.

Clearly, column-oriented symbolic factorization algorithms can also generate the structure of rows in the same asymptotic work and storage. But a direct symbolic factorization by rows is less obvious. Whitten [22], in an unpublished manuscript cited by Tarjan and Yannakakis [23], proposed a row-oriented symbolic factorization algorithm (see also [10] and [11, Sections 3.2 and 8.2]). The algorithm uses the characterization of the structure of row i in L as the row subtree $T_r(i)$. Given the elimination tree and the structure of A by rows, it is trivial to traverse the i th row subtree in time proportional to the number of nonzeros in row i of L . Hence, the elimination tree along with a row-oriented representation of A is an effective implicit symbolic row-oriented representation of L ; an explicit representation is usually not needed, but it can be generated in work and space $O(|L|)$ from this implicit representation.

61.2.2 Predicting Row and Column Nonzero Counts

In some applications the explicit structure of columns of L is not required, only the number of nonzeros in each column or each row. Gilbert, Ng, and Peyton [24] describe an almost-linear-time algorithm for determining the number of nonzeros in each row and column of L . Applications for computing these counts fast include comparisons of fill in alternative matrix orderings, preallocation of storage for a symbolic factorization, finding relaxed supernode partitions quickly, determining the load balance in parallel factorizations, and determining synchronization events in parallel factorizations.

The algorithm to compute row counts is based on Whitten's characterization [22]. We are trying to compute $|L_{i*}| = |T_r(i)|$. The column indices $j < i$ in row i of A define a subset of the vertices in the subtree of the elimination tree rooted at the vertex i , $T[i]$. The difficulty, of course, is counting the vertices in $T_r(i)$ without enumerating them. The Gilbert-Ng-Peyton algorithm counts these vertices using three relatively simple mechanisms: (1) processing the column indices $j < i$ in row i of A in postorder of the etree, (2) computing the distance of each vertex in the etree from the root, and (3) setting up a data structure to compute the least-common ancestor (LCA) of pairs of etree vertices. It is not hard to show that the once these preprocessing steps are completed, $|T_r(i)|$ can be computed using $|A_{i*}|$ LCA computations. The total cost of the preprocessing and the LCA computations is almost linear in $|A|$.

Gilbert, Ng, and Peyton show how to further reduce the number of LCA computations. They exploit the fact that the leaves of $T_r(i)$ are exactly the indices j that cause the creation of new supernodes in the Liu-Ng-Peyton supernode-finding algorithm [14]. This observation limits the LCA computations to leaves of row subtrees, that is, edges in the skeleton graph $G^-(A)$. This significantly reduces the running time in practice.

Efficiently computing the column counts in L is more difficult. The Gilbert-Ng-Peyton algorithm assigns a weight $w(j)$ to each etree vertex j , such that $|L_{*j}| = \sum_{k \in T[j]} w(k)$. Therefore, the column-count of a vertex is the sum of the column counts of its children, plus its own weight. Hence, w_j must compensate for (1) the diagonal elements of the children, which are not included in the column count for j , (2) for rows that are nonzero in column j but not in its children, and (3) for duplicate counting stemming

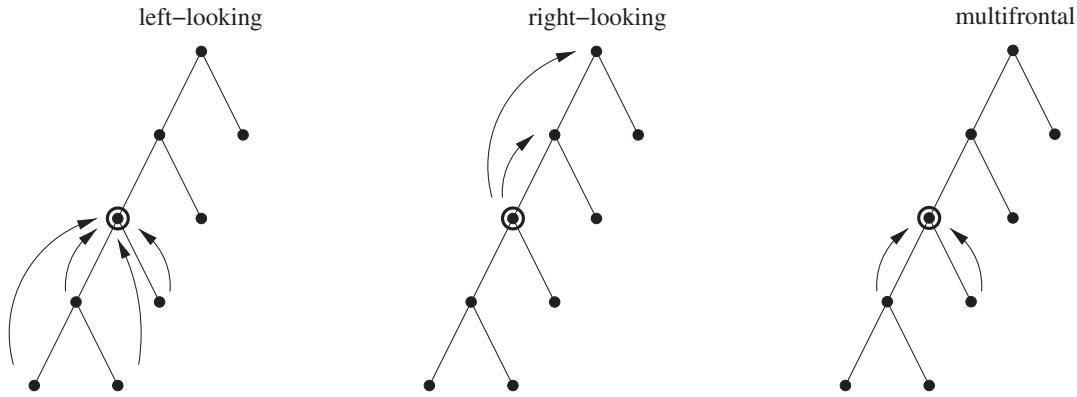

FIGURE 61.5 Patterns of data access in the left-looking, right-looking, and multifrontal algorithms. A subtree of the elimination tree is shown, and the circled node corresponds to the current submatrix being factored.

from rows that appear in more than one child. The main difficulty lies in accounting for duplicates, which is done using least-common-ancestor computations, as in the row-counts algorithm. This algorithm, too, benefits from handling only skeleton-graph edges.

Gilbert, Ng, and Peyton [24] also show in their paper how to optimize these algorithms, so that a single pass over the nonzero structure of A suffices to compute the row counts, the column counts, and the fundamental supernodes.

61.2.3 Three Classes of Factorization Algorithms

There are three classes of algorithms used to implement sparse direct solvers: left-looking, right-looking, and multifrontal; all of them use the elimination tree to guide the computation of the factors. The major difference between the first two of these algorithms is in how they schedule the computations they perform; the multifrontal algorithm organizes computations differently from the other two, and we explain this after introducing some concepts.

The computations on the sparse matrix are decomposed into subtasks involving computations among dense submatrices (supernodes), and the precedence relations among them are captured by the supernodal elimination tree. The computation at each node of the elimination tree (subtask) involves the partial factorization of the dense submatrix associated with it.

The right-looking algorithm is an eager updating scheme: Updates generated by the submatrix of the current subtask are applied immediately to future subtasks that it is linked to by edges in the filled graph of the sparse matrix. The left-looking algorithm is a lazy updating scheme: Updates generated by previous subtasks linked to the current subtask by edges in the filled adjacency graph of the sparse matrix are applied just prior to the factorization of the current submatrix. In both cases, updates always join a subtask to some ancestor subtask in the elimination tree. In the multifrontal scheme, updates always go from a child task to its parent in the elimination tree; an update that needs to be applied to some ancestor subtask is passed incrementally through a succession of vertices on the elimination tree path from the subtask to the ancestor.

Thus the major difference among these three algorithms is how the data accesses and the computations are organized and scheduled, while satisfying the precedence relations captured by the elimination tree. An illustration of these is shown in [Figure 61.5](#).

61.2.4 Scheduling Parallel Factorizations

In a parallel factorization algorithm, dependences between nonzeros in L determine the set of admissible schedules. A diagonal nonzero can only be factored after all updates to it from previous columns have been applied, a subdiagonal nonzero can be scaled only after updates to it have been applied (and after the diagonal element has been factored), and two subdiagonal nonzeros can update elements in the reduced system only after they have been scaled.

The elimination tree represents very compactly and conveniently a superset of these dependences. More specifically, the etree represents dependences between columns of L . A column can be completely factored only after all its descendants have been factored, and two columns that are not in an ancestor-descendant relationship can be factored in any order. Note that this is a superset of the element dependences, since a partially factored column can already perform some of the updates to its ancestors.

But most sparse elimination algorithms treat column operations (or row operations) as atomic operations that are always performed by a single processor sequentially and with no interruption. For such algorithms, the etree represents exactly the relevant dependences.

In essence, parallel column-oriented factorizations can factor the columns associated with different children of an etree vertex simultaneously, but columns in an ancestor-descendant relationship must be processed in postorder. Different algorithms differ mainly in how updates are represented and scheduled.

By computing the number of nonzeros in each column, a parallel factorization algorithm can determine the amount of computation and storage associated with each subtree in the elimination tree. This information can be used to assign tasks to processors in a load-balanced way.

Duff was the first to observe that the column dependences represented by the elimination tree can guide a parallel factorization [25]. In that paper Duff proposed a parallel multifrontal factorization. The paper also proposed a way to deal with indefinite and asymmetric systems, similar to Duff and Reid's sequential multifrontal approach [18]. For further references up to about 1997, see Heath's survey [26]. Several implementations described in papers published after 1997 include PaStiX [27], PARADISO [28], WSSMP [29], and MUMPS [30], which also includes indefinite and unsymmetric factorizations. All four are message-passing codes.

61.2.5 Scheduling Out-of-Core Factorizations

In an out-of-core factorization at least some of the data structures are stored on external-memory devices (today almost exclusively magnetic disks). This allows such factorization algorithms to factor matrices that are too large to factor in main memory. The factor, which is usually the largest data structure in the factorization, is the most obvious candidate for storing on disks, but other data structures, for example, the stack of update matrices in a multifrontal factorization, may also be stored on disks.

Planning and optimizing out-of-core factorization schedules require information about data dependences in the factorization and about the number of nonzeros in each column of the factor. The etree describes the required dependence information, and as explained above, it is also used to compute nonzero counts.

Following Rothberg and Schreiber [31], we classify out-of-core algorithms into *robust* algorithms and *non-robust algorithms*. Robust algorithms adapt the factorization to complete with the core memory available by performing the data movement and computations at a smaller granularity when necessary. They partition the submatrices corresponding to the supernodes and stacks used in the factorization into smaller units called panels to ensure that the factorization completes with the available memory. Non-robust algorithms assume that the stack or a submatrix corresponding to a supernode fits within the core memory provided. In general, non-robust algorithms read elements of the input matrix only once, read from disk nothing else, and they only write the factor elements to disk; Dobrian and Pothen refer to such algorithms as read-once-write-once, and to robust ones as read-many-write-many [32].

Liu proposed [33] a non-robust method that works as long as for all $j = 1, \dots, n$, all the nonzeros in the submatrix $L_{j:n,1:j}$ of the factor fit simultaneously in main memory. Liu also shows in that paper how to reduce the amount of main memory required to factor a given matrix using this technique by reordering the children of vertices in the etree.

Rothberg and Schreiber [31,34] proposed a number of robust out-of-core factorization algorithms. They proposed multifrontal, left-looking, and hybrid multifrontal/left-looking methods. Rotkin and Toledo [35] proposed two additional robust methods, a more efficient left-looking method, and a hybrid right/left-looking method. All of these methods use the etree together with column-nonzero counts to organize the out-of-core factorization process.

Dobrian and Pothen [32] analyzed the amount of main memory required for read-once-write-once factorizations of matrices with several regular etree structures, and the amount of I/O that read-many-write-many factorizations perform on these matrices. They also provided simulations on problems with irregular elimination tree structures. These studies led them to conclude that an external memory sparse solver library needs to provide at least two of the factorization methods, since each method can outperform the others on problems with different characteristics. They have provided implementations of out-of-core algorithms for all three of the multifrontal, left-looking, and right-looking factorization methods; these algorithms are included in the direct solver library OBLIO [36].

In addition to out-of-core techniques, there exist techniques that reduce the amount of main memory required to factor a matrix without using disks. Liu [37] showed how to minimize the size of the stack of update matrices in the multifrontal method by reordering the children of vertices in the etree; this method is closely related to [33]. Another approach, first proposed by Eisenstat, Schultz and Sherman [38] uses a block factorization of the coefficient matrix, but drops some of the off-diagonal blocks. Dropping these blocks reduces the amount of main memory required for storing the partial factor, but requires recomputation of these blocks when linear systems are solved using the partial factor. George and Liu [16, Chapter 6] proposed a general algorithm to partition matrices into blocks for this technique. Their algorithm uses *quotient graphs*, data structures that we describe later in this chapter.

61.3 The Clique Tree

61.3.1 Chordal Graphs and Clique Trees

The filled graph $G^+(A)$ that results from the elimination game on the matrix A (the adjacency graph of the Cholesky factor L) is a *chordal* graph, that is, a graph in which every cycle on four or more vertices has an edge joining two non-consecutive vertices on the cycle [39]. (The latter edge is called a chord, whence the name chordal graph. This class of graphs has also been called triangulated or rigid circuit graphs.)

A vertex v in a graph G is *simplicial* if its neighbors $\text{adj}(v)$ form a clique. Every chordal graph is either a clique, or it has two non-adjacent simplicial vertices. (The simplicial vertices in the filled graph in Figure 61.1 are 1, 2, 3, 4, 7, 8, and 9.) We can eliminate a simplicial vertex v without causing any fill by the rules of the elimination game, since $\text{adj}(v)$ is already a clique, and no fill edge needs to be added. A chordal graph from which a simplicial vertex is eliminated continues to be a chordal graph. A *perfect elimination ordering* of a chordal graph is an ordering in which simplicial vertices are eliminated successively without causing any fill during the elimination game. A graph is chordal if and only if it has a perfect elimination ordering.

Suppose that the vertices of the adjacency graph $G(A)$ of a sparse, symmetric matrix A have been re-numbered in an elimination ordering, and that $G^+(A)$ corresponds to the filled graph obtained by the elimination game on $G(A)$ with that ordering. This elimination ordering is a perfect elimination ordering of the filled graph $G^+(A)$. Many other perfect elimination orderings are possible for $G^+(A)$, since there are at least two simplicial vertices that can be chosen for elimination at each step, until the graph has one uneliminated vertex.

It is possible to design efficient algorithms on chordal graphs whose time complexity is much less than $O(|E \cup F|)$, where $E \cup F$ denotes the set of edges in the chordal filled graph. This is accomplished by representing chordal graphs by tree data structures defined on the maximal cliques of the graph. (Recall that a clique K is maximal if $K \cup \{v\}$ is not a clique for any vertex $v \notin K$.)

Theorem 61.7

Every maximal clique of a chordal filled graph $G^+(A)$ is of the form $K(v) = \{v\} \cup \text{hadj}^+(v)$, with the vertices ordered in a perfect elimination ordering.

The vertex v is the lowest-numbered vertex in the maximal clique $K(v)$, and is called the *representative vertex* of the clique. Since there can be at most $n \equiv |V|$ representative vertices, a chordal graph can have at most n maximal cliques. The maximal cliques of the filled graph in Figure 61.1 are: $K_1 = \{1, 2, 5, 10\}$; $K_2 = \{3, 4, 5, 6\}$; $K_3 = \{5, 6, 10, 11\}$; and $K_4 = \{7, 8, 9, 10, 11\}$. The lowest-numbered vertex in each maximal clique is its representative; note that in our notation $K_2 = K(3)$, $K_1 = K(1)$, $K_3 = K(5)$, and $K_4 = K(7)$.

Let $\mathcal{K}_G = \{K_1, K_2, \dots, K_m\}$ denote the set of maximal cliques of a chordal graph G . Define a clique intersection graph with the maximal cliques as its vertices, with two maximal cliques K_i and K_j joined by an edge (K_i, K_j) of weight $|K_i \cap K_j|$. A *clique tree* corresponds to a maximum weight spanning tree (MST) of the clique intersection graph. Since the MST of a weighted graph need not be unique, a clique tree of a chordal graph is not necessarily unique either.

In practice, a rooted clique tree is used in sparse matrix computations. Lewis, Peyton, and Pothen [40] and Pothen and Sun [41] have designed algorithms for computing rooted clique trees. The former algorithm uses the adjacency lists of the filled graph as input, while the latter uses the elimination tree. Both algorithms identify representative vertices by a simple degree test. We will discuss the latter algorithm.

First, to define the concepts needed for the algorithm, consider that the maximal cliques are ordered according to their representative vertices. This ordering partitions each maximal clique $K(v)$ with representative vertex v into two subsets: $\text{new}(K(v))$ consists of vertices in the clique $K(v)$ whose higher adjacency sets are contained in it but not in any earlier ordered maximal clique. The residual vertices in $K(v) \setminus \text{new}(K(v))$ form the ancestor set $\text{anc}(K(v))$. If a vertex $w \in \text{anc}(K(v))$, by definition of the ancestor set, w has a higher neighbor that is not adjacent to v ; then by the rules of the elimination game, any higher-numbered vertex $x \in K(v)$ also belongs to $\text{anc}(K(v))$. Thus the partition of a maximal clique into new and ancestor sets is an ordered partition: vertices in $\text{new}(K(v))$ are ordered before vertices in $\text{anc}(K(v))$. We denote the lowest numbered vertex f in $\text{anc}(K(v))$ the first ancestor of the clique $K(v)$. A rooted clique tree may be defined as follows: the parent of a clique $K(v)$ is the clique P in which the first ancestor vertex f of K appears as a vertex in $\text{new}(P)$.

The reason for calling these subsets “new” and “ancestor” sets can be explained with respect to a rooted clique tree. We can build the chordal graph beginning with the root clique of the clique tree, successively adding one maximal clique at a time, proceeding down the clique tree in in-order. When a maximal clique $K(v)$ is added, vertices in $\text{anc}(K(v))$ also belong to some ancestor clique(s) of $K(v)$, while vertices in $\text{new}(K(v))$ appear for the first time. A rooted clique tree, with vertices in $\text{new}(K)$ and $\text{anc}(K)$ identified for each clique K , is shown in Figure 61.6.

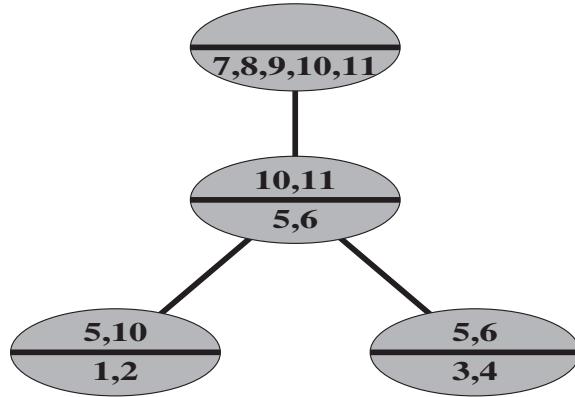

FIGURE 61.6 A clique tree of the example filled graph, computed from its elimination tree. Within each clique K in the clique tree, the vertices in $\text{new}(K)$ are listed below the bar, and the vertices in $\text{anc}(K)$ are listed above the bar.

FIGURE 61.7 An algorithm for computing a clique tree from an elimination tree, whose vertices are numbered in postorder. The variable $\text{hd}^+(v)$ is the higher degree of a vertex v in the filled graph.

This clique tree algorithm can be implemented in $O(n)$ time, once the elimination tree and the higher degrees have been computed. The rooted clique tree shown in Figure 61.6, is computed from the example elimination tree and higher degrees of the vertices in the example filled graph, using the clique tree algorithm described in Figure 61.7. The clique tree obtained from this algorithm is not unique. A second clique tree that could be obtained has the clique $K(5)$ as the root clique, and the other cliques as leaves.

A comprehensive review of clique trees and chordal graphs in sparse matrix computations, current as of 1991, is provided by Blair and Peyton [42].

61.3.2 Design of Efficient Algorithms with Clique Trees

Shortest Elimination Trees. Jess and Kees [43] introduced the problem of modifying a fill-reducing elimination ordering to enhance concurrency in a parallel factorization algorithm. Their approach was to generate a chordal filled graph from the elimination ordering, and then to eliminate a maximum independent set of simplicial vertices at each step, until all the vertices are eliminated. (This is a greedy algorithm in which the largest number of pairwise independent columns that do not cause fill are eliminated in one step.) Liu and Mirzaian [44] showed that this approach computed a shortest elimination tree over all perfect elimination orderings for a chordal graph, and provided an implementation linear in the number of edges of the filled graph. Lewis, Peyton, and Pothen [44] used the clique tree to provide a faster algorithm; their algorithm runs in time proportional to the size of the clique tree: the sum of the sizes of the maximal cliques of the chordal graph.

A vertex is simplicial if and only if it belongs to exactly one maximal clique in the chordal graph; a maximum independent set of simplicial vertices is obtained by choosing one such vertex from each maximal clique that contains simplicial vertices, and

thus the clique tree is a natural data structure for this problem. The challenging aspect of the algorithm is to update the rooted clique tree when simplicial vertices are eliminated and cliques that become non-maximal are *absorbed* by other maximal cliques.

Parallel Triangular Solution. In solving systems of linear equations by factorization methods, usually the work involved in the factorization step dominates the work involved in the triangular solution step (although the communication costs and synchronization overheads of both steps are comparable). However, in some situations, many linear systems with the same coefficient matrix but with different right-hand-side vectors need to be solved. In such situations, it is tempting to replace the triangular solution step involving the factor matrix L by explicitly computing an inverse L^{-1} of the factor. Unfortunately L^{-1} can be much less sparse than the factor, and so a more space efficient “product-form inverse” needs to be employed. In this latter form, the inverse is represented as a product of triangular matrices such that all the matrices in the product together require exactly as much space as the original factor.

The computation of the product form inverse leads to some interesting chordal graph partitioning problems that can be solved efficiently by using a clique tree data structure.

We begin by directing each edge in the chordal filled graph $G^+(A)$ from its lower to its higher numbered end point to obtain a directed acyclic graph (DAG). We will denote this DAG by $G(L)$. Given an edge (i, j) directed from i to j , we will call i the predecessor of j , and j the successor of i . The elimination ordering must eliminate vertices in a topological ordering of the DAG such that all predecessors of a vertex must be eliminated before it can be eliminated. The requirement that each matrix in the product form of the inverse must have the same nonzero structure as the corresponding columns in the factor is expressed by the fact that the subgraph corresponding to the matrix should be transitively closed. (A directed graph is *transitively closed* if whenever there is a directed path from a vertex i to a vertex j , there is an edge directed from i to j in the graph.) Given a set of vertices P_i , the *column subgraph* of P_i includes all the vertices in P_i and vertices reached by directed edges leaving vertices in P_i ; the edges in this subgraph include all edges with one or both endpoints in P_i .

The simpler of the graph partitioning problems is the following:

Find an ordered partition $P_1 \prec P_2 \prec \dots \prec P_m$ of the vertices of a directed acyclic filled graph $G(L)$ such that

1. Every $v \in P_i$ has all of its predecessors included in P_1, \dots, P_i ;
2. The column subgraph of P_i is transitively closed; and
3. The number of subgraphs m is minimum over all topological orderings of $G(L)$.

Pothen and Alvarado [45] designed a greedy algorithm that runs in $O(n)$ time to solve this partitioning problem by using the elimination tree.

A more challenging variant of the problem minimizes the number of transitively closed subgraphs in $G(L)$ over all perfect elimination orderings of the undirected chordal filled graph $G^+(A)$. This variant could change the edges in the DAG $G(L)$, (but not the edges in $G^+(A)$) since the initial ordering of the vertices is changed by the perfect elimination ordering, and after the reordering, edges are directed from the lower numbered end point to its higher numbered end point.

This is quite a difficult problem, but two surprisingly simple greedy algorithms solve it. Peyton, Pothen, and Yuan provide two different algorithms for this problem; the first algorithm uses the elimination tree and runs in time linear in the number of edges in the filled graph [46]. The second makes use of the clique tree, and computes the partition in time linear in the size of the clique tree [47]. Proving the correctness of these algorithms requires a careful study of the properties of the minimal vertex separators (these are vertices in the intersections of the maximal cliques) in the chordal filled graph.

61.3.3 Compact Clique Trees

In analogy with skeleton graphs, we can define a space-efficient version of a clique tree representation of a chordal graph, called the compact clique tree. If K is the parent clique of a clique C in a clique tree, then it can be shown that $\text{anc}(C) \subset K$. Thus trading space for computation, we can delete the vertices in K that belong to the ancestor sets of its children, since we can recompute them when necessary by unioning the ancestor sets of the children. The partition into new and ancestor sets can be obtained by storing the lowest numbered ancestor vertex for each clique. A compact clique K^c corresponding to a clique K is:

$$K^c = K \setminus \cup_{C \in \text{child}(K)} \text{anc}(C).$$

Note that the compact clique depends on the specific clique tree from which it is computed.

A compact clique tree is obtained from a clique tree by replacing cliques by compact cliques for vertices. In the example clique tree, the compact cliques of the leaves are unchanged from the corresponding cliques; and the compact cliques of the interior cliques are $K^c(5) = \{11\}$, and $K^c(7) = \{7, 8, 9\}$.

The compact clique tree is potentially sparser (asymptotically $O(n)$ instead of $O(n^2)$ even) than the skeleton graph on pathological examples, but on “practical” examples, the size difference between them is small. Compact clique trees were introduced by Pothen and Sun [41].

61.4 Clique Covers and Quotient Graphs

Clique covers and quotient graphs are data structures that were developed for the efficient implementation of minimum-degree reordering heuristics for sparse matrices. In Gaussian elimination, an elimination step that uses a_{ij} as a pivot (the elimination of the j th unknown using the i th equation) modifies every coefficient a_{kl} for which $a_{kj} \neq 0$ and $a_{il} \neq 0$. Minimum-degree heuristics attempt to select pivots for which the number of modified coefficients is small.

61.4.1 Clique Covers

Recall the graph model of symmetric Gaussian elimination discussed in Section 61.1.1. The adjacency graph of the matrix to be factored is an undirected graph $G = (V, E)$, $V = \{1, 2, \dots, n\}$, $E = \{(i, j) : a_{ij} \neq 0\}$. The elimination of a row/column j corresponds to eliminating vertex j and adding edges to the remaining graph so that the neighbors of j become a clique. If we represent the edge set E using a clique cover, a set of cliques $\mathcal{K} = \{K : K \subseteq V\}$ such that $E = \bigcup_{K \in \mathcal{K}} \{(i, j) : i, j \in K\}$, the vertex elimination process becomes a process of merging cliques [39]: The elimination of vertex j corresponds to merging all the cliques that j belongs to into one clique and removing j from all the cliques. Clearly, all the old cliques that j used to belong to are now covered by the new clique, so they can be removed from the cover. The clique-cover can be initialized by representing every nonzero of A by a clique of size 2. This process corresponds exactly to symbolic elimination, which we have discussed in Section 61.2, and which costs $\Theta(|L|)$ work. The cliques correspond exactly to frontal matrices in the multifrontal factorization method.

In the sparse-matrix literature, this model of Gaussian elimination has been sometimes called the *generalized-element* model or the *super-element* model, due to its relationship to finite-element models and matrices.

The significance of clique covers is due to the fact that in minimum-degree ordering codes, there is no need to store the structure of the partially computed factor, so when one clique is merged into another, it can indeed be removed from the cover. This implies that the total size $\sum_{K \in \mathcal{K}} |K|$ of the representation of the clique cover, which starts at exactly $|A| - n$, shrinks in every elimination step, so it is always bounded by $|A| - n$. Since exactly one clique is formed in every elimination step, the total number of cliques is also bounded, by $n + (|A| - n) = |A|$. In contrast, the storage required to explicitly represent the symbolic factor, or even to just explicitly represent the edges in the reduced matrix, can grow in every elimination step and is not bounded by $O(|A|)$.

Some minimum-degree codes represent cliques fully explicitly [48,49]. This representation uses an array of cliques and an array of vertices; each clique is represented by a linked list of vertex indices, and each vertex is represented by a linked list of clique indices to which it belongs. The size of this data structure never grows—linked-list elements are moved from one list to another or are deleted during elimination steps, but new elements never need to be allocated once the data structure is initialized.

Most codes, however, use a different representation for clique covers, which we describe next.

61.4.2 Quotient Graphs

Most minimum-degree codes represent the graphs of reduced matrices during the elimination process using *quotient graphs* [50]. Given a graph $G = (V, E)$ and a partition \mathcal{S} of V into disjoint sets $S_j \in \mathcal{S}$, the quotient graph G/\mathcal{S} is the undirected graph $(\mathcal{S}, \mathcal{E})$ where $\mathcal{E} = \{(S_i, S_j) : \text{adj}(S_i) \cap S_j \neq \emptyset\}$.

The representation of a graph G after the elimination of vertices $1, 2, \dots, j-1$, but before the elimination of vertex j , uses a quotient graph G/\mathcal{S} , where \mathcal{S} consists of sets S_k of eliminated vertices that form maximal connected components in G , and sets $S_i = \{i\}$ of uneliminated vertices $i \geq j$. We denote a set S_k of eliminated vertices by the index k of the highest-numbered vertex in it.

This quotient graph representation of an elimination graph corresponds to a clique cover representation as follows. Each edge in the quotient graph between uneliminated vertices $S_{\{i_1\}}$ and $S_{\{i_2\}}$ corresponds to a clique of size 2; all the neighbors of an eliminated set S_k correspond to a clique, the clique that was created when vertex k was eliminated. Note that all the neighbors of an uneliminated set S_k are uneliminated vertices, since uneliminated sets are maximal with respect to connectivity in G .

The elimination of vertex j in the quotient-graph representation corresponds to marking S_j as eliminated and merging it with its eliminated neighbors, to maintain the maximal connectivity invariant.

Clearly, a representation of the initial graph G using adjacency lists is also a representation of the corresponding quotient graph. George and Liu [51] show how to maintain the quotient graph efficiently using this representation without allocating more storage through a series of elimination steps.

Most of the codes that implement minimum-degree ordering heuristics, such as GENMMD [52], AMD [53], and Spindie [54,55], use quotient graphs to represent elimination graphs.

It appears that the only advantage of a quotient graph over an explicit clique cover in the context of minimum-degree algorithms is a reduction by a small constant factor in the storage requirement, and possibly in the amount of work required. Quotient graphs, however, can also represent symmetric partitions of symmetric matrices in applications that are not directly related to elimination

graphs. For example, George and Liu use quotient graphs to represent partitions of symmetric matrices into block matrices that can be factored without fill in blocks that only contain zeros [16, Chapter 6].

In [56], George and Liu showed how to implement the minimum degree algorithm without modifying the representation of the input graph at all. In essence, this approach represents the quotient graph implicitly using the input graph and the indices of the eliminated vertices. The obvious drawback of this approach is that vertex elimination (as well as other required operations) are expensive.

61.4.3 The Problem of Degree Updates

The minimum-degree algorithm works by repeatedly eliminating the vertex with the minimum degree and turning its neighbors into a clique. If the reduced graph is represented by a clique cover or a quotient graph, then the representation does not reveal the degree of vertices. Therefore, when a vertex is eliminated from a graph represented by a clique cover or a quotient graph, the degrees of its neighbors must be recomputed. These degree updates can consume much of the running time of minimum-degree algorithms.

Practical minimum-degree codes use several techniques to address this issue. Some techniques reduce the running time while preserving the invariant that the vertex that is eliminated always has the minimum degree. For example, mass elimination, the elimination of all the vertices of a supernode consecutively without recomputing degrees, can reduce the running time significantly without violating this invariant. Other techniques, such as multiple elimination and the use of approximate degrees, do not preserve the minimum-degree invariant. This does not imply that the elimination orderings that such technique produce are inferior to true minimum-degree orderings. They are often superior to them. This is not a contradiction since the minimum-degree rule is just a heuristic which is rarely optimal. For further details, we refer the reader to George and Liu's survey [57], to Amestoy, Davis, and Duff's paper on approximate minimum-degree rules [53], and to Kumfert and Pothen's work on minimum-degree variants [54,55]. Hegernes, Eisenstat, Kumfert and Pothen prove upper bounds on the running time of space-efficient minimum-degree variants [58].

61.4.4 Covering the Column-Intersection Graph and Biclique Covers

Column orderings for minimizing fill in Gaussian elimination with partial pivoting and in the orthogonal-triangular (QR, where Q is an orthogonal matrix, and R is an upper triangular matrix) factorization are often based on symmetric fill minimization in the symmetric factor of $A^T A$, whose graph is known as the column intersection graph $G_{\cap}(A)$ (we ignore the possibility of numerical cancellation in $A^T A$). To run a minimum-degree algorithm on the column intersection graph, a clique cover or quotient graph of it must be constructed. One obvious solution is to explicitly compute the edge-set of $G_{\cap}(A)$, but this is inefficient, since $G_{\cap}(A)$ can be much denser than $G(A)$.

A better solution is to initialize the clique cover using a clique for every row of A ; the vertices of the clique are the indices of the nonzeros in that row [57]. It is easy to see that each row in A indeed corresponds to a clique in $G_{\cap}(A)$. This approach is used in the COLMMD routine in MATLAB [49] and in COLAMD [59].

A space-efficient quotient-graph representation for $G_{\cap}(A)$ can be constructed by creating an adjacency-list representation of the symmetric 2-by-2 block matrix

$$\begin{pmatrix} I & A \\ A^T & 0 \end{pmatrix}$$

and eliminating vertices 1 through n . The graph of the Schur complement matrix

$$G(0 - A^T I^{(-1)} A) = G(A^T A) = G_{\cap}(A).$$

If we maintain a quotient-graph representation of the reduced graph through the first n elimination steps, we obtain a space-efficient quotient graph representation of the column-intersection graph. This is likely to be more expensive, however, than constructing the clique-cover representation from the rows of A . We learned of this idea from John Gilbert; we are not aware of any practical code that uses it.

The nonzero structure of the Cholesky factor of $A^T A$ is only an upper bound on the structure of the LU factors in Gaussian elimination with partial pivoting. If the identities of the pivots are known, the nonzero structure of the reduced matrices can be represented using biclique covers. The nonzero structure of A is represented by a bipartite graph $(\{1, 2, \dots, n\} \cup \{1', 2', \dots, n'\}, \{(i, j') : a_{ij} \neq 0\})$. A biclique is a complete bipartite graph on a subset of the vertices. Each elimination step corresponds to a removal of two connected vertices from the bipartite graph, and an addition of a new biclique. The vertices of the new biclique are the neighbors of the two eliminated vertices, but they are not the union of a set of bicliques. Hence, the storage requirement of this representation may exceed the storage required for the initial representation. Still, the storage requirement is always smaller than the storage required to represent each edge of the reduced matrix explicitly. This representation poses the same degree update

problem that symmetric clique covers pose, and the same techniques can be used to address it. Version 4 of UMFPACK, an asymmetric multifrontal LU factorization code, uses this idea together with a degree approximation technique to select pivots corresponding to relatively sparse rows in the reduced matrix [60].

61.5 Column Elimination Trees and Elimination DAGS

Elimination structures for asymmetric Gaussian elimination are somewhat more complex than the equivalent structures for symmetric elimination. The additional complexity arises because of two issues. First, the factorization of a sparse asymmetric matrix A , where A is factored into a lower triangular factor L and an upper triangular factor U , $A = LU$, is less structured than the sparse symmetric factorization process. In particular, the relationship between the nonzero structure of A and the nonzero structure of the factors is much more complex. Consequently, data structures for predicting fill and representing data-flow and control-flow dependences in elimination algorithms are more complex and more diverse.

Second, factoring an asymmetric matrix often requires *pivoting*, row and/or column exchanges, to ensure existence of the factors and numerical stability. For example, the 2-by-2 matrix $A = [0 \ 1; 1 \ 0]$ does not have an LU factorization, because there is no way to eliminate the first variable from the first equation: that variable does not appear in the equation at all. But the permuted matrix PA does have a factorization, if P is a permutation matrix that exchanges the two rows of A . In finite precision arithmetic, row and/or column exchanges are necessary even when a nonzero but small diagonal element is encountered. Some sparse LU algorithms perform either row or column exchanges, but not both. The two cases are essentially equivalent (we can view one as a factorization of A^T), so we focus on row exchanges (partial pivoting). Other algorithms, primarily multifrontal algorithms, perform both row and column exchanges; these are discussed toward the end of this section.

For completeness, we note that pivoting is also required in the factorization of sparse symmetric indefinite matrices. Such matrices are usually factored into a product LDL^T , where L is lower triangular and D is a block diagonal matrix with 1-by-1 and 2-by-2 blocks. There has not been much research about specialized elimination structures for these factorization algorithms; such codes invariably use the symmetric elimination tree of A to represent dependences for structure prediction and for scheduling the factorization.

The complexity and diversity of asymmetric elimination arises not only due to pivoting, but also because asymmetric factorizations are less structured than symmetric ones, so a rooted tree can no longer represent the factors. Instead, directed acyclic graphs (dags) are used to represent the factors and dependences in the elimination process. We discuss *elimination dags* (*edags*) in Section 61.5.2.

Surprisingly, dealing with partial pivoting turns out to be simpler than dealing with the asymmetry, so we focus next on the *column elimination tree*, an elimination structure for LU factorization with partial pivoting.

61.5.1 The Column Elimination Tree

The *column elimination tree* (*col-etree*) is the elimination tree of A^TA , under the assumption that no numerical cancellation occurs in the formation of A^TA . The significance of this tree to LU with partial pivoting stems from a series of results that relate the structure of the LU factors of PA , where P is some permutation matrix, to the structure of the Cholesky factor of A^TA .

George and Ng observed that, for any permutation matrix P , the structure of the LU factors of PA is contained in the structure of the Cholesky factor of A^TA , as long as A does not have any zeros on its main diagonal [61]. (If there are zeros on the diagonal of a nonsingular A , the rows can always be permuted first to achieve a zero-free diagonal.) Figure 61.8 illustrates this phenomenon. Gilbert [62] strengthened this result by showing that for every nonzero R_{ij} in the Cholesky factor R of $A^TA = R^TR$, where A has a zero-free diagonal and no nontrivial block triangular form, there exists a matrix $A^{(U_{ij})}$ with the same nonzero structure as A , such that in the LU factorization of $A^{(U_{ij})} = P^T L^{(U_{ij})} U^{(U_{ij})}$ with partial pivoting, $U_{ij}^{(U_{ij})} \neq 0$. This kind of result is known as a *one-at-a-time* result, since it guarantees that every element of the predicted factor can fill for some choice of numerical values in A , but not that all the elements can fill simultaneously. Gilbert and Ng [63] later generalized this result to show that an equivalent one-at-a-time property is true for the lower-triangular factor.

These results suggest that the col-etree, which is the elimination tree of A^TA , can be used for scheduling and structure prediction in LU factorizations with partial pivoting. Because the characterization of the nonzero structure of the LU factors in terms of the structure of the Cholesky factor of A^TA relies on one-at-a-time results, the predicted structure and predicted dependences are necessarily only loose upper bounds, but they are nonetheless useful.

The col-etree is indeed useful in LU with partial pivoting. If $U_{ij} \neq 0$, then by the results cited above $R_{ij} \neq 0$ (recall that R is the Cholesky factor of the matrix A^TA). This, in turn, implies that j is an ancestor of i in the col-etree. Since column i of L updates column j of L and U only if $U_{ij} \neq 0$, the col-etree can be used as a task-dependence graph in column-oriented LU factorization codes with partial pivoting. This analysis is due to Gilbert, who used it to schedule a parallel factorization code [62]. The same

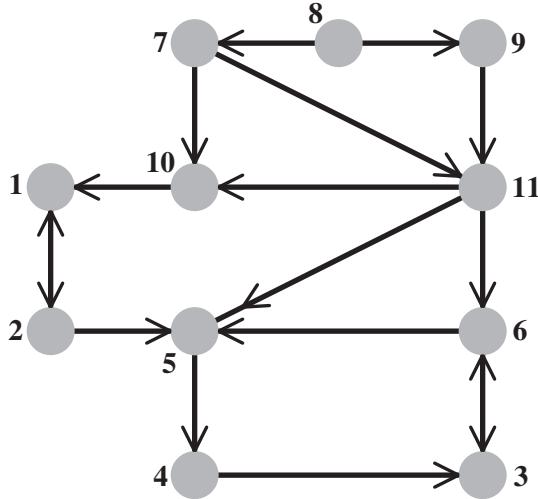

FIGURE 61.8 The directed graph $G(A)$ of an asymmetric matrix A . The column intersection graph of this graph $G_{\cap}(B)$ is exactly the graph shown in Figure 61.1, so the column elimination tree of A is the elimination tree shown in Figure 61.2. Note that the graph is sparser than the column intersection graph.

technique is used in several current factorization codes, including SuperLU [64], SuperLU_MT [65], UMFPACK 4 [60], and TAUCS [66,67]. Gilbert and Grigori [68] recently showed that this characterization is tight in a strong *all-at-once* sense: for every strong Hall matrix A (i.e., A has no nontrivial block-triangular form), there exists a permutation matrix P such that every edge of the col- etree corresponds to a nonzero in the upper-triangular factor of PA . This implies that the a-priori symbolic column-dependence structure predicted by the col- etree is as tight as possible.

Like the etree of a symmetric matrix, the col- etree can be computed in time almost linear in the number of nonzeros in A [69]. This is done by an adaptation of the symmetric etree algorithm, an adaptation that does not compute explicitly the structure of $A^T A$. Instead of constructing $G(A^T A)$, the algorithm constructs a much sparser graph G' with the same elimination tree. The main idea is that each row of A contributes a clique to $G(A^T A)$; this means that each nonzero index in the row must be an ancestor of the preceding nonzero index. A graph in which this row-clique is replaced by a path has the same elimination tree, and it has only as many edges as there are nonzeros in A . The same paper shows not only how to compute the col- etree in almost linear time, but also how to bound the number of nonzeros in each row and column of the factors L and U , using again an extension of the symmetric algorithm to compute the number of nonzeros in the Cholesky factor of $A^T A$. The decomposition of this Cholesky factor into fundamental supernodes, which the algorithm also computes, can be used to bound the extent of fundamental supernodes that will arise in L .

61.5.2 Elimination DAGs

The col- etree represents all possible column dependences for any sequence of pivot rows. For a specific sequence of pivots, the col- etree includes dependences that do not occur during the factorization with these pivots. There are two typical situations in which the pivoting sequence is known. The first is when the matrix is known to have a stable *LU* factorization without pivoting. The most common case is when A^T is strictly diagonally dominant. Even if A is not diagonally dominant, its rows can be pre-permuted to bring large elements to the diagonal. The permuted matrix, even if its transpose is not diagonally dominant, is fairly likely to have a relatively stable *LU* factorization that can be used to accurately solve linear systems of equations. This strategy is known as *static pivoting* [70]. The other situation in which the pivoting sequence is known is when the matrix, or part of it, has already been factored. Since virtually all sparse factorization algorithms need to collect information from the already-factored portion of the matrix before they factor the next row and column, a compact representation of the structure of this portion is useful.

Elimination dags (edags) are directed acyclic graphs that capture a minimal or near minimal set of dependences in the factors. Several edags have been proposed in the literature. There are two reasons for this diversity. First, edags are not always as sparse and easy to compute as elimination trees, so researchers have tried to find edags that are easy to compute, even if they represent a superset of the actual dependences. Second, edags often contain information only about a specific structure in the factors or a specific dependence in a specific elimination algorithm (e.g., data dependence in a multifrontal algorithm), so different edags are used for different applications. In other words, edags are not as universal as etrees in their applications.

The simplest edag is the graph $G(L^T)$ of the transpose of the lower triangular factor, if we view every edge in this graph as directed from the lower-numbered vertex to a higher-numbered vertex. This corresponds to orienting edges from a row index to a column index in L . For example, if $L_{6,3} \neq 0$, we view the edge $(6, 3)$ as a directed edge $3 \rightarrow 6$ in $G(L^T)$. Let us denote by $G((L^{(j-1)})^T)$ the partial lower triangular factor after $j - 1$ columns have been factored. Gilbert and Peierls showed that the nonzeros in the j th rows of L and U are exactly the vertices reachable, in $G((L^{(j-1)})^T)$, from the nonzero indices in the j th column of A [71]. This observation allowed them to use a depth-first search (DFS) to quickly find the columns in the already-factored part of the matrix that update the j th column before it can be factored. This resulted in the first algorithm that factored a general sparse matrix in time linear in the number of arithmetic operations (earlier algorithms sometimes performed much more work to manipulate the sparse data structure than the amount of work in the actual numerical computations).

Eisenstat and Liu showed that a simple modification of the graph $G((L^{(j-1)})^T)$ can often eliminate many of its edges without reducing its ability to predict fill [72]. They showed that if both L_{ik} and U_{ki} are nonzeros, then all the edges $i \rightarrow \ell$ for $\ell > i$ can be safely pruned from the graph. In other words, the nonzeros in column k of L below row i can be pruned. This is true since if $U_{ki} \neq 0$, then column k of L updates column i , so all the pruned nonzeros appear in column i , and since the edge $k \rightarrow i$ is in the graph, they are all reachable when k is reachable. This technique is called *symmetric pruning*. This edag is used in the SuperLU codes [64,65] to find the columns that update the next supernode (set of consecutive columns with the same nonzero structure in L). Note that the same codes use the col-tree to predict structure before the factorization begins, and an edag to compactly represent the structure of the already-factored block of A .

Gilbert and Liu went a step further and studied the *minimal* edags that preserve the reachability property that is required to predict fill [73]. These graphs, which they called the *elimination dags* are the transitive reductions of the directed graphs $G(L^T)$ and $G(U)$. (The graph of U can be used to predict the row structures in the factors, just as $G(L^T)$ can predict the column structures.) Since these graphs are acyclic, each graph has a unique transitive reduction; If A is symmetric, the transitive reduction is the symmetric elimination tree. For the graph $G(A)$ shown in Figure 61.8, the graph of the upper triangular factor $G(U)$ is depicted in Figure 61.9, and its minimal edag is shown in Figure 61.10. Gilbert and Liu also proposed an algorithm to compute these transitive reductions row by row. Their algorithm computes the next row i of the transitive reduction of L by traversing the reduction of U to compute the structure of row i of L , and then reducing it. Then the algorithm computes the structure of row i of U by combining the structures of earlier rows whose indices are the nonzeros in row i of L . In general, these minimal edags are often more expensive to compute than the symmetrically-pruned edags, due to the cost of transitively reducing each row. Gupta recently proposed a different algorithm for computing the minimal edags [74]. His algorithm computes the minimal structure of U by rows and of L by columns. His algorithm essentially applies to both L and U the rule that Gilbert and Liu apply to U . By computing the structure of U by rows and of L by columns, Gupta's algorithm can cheaply detect supernodes that are suitable for

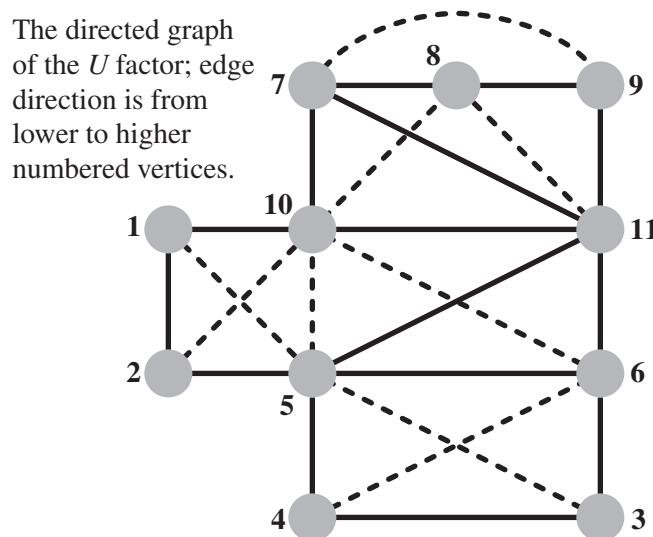

FIGURE 61.9 The directed graph of the U factor of the matrix whose graph is shown in Figure 61.8. In this particular case, the graph of L^T is exactly the same graph, only with the direction of the edges reversed. Fill is indicated by dashed lines. Note that the fill is indeed bounded by the fill in the column-intersection graph, which is shown in Figure 61.1. However, that upper bound is not realized in this case: the edge $(9, 10)$ fills in the column-intersection graph, but not in the LU factors.

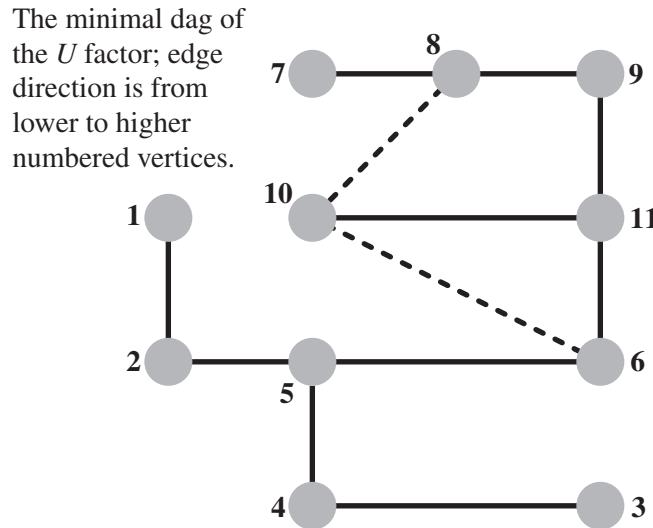

FIGURE 61.10 The minimal edag of U ; this graph is the transitive reduction of the graph shown in Figure 61.9.

asymmetric multifrontal algorithms, where a supernode consists of a set of consecutive indices for which both the rows of U all have the same structure and the columns of L have the same structure (but the rows and columns may have different structures).

61.5.3 Elimination Structures for the Asymmetric Multifrontal Algorithm

Asymmetric multifrontal LU factorization algorithms usually use both row and column exchanges. UMFPACK, the first such algorithm, due to Davis and Duff [75], used a pivoting strategy that factored an arbitrary row and column permutation of A . The algorithm tried to balance numerical and degree considerations in selecting the next row and column to be factored, but in principle, all row and column permutations were possible. Under such conditions, not much structure prediction is possible. The algorithm still used a clever elimination structure that we described earlier, a biclique cover, to represent the structure of the Schur complement (the remaining uneliminated equations and variables), but it did not use etrees or edags.

Recent unsymmetric multifrontal algorithms still use pivoting strategies that allow both row and column exchanges, but the pivoting strategies are restricted enough that structure prediction is possible. These pivoting strategies are based on *delayed pivoting*, which was originally invented for symmetric indefinite factorizations. One such code, Davis's UMFPACK 4, uses the column elimination tree to represent control-flow dependences, and a biclique cover to represent data dependences [60]. Another code, Gupta's WSMP, uses conventional minimal edags to represent control-flow dependences, and specialized dags to represent data dependences [74]. More specifically, Gupta shows how to modify the minimal edags so they exactly represent data dependences in the unsymmetric multifrontal algorithm with no pivoting, and how to modify the edags to represent dependences in an unsymmetric multifrontal algorithm that employs delayed pivoting.

62.1 Overview of the Functionality of a Database Management System

Many of the previous chapters have shown that efficient strategies for complex data-structuring problems are essential in the design of fast algorithms for a variety of applications, including combinatorial optimization, information retrieval and Web search, databases and data mining, and geometric applications. The goal of this chapter is to provide the reader with an overview of the important data structures that are used in the implementation of a modern, general-purpose database management system (DBMS). In earlier chapters of the book the reader has already been exposed to many of the data structures employed in a DBMS context (e.g., B-trees, buffer trees, quad trees, R-trees, interval trees, hashing). Hence, we will focus mainly on their application but also introduce other important data structures to solve some of the fundamental data management problems such as *query processing and optimization*, *efficient representation of data on disk*, as well as the *transfer of data from main memory to disk*. Due to space constraints, we cannot cover applications of data structures to manage non-standard data such as multi-dimensional data, spatial and temporal data, multimedia data, or XML.

Before we begin our treatment of how data structures are used in a DBMS, we briefly review the basic architecture, its components, and their functionality. Unless otherwise noted, our discussion applies to a class of DBMSs that are based on the relational data model. These so-called relational database management systems make up the majority of systems in use today and are offered by all major vendors including IBM, Microsoft, Oracle, and Sybase. Most of the components described here can also be found in DBMSs based on other models such as the object-based model or XML.

Figure 62.1 depicts a conceptual overview of the main components that make up a DBMS. Rectangles represent system components, double-sided arrows represent input and output, and the solid connectors indicate data as well as process flow between two components. Please note that the inner workings of a DBMS are quite complex and we are not attempting to provide a detailed discussion of its implementation. For an in-depth treatment the reader should refer to one of the many excellent database textbooks books, for example [1–6].

Starting from the top, users interact with the DBMS via commands generated from a variety of user interfaces or application programs. These commands can either retrieve or update the data that is managed by the DBMS or create or update the underlying metadata that describes the schema of the data. The former are called queries, the latter are called data definition statements. Both types of commands are processed by the *Query Evaluation Engine* which contains components for parsing the input, producing an execution plan, and executing the plan against the underlying database. In the case of queries, the parsed command is presented to a query optimizer component, which uses information about how the data is stored to produce an efficient execution plan from the possibly many alternatives. We discuss data structures that represent parsed queries, execution plans, and statistics about a database, including the data structures that are used by an external sorting algorithm in Section 62.2 when we focus on the query evaluation engine.

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

† We have used this author's affiliation from the first edition of this handbook, but note that this may have changed since then.

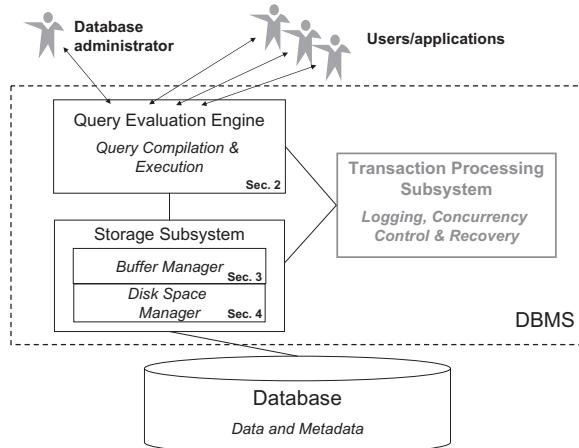

FIGURE 62.1 A simplified architecture of a database management system (DBMS).

Since databases are normally too large to fit into the main memory of a computer, the data of a database resides in secondary memory, generally on one or more magnetic disks. However, to execute queries or modifications on data, that data must first be transferred to main memory for processing and then back to disk for persistent storage. It is the job of the *Storage Subsystem* to accomplish a sophisticated placement of data on disk, to assure an efficient localization of these persistent data, to enable their bidirectional transfer between disk and main memory, and to allow direct access to these data from other DBMS subsystems. The storage subsystem consists of two components: The *Disk Space Manager* is responsible for storing physical data items on disk, managing free regions of the disk space, hiding device properties from higher architecture levels, mapping physical blocks to tracks and sectors of a disc, and controlling the transfer of data items between external and main memory. The *Buffer Manager* organizes an assigned, limited main memory area called *buffer* and may comprise several smaller buffers (buffer pool). Other subsystems may have direct access to data items in these buffers.

In Sections 62.3 and 62.4, we discuss data structures that are used to represent both data in memory as well as on disk such as fixed and variable-length records, large binary objects (LOBs), heap, sorted, and clustered files, as well as different types of index structures. Given the fact that a database management system must manage data that is both resident in main memory as well as on disk, one has to deal with the reality that the most appropriate data structure for data stored on disk is different from the data structures used for algorithms that run in main memory. Thus when implementing the storage manager, one has to pay careful attention to select not only the appropriate data structures but also to map the data between them in an efficient manner.

In addition to the above two subsystems, today's modern DBMSs include a *Transaction Management Subsystem* to support concurrent execution of queries against the database and recovery from failure. Although transaction processing is an important and complex topic, it is less interesting for our investigation of data structures and is mentioned here only for completeness.

The rest of this chapter is organized as follows. Section 62.2 describes important data structures used during query evaluation. Data structures used for buffer management are described in Section 62.3, and data structures used by the disk space manager are described in Section 62.4. Section 62.5 concludes the chapter.

62.2 Data Structures for Query Processing

Query evaluation is performed in main memory in several steps as outlined in Figure 62.2. Starting with the high-level input query expressed in a declarative language called SQL (see, e.g., [7]) the *Parser* scans, parses, and validates the query. The goal is to check whether the query is formulated according to the syntax rules of the language supported in the DBMS. The parser also validates that all attribute and relation names are part of the database schema that is being queried.

The parser produces a *parse tree* which serves as input to the *Query Translation and Rewrite* module shown underneath the parser. Here the query is translated into an internal representation, which is based on the relational algebra notation [8]. Besides its compact form, a major advantage of using relational algebra is that there exist transformations (re-write rules) between equivalent expressions to explore alternate, more efficient forms of the same query. Different algebraic expressions for a query are called *logical query plans* and are represented as *expression trees* or *operator trees*. Using the re-write rules, the initial logical query plan is transformed into an equivalent plan that is expected to execute faster. Query re-writing is guided by heuristics which help reduce the amount of intermediary work that must be performed by the query in order to arrive at the same result.

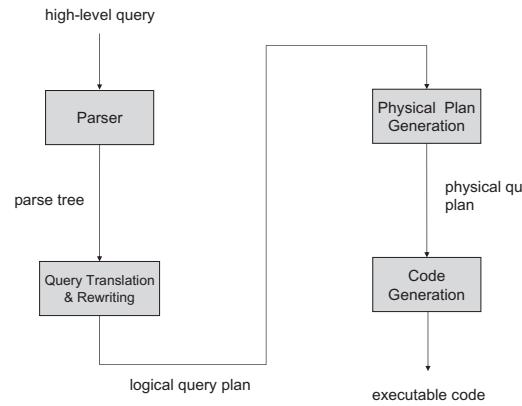

FIGURE 62.2 Outline of query evaluation.

A particularly challenging problem is the selection of the best join ordering for queries involving the join of three or more relations. The reason is that the *order* in which the input relations are presented to a join operator (or any other binary operator for that matter) tends to have an important impact on the cost of the operation. Unfortunately, the number of candidate plans grows rapidly when the number of input relations grows.

The outcome of the query translation and rewrite module is a set of “improved” logical query plans representing different execution orders or combinations of operators of the original query. The *Physical Plan Generator* converts the logical query plans into *physical query plans* which contain information about the algorithms to be used in computing the relational operators represented in the plan. In addition, physical query plans also contain information about the access methods available for each relation. Access methods are ways of retrieving tuples from a table and consist of either a file scan (i.e., a complete retrieval of all tuples) or an index plus a matching selection condition. Given the many different options for implementing relational operators and for accessing the data, each logical plan may lead to a large number of possible physical plans. Among the many possible plans, the physical plan generator evaluates the cost for each and chooses the one with the lowest overall cost.

Finally, the best physical plan is submitted to the *Code Generator* which produces the executable code that is either executed directly or is stored and executed later whenever needed. Query re-writing and physical plan generation are referred to as *query optimization*. However, the term is misleading since in most cases the chosen plan represents a reasonably efficient strategy for executing a query.

In the following paragraphs, we focus on several important data structures that are used during query evaluation, some of which have been mentioned above: The *parse tree* for storing the parsed and validated input query (Section 62.2.3), the *expression tree* for representing logical and physical query plans (Section 62.2.4), and the histogram which is used to approximate the distribution of attribute values in the input relations (Section 62.2.5). We start with a summary of the well-known *index structures* and how they are used to speed up database operations. Since sorting plays an important role in query processing, we include a separate description of the data structures used to sort large data sets using external memory (Section 62.2.2).

62.2.1 Index Structures

An important part of the work of the physical plan generator is to choose an efficient implementation for each of the operators in the query. For each relational operator (e.g., selection, projection, join) there are several alternative algorithms available for implementation. The best choice usually depends on factors such as size of the relation, available memory in the buffer pool, sort order of the input data, and availability of index structures. In the following, we briefly highlight some of the important index structures that are used by a modern DBMS.

62.2.1.1 One-dimensional Indexes

One-dimensional indexes contain a single search key, which may be composed of multiple attributes. The most frequently used data structures for one-dimensional database indexes are dynamic tree-structured indexes such as *B/B⁺-Trees* (from now on collectively referred to as B-Trees, see also Chapter 16) and *hash-based indexes* using extendible and linear hashing (see Chapter 9). In general, hash-based indexes are especially good for equality searches. For example, in the case of an equality selection operation, one can use a one-dimensional hash-based index structure to examine just the tuples that satisfy the given condition. Consider the selection of student records having a certain grade point average (GPA). Assuming students are randomly distributed throughout the relation, an index on the GPA value could lead us to only those records satisfying the selection condition and resulting in a

lot fewer data transfers than a sequential scan of the relation (if we assume the tuples satisfying the condition make up only a fraction of the entire relation).

Given their superior performance for equality searches hash-based indexes prove to be particularly useful in implementing relational operations such as joins. For example, the index-nested-loop join algorithm generates many equality selection queries, making the difference in cost between a hash-based and the slightly more expensive tree-based implementation significant.

B-Trees provide efficient support for range searches (all data items that fall within a range of values) and are almost as good as hash-based indexes for equality searches. Besides their excellent performance, B-Trees are “self-tuning,” meaning they maintain as many levels of the index as is appropriate for the size of the relation being indexed. Unlike hash-based indexes, B-Trees manage the space on the disk blocks they use and do not require any overflow blocks. As we have mentioned in Section 62.1, database index structures are an example of data structures that have been designed as secondary memory structures.

62.2.1.2 Multi-dimensional Indexes

In addition to these one-dimensional index structures, many applications (e.g., geographic database, inventory and sales database for decision-support) also require data structures capable of indexing data existing in two or higher-dimensional spaces. In these domains, important database operations are selections involving partial matches (all points that match specified values in one or more dimensions), range queries (all points that fall within a range of values in one or more dimensions), nearest-neighbor queries (closest point to a given point), and so-called “where-am-I” queries (all the regions in which a given point is located).

The following are some of the most important data structures that support these types of operations.

Grid file. A multi-dimensional extension of one-dimensional hash tables. Grid files support range queries, partial-match queries, and nearest-neighbor queries well, as long as data is uniformly distributed.

Multiple-key index. The index on one attribute leads to indexes on another attribute for each value of the first. Multiple-key indexes are useful for range and nearest-neighbor queries.

R-tree. A B-Tree generalization suitable for collections of regions. R-Trees are used to represent a collection of regions by grouping them into a hierarchy of larger regions. They are well suited to support “where-am-I” queries as well as the other types of queries mentioned above if the atomic regions are individual points. (See also [Chapter 22](#).)

Quad tree. Recursively divide a multi-dimensional data set into quadrants until each quadrant contains a minimal number of points (e.g., amount of data that can fit on a disk block). Quad trees support partial-match, range, and nearest-neighbor queries well. (See also [Chapter 20](#))

Bitmap index. A collection of bit vectors which encode the location of records with a given value in a given field. Bitmap indexes support range, nearest-neighbor, and partial-match queries and are often employed in data warehouses and decision-support systems. Since bitmap indexes tend to get large when the underlying attributes have many values, they are often compressed using a run-length encoding.

Given the importance of database support for non-standard applications, many relational database management systems support one or more of these multi-dimensional indexes, either directly (e.g., bitmap indexes), or as part of a special-purpose extension to the core database engine (e.g., R-trees in a spatial extender).

In general, indexes are also used to answer certain types of queries without having to access the data file. For example, if we need only a few attribute values from each tuple and there is an index whose search key contains all these fields, we can choose an index scan instead of examining all data tuples. This is faster since index records are smaller (and hence fit into fewer buffer pages). Note that an index scan does not make use of the search structure of the index: for example, in a B-Tree index one would examine all leaf pages in sequence. All commercial relational database management systems support B-Trees and at least one type of hash-based index structure.

62.2.2 Sorting Large Data Sets

The need to sort large data sets arises frequently in data management. Besides outputting the result of a query in sorted order, sorting is useful for eliminating duplicate data items during the processing of queries. In addition, an efficient algorithm for performing a join operation (sort-merge join) requires the input relations to be sorted. Since the size of databases routinely exceeds the amount of available main memory, most DBMSs use an external sorting technique called *merge sort*, which is based on the main-memory version with the same name. The idea behind merge sort is that a file which does not fit into main memory can be sorted by breaking it into smaller pieces (runs), sorting the smaller runs individually, and then merging them to produce a single run that contains the original data items in sorted order. External merge sort is another example where main memory versions of algorithms and data structures need to be changed to accommodate a computing environment where all data resides on secondary and perhaps even tertiary storage. We will point out more such examples in Section 62.4 when we describe the disk space manager.

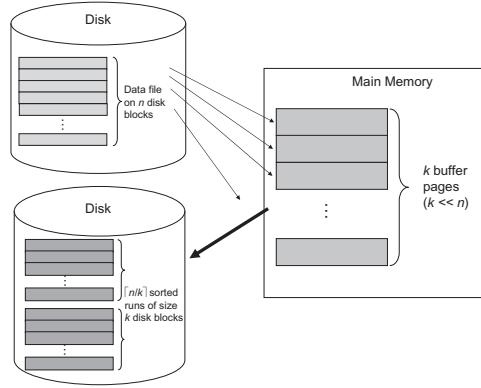

FIGURE 62.3 Arrangement of buffer pages and disk blocks during the run generation phase.

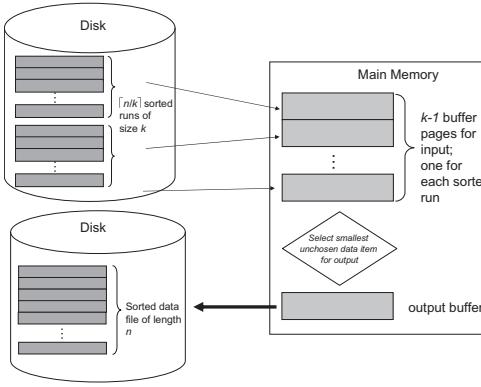

FIGURE 62.4 Arrangement of buffer pages and disk blocks during the one pass, multi-way merging phase.

During the first phase, also called the run-generation phase, merge-sort fills the available buffer pages in main memory with blocks containing the data records from a file stored on disk. We will have more to say about the management of buffer pages when we discuss data structures for buffer management in Section 62.3. Sorting is done using any of the main-memory algorithms (e.g., Heapsort, Quicksort). The sorted records are written back to new blocks on disk, forming a sorted run containing as many blocks as there are available buffer pages in main memory. This process is repeated until all records in the data file are in one of the sorted runs. The arrangement of buffer pages and disk blocks during run generation is depicted in [Figure 62.3](#).

In the second phase, also called the merging phase, all but one of the main memory buffers are used to hold input data from one of the sorted runs. In most instances, the number of sorted runs is less than the number of buffer pages and the merging can be done in one pass. Note, this so-called *multi-way merging* is different from the main-memory version of merge sort which merges pairs of runs (two-way merge). The arrangement of buffers and disk blocks to complete this one-pass multi-way merging step is shown in [Figure 62.4](#). Note that the two-way merge strategy results in reading data in and out of memory $2 * \log_2(n)$ times for n runs (versus reading all n runs only once for the n -way strategy).

In situations when the number of sorted runs exceeds the available buffer pages in main memory, the merging step must be performed in *several passes* as follows: assuming k buffer pages in main memory, each pass involves the repeated merging of $k - 1$ runs until all runs have been merged. At this point the number of runs has been reduced by a factor of $k - 1$. If the reduced number of sublists is still greater than k , the merging is repeated until the number of sublists is less than k . A final merge generates the sorted output. In this scenario, the number of merge passes required is $\lceil \log_{k-1}(n/k) \rceil$.

62.2.3 The Parse Tree

A *parse tree* is an m -ary tree data structure that represents the structure of a query. Each interior node of the tree is labeled with a non-terminal symbol from the grammar of the query language. The root node is labeled with the goal symbol. The query being parsed appears at the bottom with each token of the query being a leaf in the tree. In the case of SQL, leaf nodes are lexical elements such as keywords of the language (e.g., *SELECT*), names of attributes or relations, operators, and other schema elements.

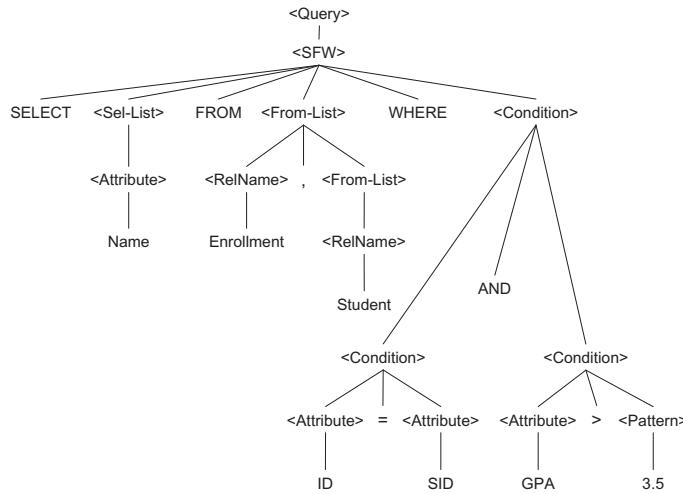

FIGURE 62.5 Sample parse tree for an SQL query showing query goal, interior and leaf nodes. Adapted from Garcia-Molina et al. [2].

The parse tree for the SQL query selecting all the enrolled students with a GPA higher than 3.5.

```
SELECT Name
FROM Enrollment, Student
WHERE ID = SID AND GPA > 3.5;
```

is shown in [Figure 62.5](#). For this example, we are tacitly assuming the existence of two relations called `Enrollment` and `Student` which store information about enrollment records for students in a school or university.

The parse tree shown in [Figure 62.5](#) is based on the grammar for SQL as defined in [2] (which is a subset of the full grammar for SQL). Non-terminal symbols are enclosed in angled brackets. At the root is the category `<Query>` which forms the goal for the parsed query. Descending down the tree, we see that this query is of the form `SFW` (select-from-where). In case one of the relations in the `FROM` clause is a view, it must be replaced by its own parse tree since a view is essentially a query. A parse tree is said to be valid if it conforms to the syntactic rules of the grammar as well as the semantic rules on the use of the schema names.

62.2.4 Expression Trees

An *expression tree* is a binary tree data structure that represents a logical query plan for a query after it has been translated into a relational algebra expression. The expression tree represents the input relations of the query as *leaf nodes* of the tree, and the relational algebra operations together with estimates for result sizes as *internal nodes*.

[Figure 62.6](#) shows an example of three expression trees representing different logical query plans for the following SQL query, which selects all the students enrolled in the course “COP 4720” during the term “Sp04” who have a grade point average of 3.5 (result sizes are omitted in the figure):

```
SELECT Name FROM Enrollment, Student
WHERE Enrollment.ID = Student.SID AND Enrollment.Course = 'COP 4720'
AND Enrollment.TermCode = 'Sp04' AND Student.GPA = 3.5;
```

An execution of a tree consists of executing an internal node operation whenever its operands are available and then replacing that internal node by the relation that results from executing the operation. The execution terminates when the root node is executed and produces the result relation for the query.

Note that expression trees representing *physical* query plans differ in the information that is stored in the nodes. For example, internal nodes contain information such as the operation being performed, any parameters if necessary, general strategy about the algorithm that is used, whether materialization of intermediate results or pipelining is used, and the anticipated number of buffers the operation will require (rather than result size as in logical query plans). At the leaf nodes table names are replaced by scan operators such as `TableScan`, `SortScan`, `IndexScan`, etc.

There is an interesting twist to the types of expression trees that are actually considered by the query optimizer. As we have previously pointed out, the number of different query plans (both logical and physical) for a given query can be very large. This is even more so the case, when the query involves the join of two or more relations since we need to take the join order into account when choosing the best possible plan. Today’s query optimizers prune a large portion of the candidate expression trees

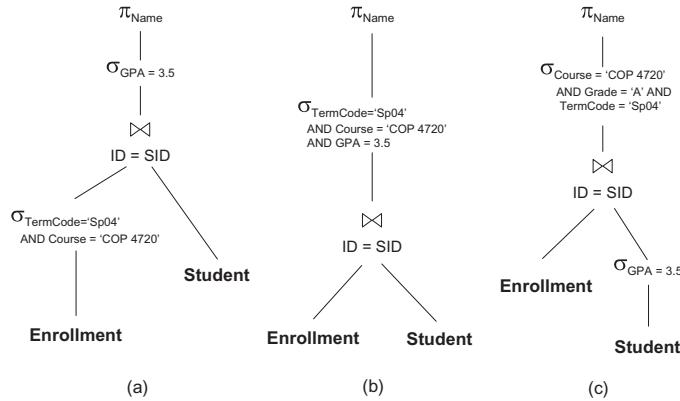

FIGURE 62.6 Three expression trees representing different logical query plans for the same query.

and concentrate only on the class of *left-deep trees*. A left-deep tree is an expression tree in which the right child of each join is a leaf (i.e., a base table). For example, in Figure 62.6, the tree labeled (a) is an example of a left-deep tree. The tree labeled (b) is an example of a *nonlinear* or *bushy* tree (a join node may have no leaf nodes), tree (c) is an example of a *right-deep tree* (the left child of each join node is a base table).

Besides the fact that the number of left-deep trees is smaller than the number of all trees, there is another advantage for considering only left-deep expression trees: Left-deep trees allow the query optimizer to generate more efficient plans by avoiding the intermediate storage (materialization) of join results. Note that in most join algorithms, the inner table must be materialized because we must examine the entire inner table for each tuple of the outer table. However, in a left-deep tree, all inner tables exist as base tables and are therefore already materialized. IBM DB2, Informix, Microsoft SQL Server, Oracle 8, and Sybase ASE all search for left-deep trees using a dynamic programming approach [5].

62.2.5 Histograms

Whether choosing a logical query plan or constructing a physical query plan from a logical query plan, the query evaluation engine needs to have information about the expected cost of evaluating the expressions in a query. Cost estimation is based on statistics about the database which include number of tuples in a relation, number of disk blocks used, distribution of values for each attribute, etc. Frequent computation of statistics, especially in light of many changes to the database, lead to more accurate cost estimates. However, the drawback is increased overhead since counting tuples and values is expensive.

An important data structure for cost estimation is the *histogram*, which is used by the DBMS to *approximate* the distribution of values for a given attribute. Note that in all but the smallest databases, counting the exact occurrence of values is usually not an option. Having access to accurate distributions is essential in determining how many tuples satisfy a certain selection predicate, for example, how many students there are with a GPA value of 3.5. This is especially important in the case of joins, which are among the most expensive operations. For example, if a value of the join attribute appears in the histograms for both relations, we can determine exactly how many tuples of the result will have this value.

Using a histogram, the data distribution is approximated by dividing the range of values, for example, GPA values, into subranges or *buckets*. Each bucket contains the number of tuples in the relation with GPA values within that bucket. Histograms are more accurate than assuming a uniform distribution across all values.

Depending on how one divides the range of values into the buckets, we distinguish between *equiwidth* and *equidepth* histograms [5]. In equiwidth histograms, the value range is divided into buckets of equal size. In equidepth histograms, the value range is divided so that the number of tuples in each bucket is the same (usually within a small delta). In both cases, each bucket contains the average frequency. When the number of buckets gets large, histograms can be compressed, for example, by combining buckets with similar distributions.

Consider the Students-Enrollments scenario from above. Figure 62.7 depicts two sample histograms for attribute GPA in relation Student. Values along the horizontal axis denote GPA, the vertical bars indicate the number of students that fall in each range. For this example we are assuming that GPA values are rounded to one decimal and that there are 50 students total. Histogram a) is an equiwidth histogram with bucket size = 2. Histogram b) is an equidepth histogram containing between 7 and 10 students per bucket.

Consider the selection $GPA = 3.5$. Using the equidepth histogram, we are led to bucket 3, which contains only the GPA value 3.5 and we arrive at the correct answer, 10 (vs. $1/2$ of 12 = 6 in the equiwidth histogram). In general, equidepth histograms

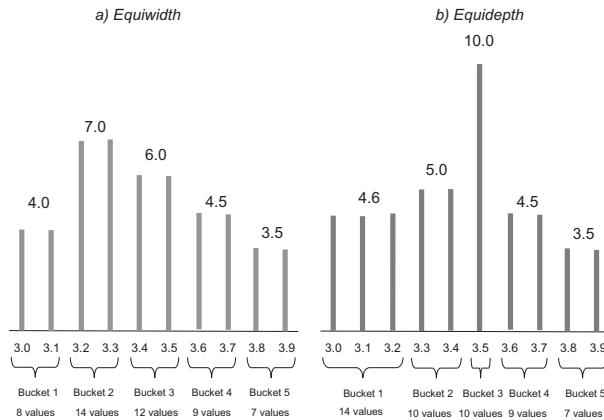

FIGURE 62.7 Two sample histograms approximating the distribution of GPA values in relation *Student*. Adapted from Ramakrishnan and Gehrke [5].

provide better estimates than equiwidth histograms. This is due to the fact that buckets with very frequently occurring values contain fewer values. Thus the uniform distribution assumption is applied to a smaller range of values, leading to a more accurate estimate. The converse is true for buckets containing infrequent values, which are better approximated by equiwidth histograms. However, in query optimization, good estimation for frequent values are more important.

Histograms are used by the query optimizers of all of the major DBMS vendors. For example, Sybase ASE, IBM DB2, Informix, and Oracle all use one-dimensional, equidepth histograms. Microsoft's SQL Server uses one-dimensional *equiarea histograms* (a combination of equiwidth and equidepth) [5].

62.3 Data Structures for Buffer Management

A *buffer* is partitioned into an array of *frames* each of which can keep a *page*. Usually a page of a buffer is mapped to a *block** of a file so that reading and writing of a page only require one disk access each. Application programs and queries make requests on the buffer manager when they need a block from disk, that contains a data item of interest. If the block is already in the buffer, the buffer manager conveys the address of the block in main memory to the requester. If the block is not in main memory, the buffer manager first allocates space in the buffer for the block, throwing out some other block if necessary, to make space for the new block. The displaced block is written back to disk if it was modified since the most recent time that it was written to the disk. Then, the buffer manager reads in the requested block from disk into the free frame of the buffer and passes the page address in main memory to the requester. A major goal of buffer management is to minimize the number of block transfers between the disk and the buffer.

Besides pages, so-called *segments* are provided as a counterpart of files in main memory. This allows one to define different segment types with additional attributes, which support varying requirements concerning data processing. A segment is organized as a contiguous subarea of the buffer in a virtual, linear address space with visible page borders. Thus, it consists of an ordered sequence of pages. Data items are managed so that page borders are respected. If a data item is required, the address of the page in the buffer containing the item is returned.

An important question now is how segments are mapped to files. An appropriate mapping enables the storage system to preserve the merits of the file concept. The distribution of a segment over several files turns out to be unfavorable in the same way as the representation of a data item over several pages. Hence, a segment S_k is assigned to exactly one file F_j , and m segments can be stored in a file. Since block size and page size are the same, each page $P_{k_i} \in S_k$ is assigned to a block $B_{j_l} \in F_j$. We distinguish four methods of realizing this mapping.

The *direct page addressing* assumes an implicitly given mapping between the pages of a segment S_k and the blocks of a file F_j . The page P_{k_i} ($1 \leq i \leq s_k$) is stored in the block B_{j_l} ($1 \leq l \leq d_j$) so that $l = K_j - 1 + i$ and $d_j \geq K_j - 1 + s_k$ holds. K_j denotes the number of the first block reserved for S_k (Figure 62.8). Frequently, we have a restriction to a 1:1-mapping, that is, $K_j = 1$ and $s_k = d_j$ hold. Only in this case, a dynamic extension of segments is possible. A drawback is that at the time of the segment creation

* A block is a contiguous sequence of bytes and represents the unit used for both storage allocation and data transfer. It is usually a multiple of 512 Bytes and has a typical size of 1KB to 8KB. It may contain several data items. Usually, a data item does not span two or more blocks.

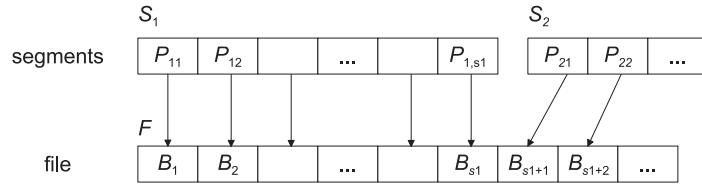

FIGURE 62.8 Direct page addressing.

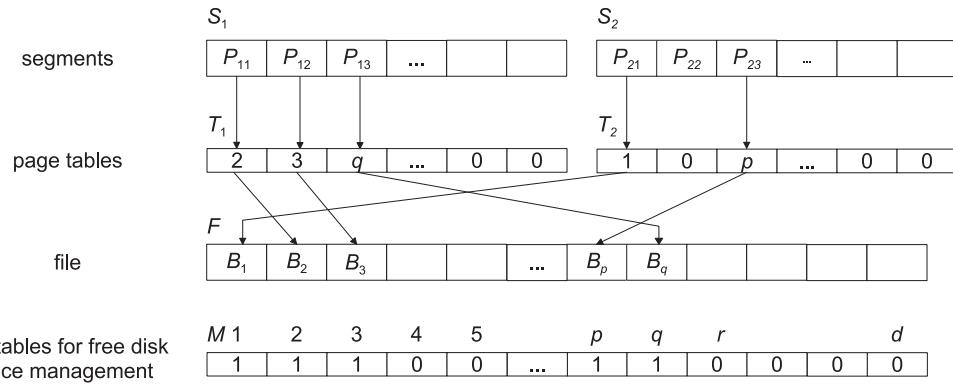

FIGURE 62.9 Indirect page addressing.

the assigned file area has to be allocated so that a block is occupied for each empty page. For segments whose data stock grows slowly, the fixed block allocation leads to a low storage utilization.

The *indirect page addressing* offers a much larger flexibility for the allocation of pages to blocks and, in addition, dynamic update and extension functionality (Figure 62.9). It requires two auxiliary data structures.

- Each segment S_k is associated with a *page table* T_k which for each page of the segment contains an entry indicating the block currently assigned to the page. Empty pages obtain a special null value in the page table.
- Each file F_j is associated with a *bit table* M_j which serves for free disk space management and quotes for each block whether currently a page is mapped to it or not. $M_j(l) = 1$ means that block B_{ji} is occupied; $M_j(l) = 0$ says that block B_{ji} is free. Hence, the bit table enables a dynamic assignment between pages and blocks.

Although this concept leads to an improved storage utilization, for large segments and files, the page tables and bit tables have to be split because of their size, transferred into main memory and managed in a special buffer. The provision of a page $P_{k,i}$ that is not in the buffer can require two physical block accesses (and two enforced page removals), because, if necessary, the page table T_k has to be loaded first in order to find the current block address $j = T_k(i)$.

The two methods described so far assume that a modified page is written back to the block that has once been assigned to it (*update in place*). If an error occurs within a transaction, as a result of the direct placement of updates, the recovery manager must provide enough log information (*undo* information) to be able to restore the old state of a page. Since the writing of large volumes of log data leads to notable effort, it is often beneficial to perform updates in a page in a manner so that the old state of the page is available until the end of the transaction. The following two methods are based on an indirect update of changes and provide extensive support for recovery.

The *twin slot method* can be regarded as a modification of the direct page addressing. It causes very low costs for recovery but partially compensates this advantage through double disk space utilization. For a page $P_{k,i}$ of a segment S_k , two physically consecutive blocks B_{ji-1} and B_{ji} of a file F_j with $l = K_j - 1 + 2 \cdot i$ are allocated. Alternately, at the beginning of a transaction, one of both block keeps the current state of the page whereas changes are written to the other block. In case of a page request, both blocks are read, and the block with the more recent state is provided as the current page in the buffer. The block with the older state then stores the changed page. By means of page locks, a transaction-oriented recovery concept can be realized without explicitly managing log data.

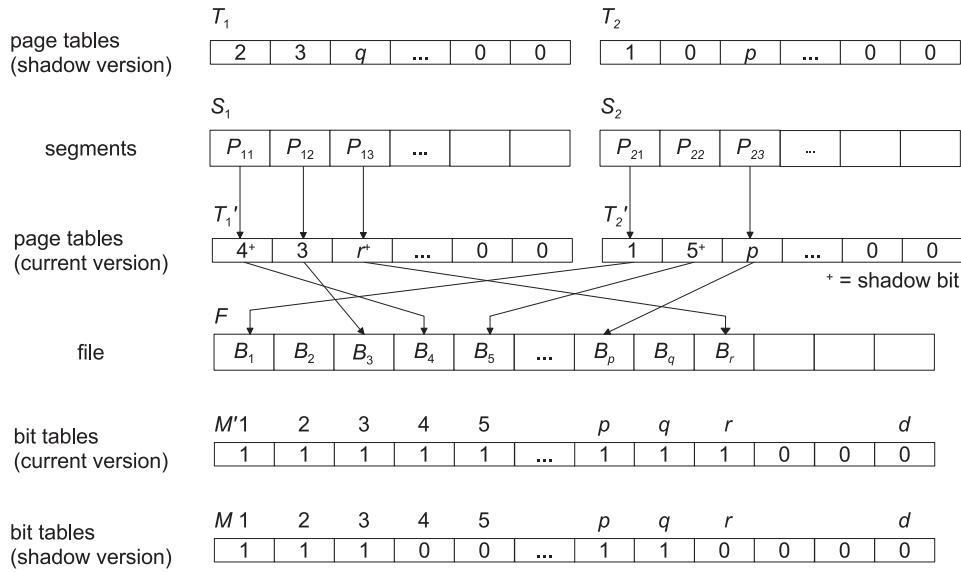

FIGURE 62.10 The shadow paging concept (segments S_1 and S_2 currently in process).

The *shadow paging concept* (Figure 62.10) represents an extension of the indirect page addressing method and also supports indirect updates of changes. Before the beginning of a new *save-interval* given by two *save-points*[†] the contents of all current pages of a segment are duplicated as so-called *shadow pages* and can thus be kept unchanged and consistent. This means, when a new save-point is created, all data structures belonging to the representation of a segment S_k (i.e., all occupied pages, the page table T_k , the bit table M) are stored as a consistent snapshot of the segment on disk. All modifications during a save-interval are performed on copies T'_k and M' of T_k and M . Changed pages are not written back to their original but to free blocks. At the creation of a new save-point, which must be an atomic operation, the tables T'_k and M' as well as all pages that belong to this state and have been changed are written back to disk. Further, all those blocks are released whose pages were subject to changes during the last save-interval. This just concerns those shadow pages for which a more recent version exists. At the beginning of the next save-interval the current contents of T'_k and M' has to be copied again to T_k and M . In case of an error within a save-interval, the DBMS can roll back to the previous consistent state represented by T_k and M .

As an example, Figure 62.10 shows several changes of pages in two segments S_1 and S_2 . These changes are marked by so-called *shadow bits* in the page tables. Shadow bits are employed for the release of shadow pages at the creation time of new save-points. If a segment consists of s pages, the pertaining file must allocate s further blocks, because each changed page occupies two blocks within a save-interval.

The save-points orientate themselves to segments and not to transaction borders. Hence, in an error case, a *segment-oriented recovery* is executed. For a *transaction-oriented recovery* additional log data have to be collected.

62.4 Data Structures for Disk Space Management

Placing data items on disc is usually performed at different logical granularities. The most basic items found in relational or object-oriented database systems are the values of attributes. They consist of one or several bytes and are represented by *fields*. Fields, in turn, are put together in collections called *records*, which correspond to tuples or objects. Records need to be stored in physical *blocks* (see Section 62.3). A collection of records that forms a relation or the extent of a class is stored in some useful way as a collection of blocks, called a *file*.

62.4.1 Record Organizations

A collection of field names and their corresponding data types constitute a *record format* or *record type*. The data type of a field is usually one of the standard data types (e.g., *integer*, *float*, *bool*, *date*, *time*). If all records in a file have the same size in bytes,

[†] Transactions are usually considered as being atomic. But a limited concept of “subtransactions” allows one to establish intermediate *save-points* while the transaction is executing, and subsequently to roll back to a previously established save-point, if required, instead of having to roll back all the way to the beginning. Note that updates made at save-points are invisible to other transactions.

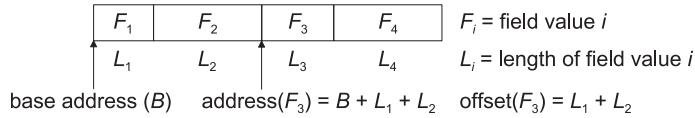

FIGURE 62.11 Organization of records with fields of fixed length.

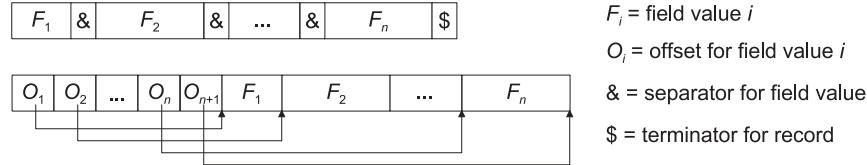

FIGURE 62.12 Alternative organizations of records with fields of variable length.

we call them *fixed-length records*. The fields of a record all have a fixed length and are stored consecutively. If the *base address*, that is, the start position, of a record is given, the address of a specific field can be calculated as the sum of the lengths of the preceding fields. The sum assigned to each field is called the *offset* of this field. Record and field information are stored in the data dictionary. Figure 62.11 illustrates this record organization.

Fixed-length records are easy to manage and allow the use of efficient search methods. But this implies that all fields have a size so that all data items that potentially are to be stored may find space. This can lead to a waste of disk space and to more unfavorable access times.

If we assume that each record of a file has the same, fixed number of fields, a *variable-length record* can only be formed if some fields have a variable length. For example, a string representing the name of an employee can have a varying length in different records. Different data structures exist for implementing variable-length records. A first possible organization amounts to a consecutive sequence of fields which are interrupted by separators (such as ? or % or \$). *Separators* are special symbols that do not occur in data items. A special *terminator* symbol indicates the end of the record. But this organization requires a pass (scan) of the record to be able to find a field of interest (Figure 62.12). Instead of separators, each field of variable length can also start with a counter that specifies the needed number of bytes of a field value.

Another alternative is that a header precedes the record. A *header* represents the “administrative” part of the record and can include information about integer offsets of the beginnings of the field values (Figure 62.12). The i th integer number is then the start address of the i th field value relatively to the beginning of the record. Also for the end of the record we must store an offset in order to know the end of the last field value. This alternative is usually the better one. Costs arise due to the header in terms of storage; the benefit is direct field access. Problems arise with changes. An update can let a field value grow which necessitates a “shift” of all consecutive fields. Besides, it can happen that a modified record does not fit any more on the page assigned to it and has to be moved to another page. If record identifiers contain a page number, on this page the new page number has to be left behind pointing to the new location of the record.

A further problem of variable - length records arises if such a record grows to such an extent that it does not fit on a page any more. For example, field values storing image data in various formats (e.g., GIF or JPEG), movies in formats such as MPEG, or spatial objects such as polygons can extend from the order of many kilobytes to the order of many megabytes or even gigabytes. Such truly large values for records or field values of records are called *large objects (lobs)* with the distinction of *binary large objects (blobs)* for large byte sequences and *character large objects!character (clobs)* for large strings.

Since, in general, lobs exceed page borders, only the non - lob fields are stored on the original page. Different data structures are conceivable for representing lobs. They all have in common that a lob is subdivided into a collection of linked pages. This organization is also called *spanned*, because records can span more than one page, in contrast to the *unspanned* organization where records are not allowed to cross page borders. The first alternative is to keep a pointer instead of the lob on the original page as attribute value. This pointer (also called *page reference*) points to the start of a linked page or block list keeping the lob (Figure 62.13a). Insertions, deletions, and modifications are simple but direct access to pages is impossible. The second alternative is to store a *lob directory* as attribute value (Figure 62.13b). Instead of a pointer, a directory is stored which includes the lob size, further administrative data, and a *page reference list* pointing to the single pages or blocks on a disk. The main benefit of this structure is the direct and sequential access to pages. The main drawback is the fixed and limited size of the lob directory and thus the lob. A lob directory can grow so much that it needs itself a lob for its storage.

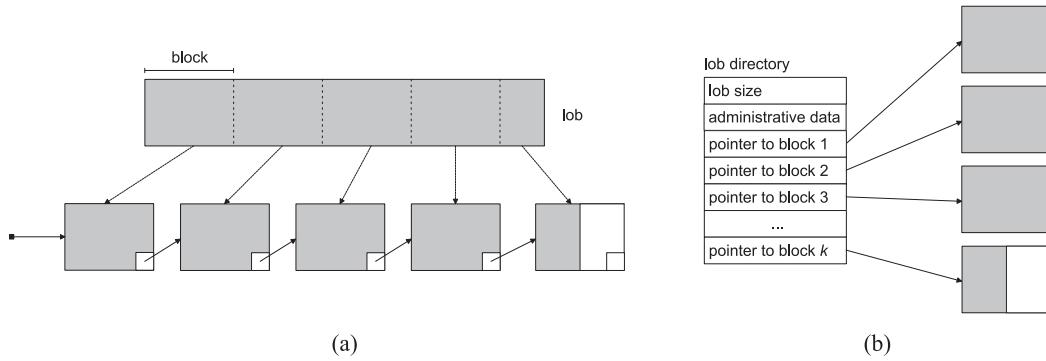

FIGURE 62.13 A lob as a linked list of pages (a), and the use of a lob directory (b).

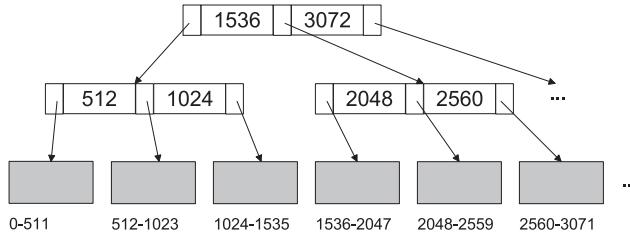

FIGURE 62.14 A lob managed by a positional B⁺ - tree.

The third alternative is the usage of *positional B⁺ - trees* (Figure 62.14). Such a B - tree variant stores relative byte positions in its inner nodes as separators. Its leaf nodes keep the actual data pages of the lob. The original page only stores as the field value a pointer to the root of the tree.

62.4.2 Page Organizations

Records are positioned on pages (or blocks). In order to reference a record, often a *pointer* to it suffices. Due to different requirements for storing records, the structure of pointers can vary. The most obvious pointer type is the *physical address* of a record on disk or in a virtual storage and can easily be used to compute the page to be read. The main advantage is a direct access to the searched record. But it is impossible to move a record within a page, because this requires the locating and changing of all pointers to this record. We call these pointers *physical pointers*. Due to this drawback, a pointer is often described as a pair (p, n) where p is the number of the page where the record can be found and where n is a number indicating the location of the record on the page. The parameter n can be interpreted differently, for example, as a relative byte address on a page, as a number of a slot, or as an index of a directory in the *page header*. The entry at this index position yields the relative position of the record on the page. All pointers (s, p) remain unchanged and are named *page - related pointers*. Pointers that are completely stable against movements in main memory can be achieved if a record is associated with a *logical address* that reveals nothing about its storage. The record can be moved freely in a file without changing any pointers. This can be realized by *indirect addressing*. If a record is moved, only the respective entry in a *translation table* has to be changed. All pointers remain unchanged, and we call them *logical pointers*. The main drawback is that each access to a record needs an additional access to the translation table. Further, the table can become so large that it does not fit completely in main memory.

A page can be considered as a collection of *slots*. Each slot can capture exactly one record. If all records have the same length, all slots have the same size and can be allocated consecutively on the page. Hence, a page contains so many records as slots fit on a page plus page information like directories and pointers to other pages. A first alternative for arranging a set of N fixed - length records is to place them in the first N slots (see Figure 62.15). If a record is deleted in slot $i < N$, the last record on the page in slot N is moved to the free slot i . However, this causes problems if the record to be moved is pinned[‡] and the slot number has to be changed. Hence, this “packed” organization is problematic, although it allows one to easily compute the location of the i th record. A second alternative is to manage deletions of records on each page and thus information about free slots by means of a directory represented as a bitmap. The retrieval of the i th record as well as finding the next free slot on a page require a traversal

[‡] If pointers of unknown origin reference a record, we call the record *pinned*, otherwise *unpinned*.

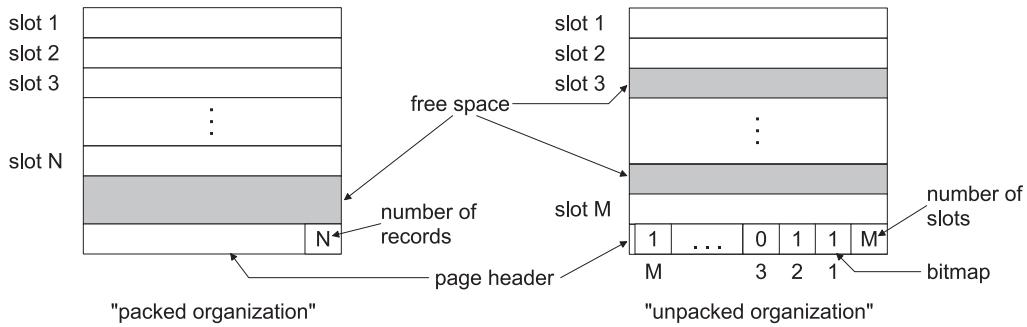

FIGURE 62.15 Alternative page organizations for fixed - length records.

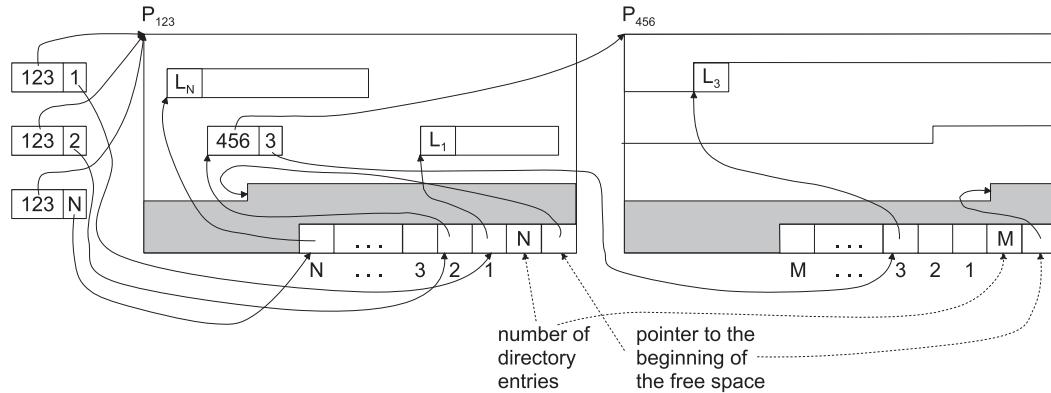

FIGURE 62.16 Page organization for variable - length records.

of the directory. The search for the next free slot can be sped up if an additional, special field stores a pointer on the first slot whose deletion flag is set. The slot itself then contains a pointer to the next free slot so that a chaining of free slots is achieved.

Also variable-length records can be positioned consecutively on a page. But deletions of records must be handled differently now because slots cannot be reused in a simple manner any more. If a new record is to be inserted, first a free slot of "the right size" has to be found. If the slot is too large, storage is wasted. If it is too small, it cannot be used. In any case, unused storage areas (*fragmentation*) at the end of slots can only be avoided if records on a page are moved and condensed. This leads to a connected, free storage area. If the records of a page are unpinned, the "packed" representation for fixed-length records can be adapted. Either a special terminator symbol marks the end of the record, or a field at the beginning of the record keeps its length. In the general case, indirect addressing is needed which permits record movements without negative effects and without further access costs. The most flexible organization of variable-length records is provided by the *tuple identifier* (TID) concept (Figure 62.16). Each record is assigned a unique, stable pointer consisting of a page number and an index into a page-internal directory. The entry at index i contains the relative position, that is, the offset, of slot i and hence a pointer to record i on the page. The length information of a record is stored either in the directory entry or at the beginning of the slot (L_i in Figure 62.16). Records which grow or shrink can be moved on the page without being forced to modify their TIDs. If a record is deleted, this is registered in the corresponding directory entry by means of a deletion flag.

Since a page cannot be subdivided into predefined slots, some kind of free disk space management is needed on each page. A pointer to the beginning of the free storage space on the page can be kept in the page header. If a record does not fit into the currently available free disk space, the page is compressed (i.e., defragmented) and all records are placed consecutively without gaps. The effect is that the maximally available free space is obtained and is located after the record representations.

If, despite defragmentation, a record does still not fit into the available free space, the record must be moved from its "home page" to an "overflow page". The respective TID can be kept stable by storing a "proxy TID" instead of the record on the home page. This proxy TID points to the record having been moved to the overflow page. An overflow record is not allowed to be moved to another, second overflow page. If an overflow record has to leave its overflow page, its placement on the home page is attempted. If this fails due to a lack of space, a new overflow page is determined and the overflow pointer is placed on the home page. This procedure assures that each record can be retrieved with a maximum of two page accesses.

If a record is deleted, we can only replace the corresponding entry in the directory by a deletion flag. But we cannot compress the directory since the indexes of the directory are used to identify records. If we deleted an entry and compress, the indexes of the subsequent slots in the directory would be decremented so that TIDs would point to wrong slots and thus wrong records. If a new record is inserted, the first entry of the directory containing a deletion flag is selected for determining the new TID and pointing to the new record.

If a record represents a large object, that is, it does not fit on a single page but requires a collection of linked pages, the different data structures for blobs can be employed.

62.4.3 File Organization

A *file (segment)* can be viewed as a sequence of *blocks (pages)*. Four fundamental file organizations can be distinguished, namely files of unordered records (heap files), files of ordered records (sorted files), files with dispersed records (hash files), and tree-based files (index structures).

Heap files are the simplest file organization. Records are inserted and stored in their unordered, chronological sequence. For each heap file we have to manage their assigned pages (blocks) to support scans as well as the pages containing free space to perform insertions efficiently. Doubly-linked lists of pages or directories of pages using both page numbers for page addressing are possible alternatives. For the first alternative, the DBMS uses a *header page* which is the first page of a heap file, contains the address of the first data page, and information about available free space on the pages. For the second alternative, the DBMS must keep the first page of the heap file in mind. The directory itself represents a collection of pages and can be organized as a linked list. Each directory entry points to a page of the heap file. The free space on each page is recorded by a counter associated with each directory entry. If a record is to be inserted, its length can be compared to the number of free bytes on a page.

Sorted files physically order their records based on the values of one (or several) of their fields, called the *ordering field(s)*. If the ordering field is also a *key field* of the file, that is, a field guaranteed to have a unique value in each record, then the field is called the *ordering key* for the file. If all records have the same fixed length, binary search on the ordering key can be employed resulting in faster access to records.

Hash files are a file organization based on hashing and representing an important indexing technique. They provide very fast access to records on certain search conditions. Internal hashing techniques have been discussed in different chapters of this book; here we are dealing with their external variants and will only explain their essential features. The fundamental idea of hash files is the distribution of the records of a file into so-called *buckets*, which are organized as heaps. The distribution is performed depending on the value of the *search key*. The direct assignment of a record to a bucket is computed by a *hash function*. Each bucket consists of one or several pages of records. A *bucket directory* is used for the management of the buckets, which is an array of pointers. The entry for index i points to the first page of bucket i . All pages for bucket i are organized as a linked list. If a record has to be inserted into a bucket, this is usually done on its last page since only there space can be found. Hence, a pointer to the last page of a bucket is used to accelerate the access to this page and to avoid traversing all the pages of the bucket. If there is no space left on the last page, overflow pages are provided. This is called a *static hash file*. Unfortunately, this strategy can cause long chains of overflow pages. *Dynamic hash files* deal with this problem by allowing a variable number of buckets. *Extensible hash files* employ a directory structure in order to support insertion and deletion efficiently without the employment of overflow pages. *Linear hash files* apply an intelligent strategy to create new buckets. Insertion and deletion are efficiently realized without using a directory structure.

Index structures are a fundamental and predominantly tree-based file organization based on the search key property of values and aiming at speeding up the access to records. They have a paramount importance in query processing. Many examples of index structures are already described in detail in this handbook, for example, B-trees and variants, quad-trees and octrees, R-trees and variants, and other multidimensional data structures. We will not discuss them further here. Instead, we mention some basic and general organization forms for index structures that can also be combined. An index structure is called a *primary organization* if it contains search key information together with an embedding of the respective records; it is named a *secondary organization* if it includes besides search key information only TIDs or TID lists to records in separate file structures (e.g., heap files or sorted files). An index is called a *dense index* if it contains (at least) one index entry for each search key value which is part of a record of the indexed file; it is named a *sparse index* (Figure 62.17) if it only contains an entry for each page of records of the indexed file. An index is called a *clustered index* (Figure 62.17) if the logical order of records is equal or almost equal to their physical order, that is, records belonging logically together are physically stored on neighbored pages. Otherwise, the index is named *non-clustered*. An index is called a *one-dimensional index* if a linear order is defined on the set of search key values used for organizing the index entries. Such an order cannot be imposed on a *multi-dimensional index* where the organization of index entries is based on spatial relationships. An index is called a *single-level index* if the index only consists of a single file; otherwise, if the index is composed of several files, it is named a *multi-level index*.

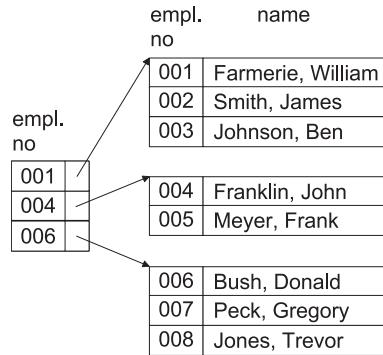

FIGURE 62.17 Example of a clustered, sparse index as a secondary organization on a sorted file.

62.5 Conclusion

A modern database management system is a complex software system that leverages many sophisticated algorithms, for example, to evaluate relational operations, to provide efficient access to data, to manage the buffer pool, and to move data between disk and main memory. In this chapter, we have shown how many of the data structures that were introduced in earlier parts of this book (e.g., B-trees, buffer trees, quad trees, R-trees, interval trees, hashing) including a few new ones such as histograms, LOBs, and disk pages, are being used in a real-world application. However, as we have noted in the introduction, our coverage of the data structures that are part of a DBMS is not meant to be exhaustive since a complete treatment would have easily exceeded the scope of this chapter. Furthermore, as the functionality of a DBMS must continuously grow in order to support new applications (e.g., GIS, federated databases, data mining), so does the set of data structures that must be designed to efficiently manage the underlying data (e.g., spatio-temporal data, XML, bio-medical data). Many of these new data structure challenges are being actively studied in the database research communities today and are likely to form a basis for tomorrow's systems.

63.1 Introduction

The emergence of large-scale web services, smartphones, social media, and high throughput scientific instruments within the last decade or so has resulted in a deluge of data. For example, Facebook has an incoming daily data rate of 600 TB with data warehouses storing upwards of 300 PB of data [1]. The amount of data generated by DNA sequencing centers is many terabytes every day with the amount doubling every 7 months [2]. The data problem is expected to worsen with the roll out of the Internet-of-Things (IoT) [3]. A key feature of IoT is equipping physical infrastructure with sensing and information transmission capabilities with the goal of realizing intelligent transportation, energy management, environmental monitoring, manufacturing, and health care systems.

In addition to the sheer *volume* of data generated by current and emerging applications, big-data is characterized by *velocity* and *variety*. Velocity pertains to the high data throughput and often real-time data processing requirements. Variety refers to the different types of data that need to be aggregated for storage, querying, and processing. File systems and databases are two ways of persisting the data on storage devices. Unlike file systems, databases allow for efficient querying of the data while supporting concurrent access and often providing ACID semantics: (1) *Atomicity*, which guarantees all-or-nothing execution of transactions, (2) *Consistency*, which ensures that relationship constraints among data are preserved, (3) *Isolation*, which allows for multiple transactions to execute without unintentionally affecting each other, and (4) *Durability*, for persistence of transactions. While traditional relational database management systems (RDBMS) allow complex querying of the data, their reliance on static schema and their inability to scale-out with additional nodes, seriously limit their utility for big-data applications [4].

The NoSQL or Not Only SQL paradigm refers to the new class of nonrelational data stores designed to address the big-data characteristics outlined above. NoSQL data stores typically employ a scale-out architecture with a distributed approach where commodity servers can be added on the fly. According to the CAP theorem [5], in distributed systems, only two out of the three *Consistency*, *Availability*, and *Partition tolerance* properties are achievable. The intuition behind the CAP theorem is that in the presence of partitions where one set of nodes in the distributed system is not reachable from the other, access to nodes from different partitions may result in inconsistent data. On the other hand, if the node partitions are to have consistent data, then they should not be made available. To achieve both consistency and availability, no partitions should be allowed in the distributed system. Unlike RDBMS which are designed to be consistent and available, NoSQL data stores choose partition tolerance, and either consistency or availability. Also, many NoSQL data stores do not support ACID transactions. Further, they support a

variety of data models ranging from simple key-value stores to NewSQL data stores that bring a semirelational model to NoSQL data stores.

In this chapter, we present an overview of the key data structures used by NoSQL data stores, providing references to the literature for details. We first give a short summary of the different data models used by NoSQL systems. We then outline the key design features of NoSQL data stores with a brief description of the algorithms and the associated data structures. These features include partitioning, replication, consistency, persistence, and concurrency. Among these features, persistence is treated in greater detail since the choice of data structures is particularly important in the overall performance of the data store.

63.2 Data Models

NoSQL databases can be classified into five types based on the data model realized—key-value stores, column-family stores, documents stores, graph databases, and NewSQL databases [6].

Key-Value Stores: Key-value stores use a schema-free key-value data model similar to associative maps or dictionary data structures. The value data type is opaque, that is, all querying and indexing is done through keys. Key-value stores such as Memcached [7] and Redis [8] are in-memory, while others such as BerkeleyDB [9], Amazon Dynamo [10], LevelDB [11], Voldemort [12], and Riak [13] persist data on disk.

Column Family Stores: A column family store is a multidimensional sorted map where a key has multiple attributes such as row-key, column family, column, and timestamp. Examples of column family stores include Big Table [14], Cassandra [15], and HBase [16].

Document Stores: Document stores are a type of key-value store where the values are documents stored in a format such as XML or JSON that can be interpreted by the data store. Document stores are schema free and allow storing of arbitrarily complex data. They are more flexible than key-value stores since, in addition to the key, data can also be accessed by the queries supported by the document format. Examples of document stores include MongoDB [17], CouchDB [18], and RavenDB [19].

Graph Databases: Graph data stores use graph-like nodes and edges where each node maintains direct references to adjacent nodes allowing for efficient graph traversals. The different graph components such as nodes, edges, labels, and properties are stored in separate files with pointers linking the corresponding elements across files allowing for rapid traversal. The properties of the nodes and edges are stored as key-value pairs. Graph databases are well suited to represent relationships between elements (e.g., determining relations in a social network, recommendations, and route finding). Examples of graph databases include Neo4j [20] and HypergraphDB [21].

NewSQL Databases: NewSQL data stores seek to extend the NoSQL data stores by providing a semirelational model, ACID semantics, and use of SQL as their primary interface. They try to achieve scalability by using techniques such as nonlocking concurrency control, in-memory architectures, and short-lived limited scope transactions. Examples of NewSQL databases include Google Spanner [22], VoltDB [23], NuoDB [24], TokuDB [25], and ScaledDB [26].

63.3 Partitioning

The goal of partitioning is to divide the key-values among multiple nodes in a distributed system so as to realize a distributed data store. The partition scheme seeks to balance the load between the nodes while enabling quick access of key-values. Moreover, nodes should be able to join and leave the distributed system with minimum disruption. The most commonly used partition scheme is consistent hashing [27]. Among the NoSQL databases that use consistent hashing are Voldemort [12], Riak [13], Cassandra [15], DynamoDB [10], CouchDB [18], and VoltDB [23].

63.3.1 Consistent Hashing

In a standard hash table, when the number of buckets changes, the mapping from keys to buckets changes completely. In the data store context, the storage nodes represent the buckets. As a result, all the data has to be reshuffled to be consistent with the new mapping scheme. In a distributed system with many nodes, where node failures are frequent and new machines are added regularly, such reshuffling of data between nodes can be expensive. Also, consistency issues may arise due to the delays associated with notifying the nodes of the new key to node mapping, thus resulting in multiple system views. “Multiple views” refers to differing key ownership information among the nodes. To support such multiple views, a given node may have to host keys consistent with different views, leading to both an increase in the load per node, and an increase in the node-spread of keys (the number of nodes responsible for a key). Therefore, among the requirements of a good hashing scheme are—load balance, minimal data reshuffling with addition or removal of nodes, and minimal load increase and key spread in maintaining multiple views. Consistent hashing aims to achieve these goals.

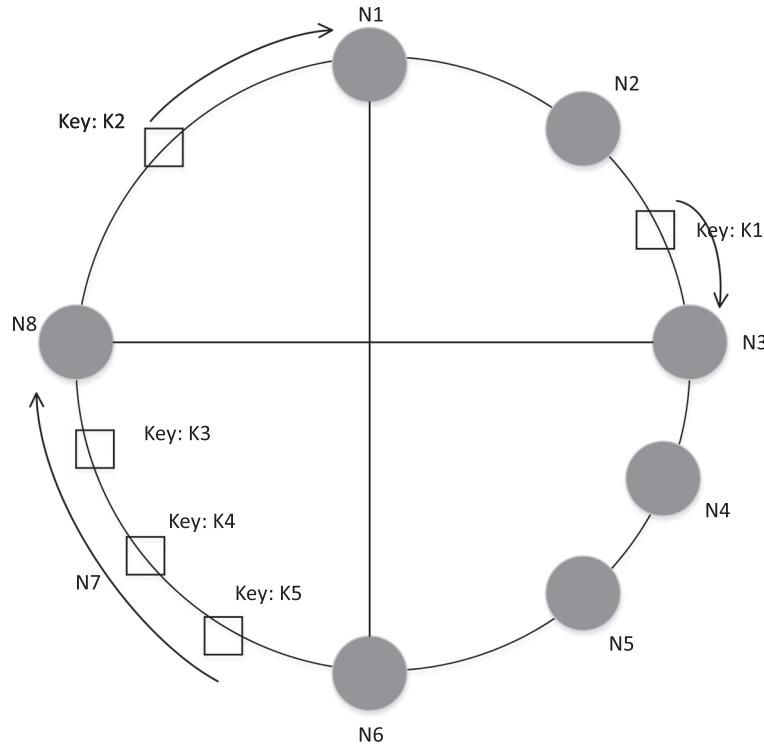

FIGURE 63.1 Consistent Hashing—Key Assignment: Key K1 is assigned to node N3, K2 to N1, and keys K3, K4, and K5 are assigned to N8.

In consistent hashing, data and nodes are mapped to points on a circle using a standard hash function. The data is then assigned to the closest node in a clockwise traversal from the point it is mapped on the circle (Figure 63.1). When a new node is inserted (Figure 63.2), only data mapped to points near the new node are copied to the new node. Since data is assigned to nodes that are at close by points on the circle, even in the presence of a large number of views, the spread of the data is limited. Also, since the data is assumed to be distributed randomly, only a limited amount of data will have their mapped points on the circle close to that of a given node. Thus the load on the node does not increase drastically with multiple views. Karger et al. [27] show that both load and the spread only increases logarithmically in the number of nodes when consistent hashing is used, as compared to linear increase with standard hashing. To ensure that the nodes are not assigned to disproportionate sections of the circle, each node is assigned m points around the circle ($m \geq 1$) where $m = k \log N$. Here, N is the number of nodes and k is a constant. A balanced binary search tree is used to store the mapping between segments of the circle and the nodes. For N nodes, there are $kN \log N$ segments since each node is virtually replicated $k \log N$ times. The search tree thus has a depth of $O(\log N)$. Since we insert or delete $k \log N$ points for each node, the addition or deletion of a node is $O(\log^2 N)$. Typical hash functions used include linear congruential function ($x \mapsto ax + b \text{ (mod } p)$) and cryptographic hash functions such as the secure hash algorithm [28].

63.4 Replication and Consistency

Replication not only improves fault tolerance but also increases performance by spreading data accesses among multiple nodes. A coordinator node keeps track of the location of the keys and their replicas, directing client key-value access requests to appropriate nodes. Note that separate coordinators could be maintained for different keys. Among the distributed computing primitives required to implement replication are—election of a coordinator, maintenance of a membership list, detection of node failures, and reaching consensus on the replicated value. Replication consistency involves keeping the replicated data consistent with each other. According to the CAP theorem [5], in a distributed system, it is impossible to simultaneously achieve consistency, availability, and partition tolerance. Traditional RDBMS trade-off partition tolerance for consistency and availability. Since the ability to scale out is an important goal of big data stores, NoSQL stores try to maintain partition tolerance while giving up on either consistency or availability. NoSQL stores, such as Cassandra [29] and DynamoDB [10], trade-off consistency for availability and partition tolerance. Cassandra, for example, implements an eventual consistency model [30], where typically a quorum of replicas acknowledge a read and write operation. Cassandra also supports consistency levels ranging from a single replica response, to

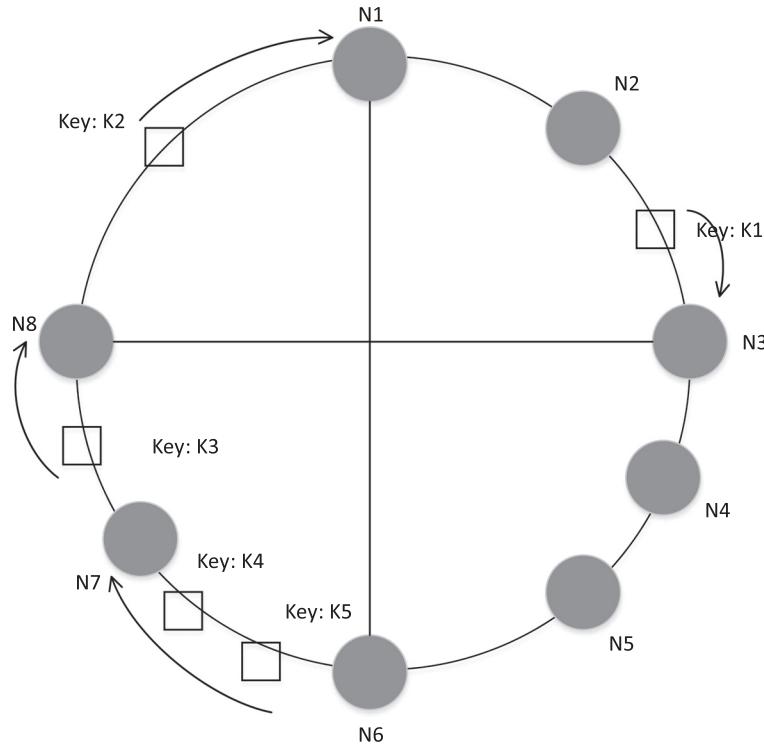

FIGURE 63.2 Consistent Hashing—Node addition: When new node N7 is added, only K4 and K5 are reassigned to N7. The mapping of the remaining keys is not affected.

all the replicas responding (strong consistency). Other NoSQL stores such as HBase [16] and NewSQL databases such as Google Spanner [22] and VoltDB [23] trade-off availability for partition tolerance and consistency.

The coordinator election and consensus on replicated values is achieved through distributed consensus algorithms such as Zab [31] and Paxos [32,33]. In order to bring the divergent replicas to a consistent state, the Merkle Tree data structure [34] is commonly used.

63.4.1 Merkle Tree

A Merkle tree is a tree of hashes where the leaf vertices are the hashes of data blocks, and the internal vertices are the hashes (actually, concatenations of the hashes) of their children. Figure 63.3 shows a binary Merkle tree. In this example, hash(3,4) is the result of concatenating hash of data block 0 and hash of data block 1. A cryptographic hash function such as the secure hash function could be used [28]. To determine if the two replicas are consistent, the root vertices of their corresponding Merkle trees are compared. If the roots are equal, the two replicas are considered to be consistent. If the root vertices do not match, the two trees are recursively searched until corresponding matching vertices are found. A matching vertex pair indicates that the data blocks in the two replicas that have the vertices as the root are consistent. For example, in Figure 63.3 if vertex hash (5,6) between the two trees match, then data blocks 2 and 3 are consistent. The search terminates when the leaf vertices are reached. Unmatched leaf vertices indicate that the corresponding data blocks between the two replicas are not consistent. The Merkle tree thus allows us to drill down the two replicas, to determine the blocks that do not match. Since only hash values are stored, the entire tree can be maintained in memory and transferred between the replica nodes with low overhead. Moreover, comparisons can proceed even with a partial tree. For example, in Figure 63.3, the consistency of data block 0 can be checked by knowing hash(data1) and hash (5,6). The root hash can then be computed and compared against the root vertex of the Merkle tree associated with the replica.

A gossip-style protocol can be used to implement both failure detection and membership lists. For example, Cassandra uses the Scuttlebutt gossip-style protocol [29] for maintaining membership lists. Examples of failure-detection protocols include SWIM [35] and adaptive-phi [36]. Apache Zookeeper [37] and Google Chubby [38] are projects used by many NoSQL stores for services such as consensus, failure detection, and distributed locks.

63.5 Persistence

NoSQL database workloads are characterized by high throughput inserts, and point or range queries [39,40]. Workloads such as interactive web and online gaming require low latency reads and writes. Analytics workloads such as predictive modeling and web analytics are characterized by sequential reads and high write throughputs. However, with the explosion of mobile devices and the emergence of the IoT paradigm, the need for integrating interactive applications with analytics is fast rising. Example use cases include gaining real-time behavioral insights from user mobile activity, and remote monitoring and control of physical infrastructure such as smart power grids. This has resulted in workloads that are both write heavy, and have stringent latency requirements. For example, as reported by Yahoo [41], the percentage of writes in their workloads has increased from 10% to 20% in 2010 to 50% in 2012, with a further increase expected.

On the storage side, hard disk seek times have improved much more slowly compared to disk bandwidths. Utilizing typical hard disk performance numbers of 3 ms access time, 2 ms rotational latency, and disk bandwidth of 200 MB/s—for a block size of 4 KB, the seek time of 5 ms is $250\times$ compared to the 0.02 ms time required for data transfer. High I/O performance thus requires long sequential I/Os to amortize disk seek times. Another trend is the growth of popularity of solid state drives (SSDs) in cloud computing systems due to their falling costs and growing capacity. Since SSDs have no moving parts, random read is about $100\times$ times faster than hard disks. However unlike hard disks, data cannot be directly overwritten in SSDs. Instead, data needs to be erased at a much higher level of granularity before the write operation. As a result, SSD random writes are $100\times$ slower than random reads. Also, write bandwidths are further reduced by $10\times$ if the data is fragmented [42]. Therefore, SSDs favor sequential writes over random writes to achieve high write performance. Moreover, SSDs are characterized by a finite number of write cycles and require data structures that reduce the number of writes. Write-optimized data structures are thus crucially important in providing data persistence in NoSQL databases.

In this section, we review the two most widely used data structures for persistence used by NoSQL data stores today—the B+ tree and the Log Structured Merge (LSM) tree. After a brief description of the LSM tree, we carry out a simplified analysis of its behavior to provide the reader some intuition about its performance. We also examine optimizations that seek to improve the performance of these data structures.

63.5.1 Performance Metrics

Traditional metrics used to evaluate data structure performance include asymptotic time complexity for random point query, scan, insert, update, and delete operations. Point query involves finding a value for the queried key, while scan involves finding all values in sorted order that come after the queried key. Insert and delete have their usual meaning and update is a read-modify-write operation. Additional performance metrics include write amplification and read amplification. Write amplification is the ratio of the amount of data written to the size of the object. A higher write amplification means worse performance especially if the extra writes are not sequential. Additionally, for SSDs, a higher writer amplification leads to a quicker drive wear out. Read

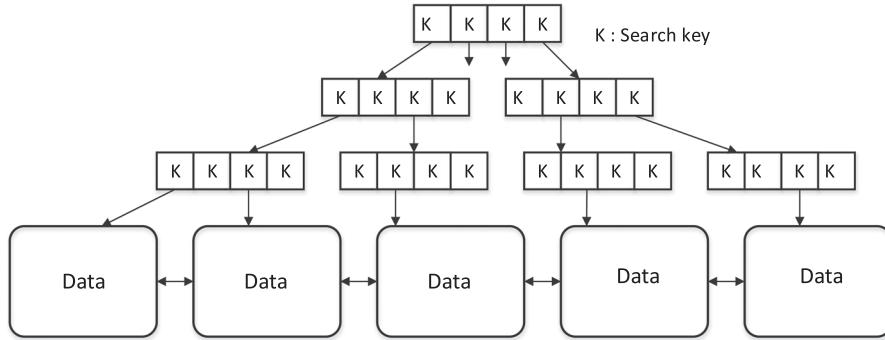

FIGURE 63.4 Structure of B+ tree.

amplification is defined as the worst-case number of I/Os for a read. Similar to write amplification, a higher read amplification results in degraded performance.

63.5.2 B+ Trees

The most widely used data structure for data indexing is the B+ tree. B+ trees are search trees with a high degree of fanout (child nodes) with data held in leaf nodes and index keys stored in interior nodes (Figure 63.4). In the analysis below, the size of the nodes (block size) of the B+ tree is denoted by B and the size of the database by N . Assuming the Disk Access Model (DAM) which counts the number of memory transfers from slow to faster memory [43], the cost of query and insertion is given by the height $O(\log_B(N/B))$ of the tree. If the keys fit in memory (i.e., the internal nodes are cached), the B+ tree takes a single I/O for a random point query. Two I/Os are required if the data to be inserted or updated is not cached in memory (one to read it to memory from disk and one to write the updated leaf node to disk). However, as mentioned earlier, random in-place writes lead to poor performance due to large disk seek times. The choice of B is impacted by the following observations: (1) reads perform better with larger block sizes (e.g., 1 MB) since a larger block size reduces the depth of the tree. The read amplification is $O(\log_B N/B)$ for uncached keys and 1 for cached keys [44]. (2) However, the worst-case write amplification is $O(B)$ since a random write requires the entire block to be written. Thus a smaller block size is preferred for write-intensive databases. Block size is a configurable parameter. For example, in MongoDB, where the blocks are referred to as buckets, the `db.collection.indexStats()` method has a parameter `bucketBodyBytes` with a default size of 8 KB.

63.5.3 Log Structured Merge Trees

The Log Structured Merge Tree [45] is a tree data structure used by a number of NoSQL databases such as Bigtable [14], Cassandra [29], and HBase [16]. While random point queries run slower than B+ trees, LSM-trees can perform random insertions and updates without incurring external I/O. This trade-off of a slight slowdown in read performance for a much greater speed up in write performance is well suited for increasingly write-intensive NoSQL workloads.

The LSM-tree is a collection of exponentially larger trees treated as a single key-value store. The individual trees in the collection can be implemented using B+ trees or Sorted String Table (SSTable) [14,29,46]. An SSTable is a simplified B+ tree which only maintains a single layer of index nodes with the leaf nodes pointed at by the entries in the index node. The leaf nodes are written to a storage device in a single contiguous allocation with the index nodes stored at the end of the leaf nodes along with the offsets of their values. In an SSTable, insertions are performed by adding elements into the last empty leaf node with a new leaf node created if required. The offset of the new leaf node is then appended to the last empty index node. New index nodes are created if required. A look up on a key K is performed by a binary search on the index nodes to determine keys K_i and K_{i+1} such that $K_i \leq K \leq K_{i+1}$. The leaf pointed to by index K_i is the leaf node with the value associated with K [46].

The basic LSM-tree design is shown in Figure 63.5. When a tree at level i is filled, it is flushed out and its contents merged, sorted, and packed with the tree at level $i + 1$. This process is known as tree compaction. Since the trees are stored in sorted key order, the merges can be done in a single pass [47]. The updated tree is then written to a new part of the disk allowing sequential writes at storage bandwidth speeds. The smallest tree, that is, the tree at the lowest level is kept in memory thus requiring no external I/O access. Upon merging with higher level trees, the tree in memory is ready to accept new insertions. To perform updates, the merge process selects the most recent of the values with the same key to flush to the larger tree. Deletes are similar to updates and involves setting the key with a special tombstone flag. The tombstones are then removed during the merge process. Regarding query performance, for uncached data, in the worst case, a query involves binary search of each of the trees. Since there

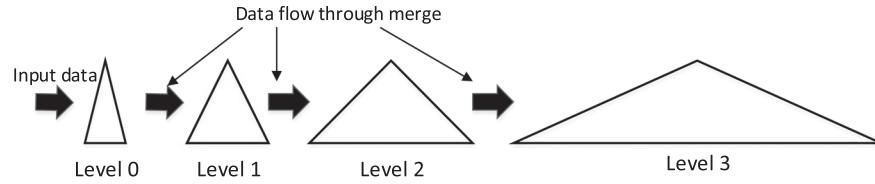

FIGURE 63.5 Basic LSM-tree design. When a tree at level i is filled, it is merged with the tree at level $i + 1$.

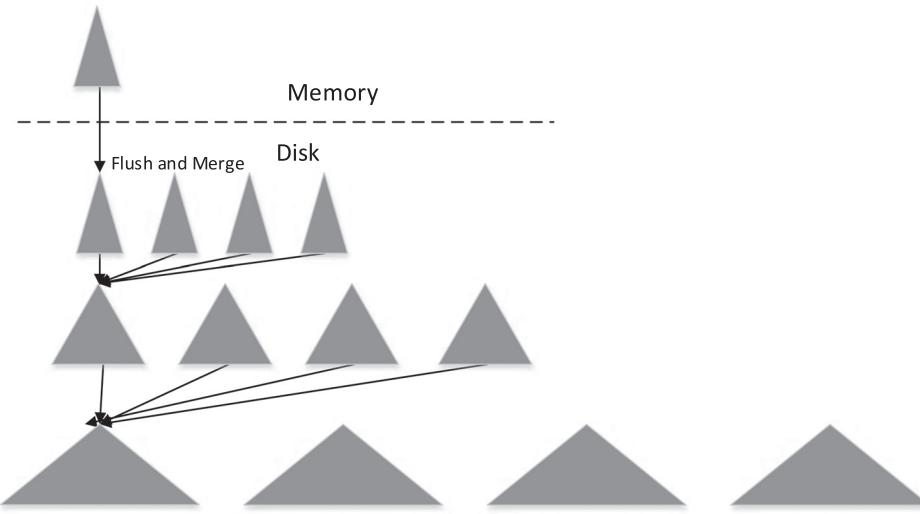

FIGURE 63.6 Size tiered LSM tree with 4 trees per level.

are $O(\log_k N/B)$ levels, where k is the tree growth factor, the query complexity is $O(\log N/B * \log_k N/B)$ or $O(\log^2 N/B)/\log k$. This is the read amplification factor as well. Similarly, since there are $O(\log_k N/B)$ levels, and on an average the data written to a level is merged again to the same level $k/2$ times, the asymptotic update I/O cost is $\Theta(k \log_k N/B)$. However, updates use sequential I/O, and hence can handle more intense update loads than B+ trees. The write amplification factor is $\Theta(k \log_k N/B)$ as well [44] which if amortized for sequential transfers, leads to an effective write amplification less than 1. Thus while LSM trees have superior insert and update performance, their random query performance is unsatisfactory. Moreover, the time required to merge two trees is unbounded since the size of the trees is unbounded. Such unbounded merges can potentially lead to sporadic write outages [41].

The data structure described above can be thought of as a level-tiered LSM tree [44]. As shown in Figure 63.6, in a size-tiered LSM-tree (also known as Stepped Merge Method and Sorted Array Merge Tree when implemented using SSTables) rather than storing one tree per level, N_T trees are stored at each level [44,46,48]. The merge is performed after N_T smaller trees are flushed to the larger tree. Cassandra [15] provides both size-tiered and level-tiered LSMs. Compared to the level-tiered approach, the size-tiered LSM has a write amplification $O(\log_k N/B)$ which is k times smaller than the level-tiered approach since the data is written to each level only once. However, read amplification is $O\left(k \frac{\log_k N/B}{\log k}\right)$ which is k times larger than the level-tiered approach. Thus level-tiered LSM trees are better suited for read-intensive workloads while size-tiered LSM trees are better suited for write-intensive workloads. NoSQL databases such as BigTable [14], Cassandra [15], and Hbase [16] maintain a commit log to disk for crash recovery. The write to the in-memory LSM-tree is performed only after a successful write to the commit log. A rolling commit log is used to purge old commit log entries.

63.5.4 Intuition behind LSM

We present a somewhat simplified analysis of the LSM tree data structure to provide the reader with some intuition of its advantages over traditional disk-based data structures. To facilitate this analysis, we make three assumptions.

- A (random) insertion into a dictionary data structure in internal memory requires $c \log n$ time, where n is the size of the data structure and c is a constant associated with writes in main memory.

- A similar insertion into a dictionary on disk requires $D \log n$ time. Here D is a constant associated with random writes to disk. Clearly $c \ll D$.
- Finally, we assume that the merging of the contents of two dictionaries of size n_1 and n_2 that results in a merged dictionary of size $n_1 + n_2$ on disk requires $d(n_1 + n_2)$ time. Here, d is a constant associated with sequential writes to a disk. Clearly $d \ll D$ (sequential writes are faster than random writes).

In both of the following scenarios, assume that a dictionary of size N is already present on disk. In Scenario 1 (traditional), n insertions are directly made into the dictionary on disk. This will require approximately $Dn \log(N + n)$ time. In Scenario 2 (essence of LSM), n insertions are first made into an initially empty in-memory dictionary ($cn \log n$) followed by a merge with the dictionary on disk ($d(n + N)$). To compare the two scenarios, we compare

$$cn \log n + d(n + N) \quad \text{vs.} \quad Dn \log(N + n).$$

Here, $cn \log n$ is negligible relative to $Dn \log(N + n)$ because $c \ll D$ and $n < N + n$. We therefore restrict our analysis of the two data structuring approaches to

$$d(n + N) \quad \text{vs.} \quad Dn \log(N + n).$$

Now, if $n = N$, we find that the LSM term is again dominated by the traditional data structuring term. Specifically,

$$\begin{aligned} 2dn &\quad \text{vs.} \quad Dn \log(2n) \\ 2d &\quad \text{vs.} \quad D \log(2n). \end{aligned}$$

Here $d \ll D$ and $2 < \log(2n)$ for most n . It is instructive to note that if $N \gg n$, we would evaluate dN versus $Dn \log N$ and the outcome of the comparison is unclear.

The main intuition of the LSM tree can be summarized as follows: relatively expensive random writes that result in an initial sorted structure are performed in fast memory rather than on disk. The sorted structure so obtained can then be efficiently merged with the existing sorted structure on disk (merges require linear scans, a strength of disk technology), provided their relative sizes are about the same. If the size of the sorted structure on disk is much larger than the one in main memory, we are going to the expense of reading and writing this large structure to accommodate only a relatively small set of new insertions. This observation motivates the need for several levels of gradually increasing sized structures in an LSM tree.

63.5.5 Performance Optimizations

A number of optimizations have been proposed in the literature to improve the performance of LSM trees. Some of these techniques have been implemented in production NoSQL databases. We give a brief description of these techniques below.

Bloom Filter: Point queries can be made more efficient by adding an in-memory Bloom filter to each level, thus avoiding I/Os for levels that do not contain the key of interest. A Bloom filter is a space-efficient probabilistic data structure that is used to test whether an element is a member of a set. The basic data structure in a Bloom filter is a bit vector. For a given input, a series of independent hash functions is used to set different bits of the bit vector. If two inputs map to the same bits, a look-up for one of the inputs can result in a false positive. However, no false negatives occur. The false positive rate can be controlled through the choice of number of hash functions and the length of the bit vector. With the use of a Bloom filter, the read amplification factor can be made 1 for random point queries. Bloom filters are used by a number of NoSQL databases including Cassandra [15], HBase [16], TokuDB [25], and LevelDB [11]. In the LSM tree variant, bLSM, 10 bits are used per key leading to a false-positive rate of 1% [41]. Note that Bloom filters do not improve scan performance.

Fractional Cascading: Fractional cascading is a data structuring technique that has its origins in the computational geometry literature from the 1980s [49,50]. We first describe the general principle through an example followed by a brief description of its use in LSM trees. Consider three sorted lists:

$L_1: 5, 15, 16, 30, 50, 65$

$L_2: 4, 6, 9, 10$

$L_3: 2, 12, 13, 20, 25.$

Suppose we wish to search for 14 in the three lists. This is accomplished by performing three independent binary searches. Adopting the convention that a failed search returns the predecessor, this will return 5 in L_1 , 10 in L_2 , and 13 in L_3 . Assuming k lists, each of size n , the time and space complexity of this approach are $O(k \log n)$ and $\Theta(kn)$, respectively.

Fractional cascading gives an improved run time of $O(\log n + k)$ while retaining a space complexity of $\Theta(kn)$. The individual lists are preprocessed and modified in order to achieve these bounds as follows: list F_k is identical to L_k ; list F_i is obtained by merging L_i with every second element of F_{i+1} for all $i < k$. In our example, the F_i s are shown in the order in which they are computed.

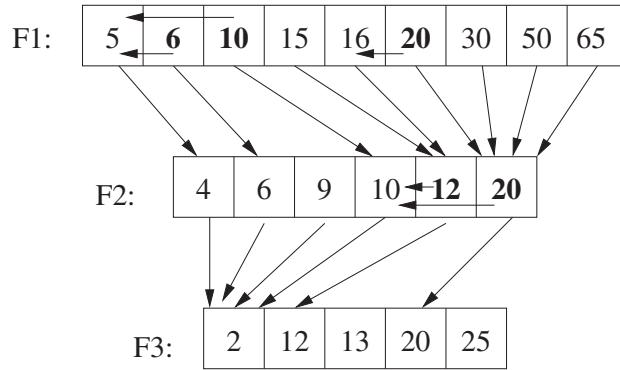

FIGURE 63.7 Fractional cascading structure.

$F_3: 2, 12, 13, 20, 25$

$F_2: 4, 6, 9, \mathbf{10}, \mathbf{12}, \mathbf{20}$

$F_1: 5, \mathbf{6}, \mathbf{10}, 15, 16, \mathbf{20}, 30, 50, 65$.

Bold-face is used to denote elements in F_i that were obtained from F_{i+1} rather than from L_i . The F_i arrays are further augmented to include

1. An *internal* pointer from each bold-faced element in F_i to its largest nonbold-faced predecessor in F_i . For example, the **10** in F_1 points to 5 in the same list.
2. An *external* pointer from each element x in F_i to the largest element less than or equal to x in F_{i+1} .

The resulting data structure is shown in [Figure 63.7](#).

Consider now a search for 14 in F_1 . A binary search in F_1 gives 10, whose internal pointer yields 5 (the correct response to a query in the original list L_1). 10's external pointer points to the element 10 in F_2 . A $\Theta(1)$ time scan yields 12 as being the predecessor of 14 in F_2 . Since 12 is bold-faced, its internal pointer returns 10 as the response to the query in L_2 . Next, 12's external pointer gives 12 in F_3 . The $\Theta(1)$ local search yields 13, which is the correct response to the query in L_3 . Fractional cascading does result in an increase in space because of duplicated elements, but the total space remains $\Theta(kn)$.

In an LSM tree, forwarding pointers are stored from keys at one level to the same or predecessor key at the next level. So instead of performing binary search to find a key or its predecessor at all $O(\log_k N/B)$ levels at $O(\log_k N/B * \log N/B)$ cost, a binary search need only be performed at one level, followed by constant number access down the higher levels through the forwarding pointers. In practice, only one forwarding pointer per block needs to be maintained. However, to ensure forwarding pointers to the higher level in the absence of the corresponding blocks in the lower level, ghost pointers are added to the lower level. The point query cost is thus $O(\log N/B + \log_k N/B)$. Fractional cascading has been used in LSM-tree variants such as FD-tree [42], cache oblivious lookup arrays (COLA) [51,52], write buffer tree [53], and in LevelDB [11], AsterixDB [54], and TokuDB [25] databases.

Key-Based Partitioning: In the partitioning technique, the LSM trees are divided into many partitions with each partition storing data within a range of keys [55]. Each partition is of a bounded size thus improving merge performance. Query performance is also improved since the partition key ranges are disjoint allowing for searches to be limited to a partition. Additionally, the partitioning is a natural unit of concurrency control and handles write skews well by concentrating merges on frequently updated key ranges [41]. LSM tree partitioning is used in LSM-tree variants such as write buffer tree [53], range table [56] and in LevelDB [11], AsterixDB [54], and TokuDB [25] databases.

Merge Scheduling: A merge schedule defines when and which LSM trees are merged. The merge time needs to be minimized for reducing write pauses and improving read latencies. Cassandra [15] prioritizes merging of trees with recent reads to improve read latency. The spring and gear merge scheduler used in bLSM [41] attempts to keep the size of the tree between a low and a high watermark. If the size of the tree dips below the low watermark, the scheduler pauses the merge of the higher level trees. On the other hand, if the size of the tree exceeds the high watermark, the scheduler puts back pressure on the application. However, as described by Sears and Ramakrishnan [41], the implementation is tricky due to the costs associated with acquiring coarse-grained mutex for each merged tuple-page, and the risk of deadlocks or disk idling. A theoretical analysis of compaction algorithms is presented in References 57 and 58 where compaction is presented as an optimization problem that minimizes system costs such disk I/O [58] and CPU load [57].

Fractal Tree: Fractal trees [44,59] are a variant of B+ trees in which each internal node of the tree is partitioned into two regions. The first region is used to store pointers to child nodes as before. The second region is used to maintain a buffer which is used

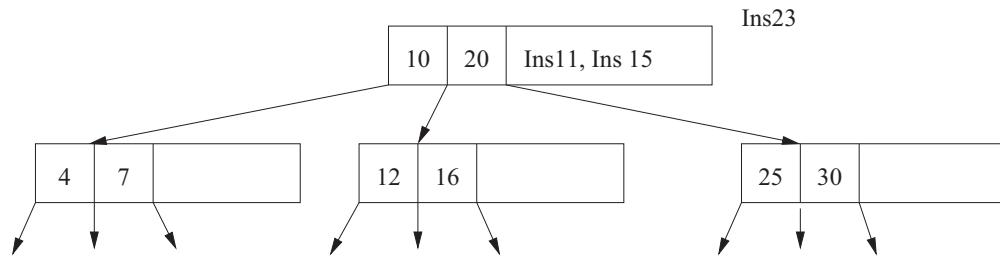

FIGURE 63.8 Fractal tree's root node's buffer region is filled to capacity with two pending operations “Insert 11” and “Insert 15.” The remaining nodes' buffer regions are empty.

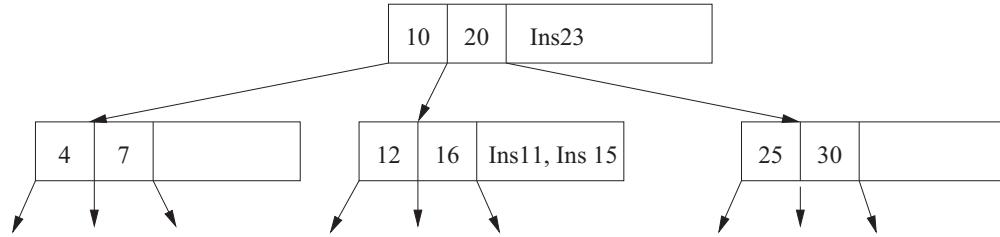

FIGURE 63.9 The addition of the “Insert 23” operation causes the “Insert 11” and “Insert 15” operations to be propagated down the middle pointer (both are in the [10, 20] range) and placed in the child node's buffer.

to store pending operations such as insert, delete, and update. When a key-value pair is inserted, it is considered to be a pending operation and is stored in the root node's *buffer* region (as opposed to being propagated down the tree to a leaf node). When the root node's buffer gets filled with pending operations, they are recursively cascaded to an appropriate child node and stored in its buffer. As buffers in the tree get filled, pending operations ultimately reach the leaves and are executed just like in a B+ tree. Figures 63.8 and 63.9, respectively, show a fractal tree before and after the execution of an “Insert 23” operation, which causes some pending buffer operations to be propagated down the tree.

Part of the block is used for implementing the buffer. The write amplification is k for each level of the tree where k is the number of children. Since there are $O(\log_k N/B)$ levels, the write amplification for the fractal tree is $O(k \log_k N/B)$. Read amplification is $O(\log_k N/B)$. Additionally write performance is improved by batching the writes of leaf nodes. Regarding the choice of parameters, Kuzmaul recommends the number of children $k = 10$, and block size of 64 KB [44].

63.6 Concurrency

The traditional approach of using read/write locks to support concurrent transactions suffers from performance issues due to readers and writers blocking each other. For example, an analytics application may execute a long read transaction, blocking out transactions that need to perform short updates on the data store. A solution adopted by data stores such as Voldemort [12], Riak [13], Hbase [16], NuoDB [24], HypergraphDB [21] is Multi Version Concurrency Control (MVCC). In MVCC, multiple versions of the key-value are maintained with writers updating a new version of the key-value. The read visibility set consists of the committed transactions. MVCC thus allows reads and writes to proceed concurrently. Locking is only required if two writes seek to update the same key-values in the same version. The versioned dictionary data structure supports implementation of MVCC. In a versioned dictionary, in addition to the key and value, a version number is also stored. The query and modify operations have the version number as an additional parameter. A significant challenge in implementing such a data structure is in realizing optimal query/update operations similar to B+ trees or LSM trees while maintaining linear space usage. The traditional Copy-On-Write (CoW) B+ trees result in excessive space usage since each update may cause an entire new path to be written. A large space usage in turn makes garbage collection expensive.

The stratified B-tree (also known as stratified doubling array) [60] supports multiversioning, optimal query/update performance ($O(\log(N_v)/B)$), where N_v is the number of keys live at version v , and optimal space ($O(N)$). The basic organization is similar to the SSTables described in Section 63.5 with the addition that the arrays are tagged with a set of version IDs. The arrays double in size going up the levels. Disjoint sets of versions are maintained in the arrays at the same level. The density of the array for a particular version is the fraction of the elements of that version that is live. A high density, where the array is dominated by elements from a single version, results in inefficient space usage and costly updates. On the other hand, low density results in

poor point and range query performance. A density of 1/3 was found to be a good compromise value [60]. In the merge process, additional care has to be taken to ensure that the density is maintained for all versions. A technique known as density amplification achieves this by replacing large arrays with smaller density arrays by carefully choosing the versions to be included in the denser array. The details of the algorithm are described in Reference 61.

An additional consideration for high performance data stores is the concurrency of in-memory data structures so as to achieve vertical scaling on servers with a large number of processor cores. A very recent work in this space is the concurrent LSM (cLSM) data structure [62] which enhances Google's LevelDB [11] data store to achieve 1.5 \times to 2.5 \times performance. The key-ideas employed by cLSM are the use of highly concurrent in-memory data structures [63–65], careful minimization of critical sections to pointer update operations, use of time-stamp based version control to support snapshot scans and range queries, and optimistic concurrency control with efficient in-memory conflict detection to support atomic read-modify-write operations.

63.7 Conclusion

The rise of big-data has resulted in the emergence of diverse set of data store designs and products tailored to meet different application needs. A key feature of these NoSQL and NewSQL big-data stores is the distributed storage needed to accommodate massive datasets (exabytes and beyond), and replication for fault tolerant operation. Meanwhile, application requirements are rapidly changing from traditional read-heavy workloads, to both read and write-heavy workloads. Currently, considerable research and industry efforts are focused on providing ACID properties to the new generation data stores. On the hardware side, solid state storage is increasingly being adopted in large data centers. Also, the increasing memory capacity and falling prices give rise to the possibility of some databases entirely residing in memory. With the rise of cloud computing, an emerging paradigm is that of database-as-a-service. Some of the challenges associated with this paradigm are outlined in the Beckman report on database research [66]. In this chapter, we have provided a brief overview of the techniques involved in the design of the these new generation data store with an emphasis on the data structures required to persist data. As big-data applications become more ubiquitous with stringent performance and power requirements, the coming years will likely see work on data structures that are highly scalable, concurrent, and adaptive [67].

64.1 Introduction

Recent years have witnessed an explosive growth in the amounts of data collected, stored, and disseminated by various organizations. Examples include (1) the large volumes of point-of-sale data amassed at the checkout counters of grocery stores, (2) the continuous streams of satellite images produced by Earth-observing satellites, and (3) the avalanche of data logged by network monitoring software. To illustrate how much the quantity of data has grown over the years, [Figure 64.1](#) shows an example of the number of Web pages indexed by a popular Internet search engine since 1998.

In each of the domains described above, data is collected to satisfy the information needs of the various organizations: Commercial enterprises analyze point-of-sale data to learn the purchase behavior of their customers; Earth scientists use satellite image data to advance their understanding of how the Earth system is changing in response to natural and human-related factors; and system administrators employ network traffic data to detect potential network problems, including those resulting from cyber-attacks.

One immediate difficulty encountered in these domains is how to extract useful information from massive data sets. Indeed, getting information out of the data is like *drinking from a fire hose*. The sheer size of the data simply overwhelms our ability to manually sift through the data, hoping to find useful information. Fueled by the need to rapidly analyze and summarize the data, researchers have turned to *data mining* techniques [1–5]. In a nutshell, data mining is the task of *discovering interesting knowledge automatically from large data repositories*.

Interesting knowledge has different meanings to different people. From a business perspective, knowledge is interesting if it can be used by analysts or managers to make profitable business decisions. For Earth Scientists, knowledge is interesting if it reveals previously unknown information about the characteristics of the Earth system. For system administrators, knowledge is interesting if it indicates unauthorized or illegitimate use of system resources.

Data mining is often considered to be an integral part of another process, called *Knowledge Discovery in Databases* (or KDD). KDD refers to the overall process of turning raw data into interesting knowledge and consists of a series of transformation steps, including data preprocessing, data mining, and postprocessing. The objective of data preprocessing is to convert data into the right format for subsequent analysis by selecting the appropriate data segments and extracting attributes that are relevant to the data mining task (feature selection and construction). For many practical applications, more than half of the knowledge discovery efforts are devoted to data preprocessing. Postprocessing includes all additional operations performed to make the data mining

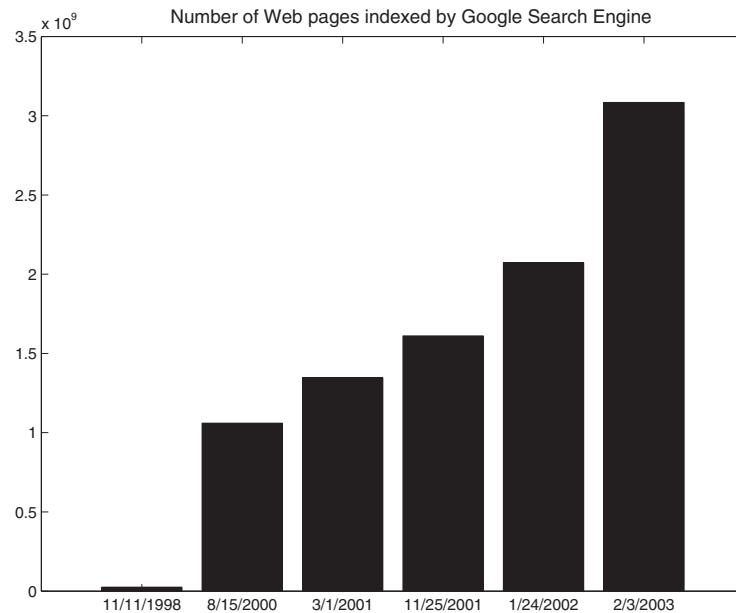

FIGURE 64.1 Number of Web pages indexed by the Google[®] search engine (Source: Internet Archive, <http://www.archive.org>).

results more accessible and easier to interpret. For example, the results can be sorted or filtered according to various *measures* to remove uninteresting patterns. In addition, *visualization* techniques can be applied to help analysts explore data mining results.

64.1.1 Data Mining Tasks and Techniques

Data mining tasks are often divided into two major categories:

Predictive The goal of predictive tasks is to use the values of some variables to predict the values of other variables. For example, in Web mining, e-tailers are interested in predicting which online users will make a purchase at their Web site. Other examples include biologists, who would like to predict the functions of proteins, and stock market analysts, who would like to forecast the future prices of various stocks.

Descriptive The goal of descriptive tasks is to find human-interpretable patterns that describe the underlying relationships in the data. For example, Earth Scientists are interested in discovering the primary forcings influencing observed climate patterns. In network intrusion detection, analysts want to know the kinds of cyber-attacks being launched against their networks. In document analysis, it is useful to find groups of documents, where the documents in each group share a common topic.

Data mining tasks can be accomplished using a variety of data mining techniques, as shown in [Figure 64.2](#).

- **Predictive modeling** is used primarily for predictive data mining tasks. The input data for predictive modeling consists of two distinct types of variables: (1) explanatory variables, which define the essential properties of the data, and (2) one or more target variables, whose values are to be predicted. For the Web mining example given in the previous section, the input variables correspond to the demographic features of online users, such as age, gender, and salary, along with their browsing activities, for example, what pages are accessed and for how long. There is one binary target variable, *Buy*, which has values, Yes or No, indicating, respectively, whether the user will buy anything from the Web site or not. Predictive modeling techniques can be further divided into two categories: *classification* and *regression*. Classification techniques are used to predict the values of discrete target variables, such as the *Buy* variable for online users at a Web site. For example, they can be used to predict whether a customer will most likely be lost to a competitor, that is, customer churn or attrition, and to determine the category of a star or galaxy for sky survey cataloging. Regression techniques are used to predict the values of continuous target variables, for example, they can be applied to forecast the future price of a stock.
- **Association rule mining** seeks to produce a set of dependence rules that predict the occurrence of a variable given the occurrences of other variables. For example, association analysis can be used to identify products that are often purchased together by sufficiently many customers, a task that is also known as *market basket analysis*. Furthermore, given a database that records a sequence of events, for example, a sequence of successive purchases by customers, an important task is that

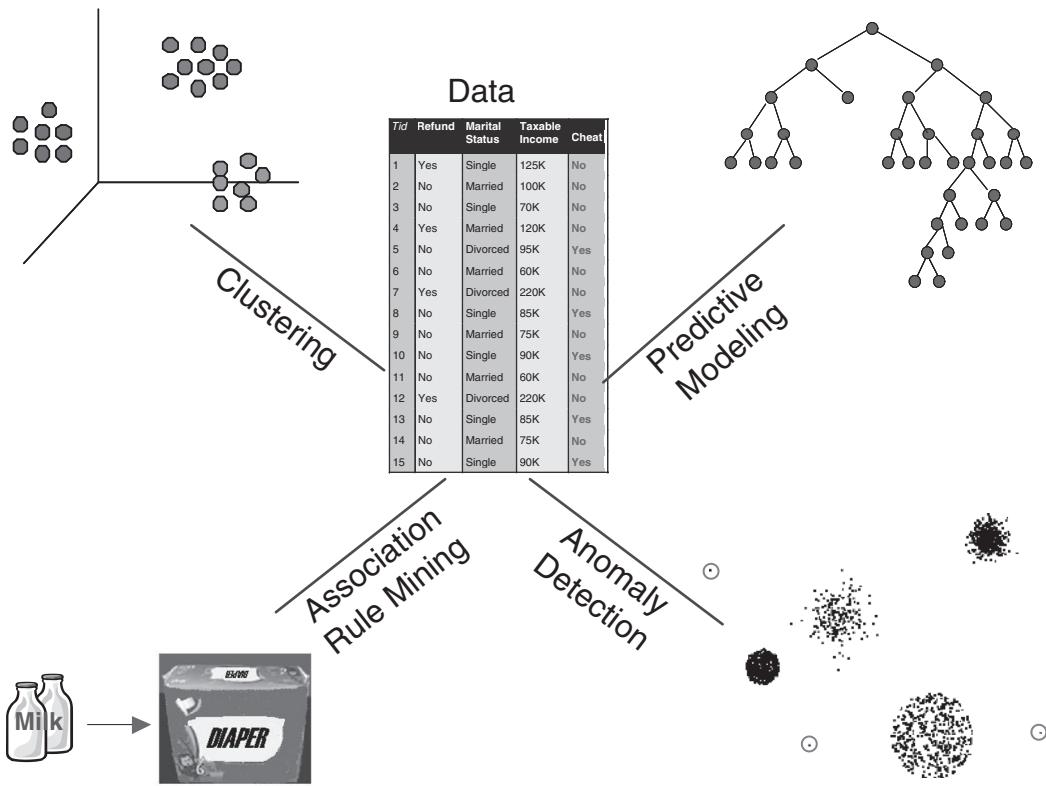

FIGURE 64.2 Data mining techniques.

of finding dependence rules that capture the temporal connections of events. This task is known as *sequential pattern analysis*.

- **Cluster analysis** finds groupings of data points so that data points that belong to one cluster are more similar to each other than to data points belonging to a different cluster, for example, clustering can be used to perform market segmentation of customers, document categorization, or land segmentation according to vegetation cover. While cluster analysis is often used to better understand or describe the data, it is also useful for summarizing a large data set. In this case, the objects belonging to a single cluster are replaced by a single *representative* object, and further data analysis is then performed using this reduced set of representative objects.
- **Anomaly detection** identifies data points that are significantly different than the rest of the points in the data set. Thus, anomaly detection techniques have been used to detect network intrusions and to predict fraudulent credit card transactions. Some approaches to anomaly detection are statistically based, while others are based on distance or graph-theoretic notions.

64.1.2 Challenges of Data Mining

There are several important challenges in applying data mining techniques to large data sets:

Scalability Scalable techniques are needed to handle the massive size of some of the datasets that are now being created. As an example, such datasets typically require the use of efficient methods for storing, indexing, and retrieving data from secondary or even tertiary storage systems. Furthermore, parallel or distributed computing approaches are often necessary if the desired data mining task is to be performed in a timely manner. While such techniques can dramatically increase the size of the datasets that can be handled, they often require the design of new algorithms and data structures.

Dimensionality In some application domains, the number of dimensions (or attributes of a record) can be very large, which makes the data difficult to analyze because of the “curse of dimensionality” [6]. For example, in bioinformatics, the development of advanced microarray technologies allows us to analyze gene expression data with thousands of attributes. The dimensionality of a data mining problem may also increase substantially due to the temporal, spatial, and sequential nature of the data.

Complex Data Traditional statistical methods often deal with simple data types such as continuous and categorical attributes. However, in recent years, more complicated types of structured and semi-structured data have become more important. One example of such data is graph-based data representing the linkages of web pages, social networks, or chemical structures. Another example is the free-form text that is found on most web pages. Traditional data analysis techniques often need to be modified to handle the complex nature of such data.

Data Quality Many data sets have one or more problems with data quality, for example, some values may be erroneous or inexact, or there may be missing values. As a result, even if a “perfect” data mining algorithm is used to analyze the data, the information discovered may still be incorrect. Hence, there is a need for data mining techniques that can perform well when the data quality is less than perfect.

Data Ownership and Distribution For a variety of reasons, for example, privacy and ownership, some collections of data are distributed across a number of sites. In many such cases, the data cannot be centralized, and thus, the choice is either distributed data mining or no data mining. Challenges involved in developing distributed data mining solutions include the need for efficient algorithms to cope with distributed and heterogeneous data sets, the need to minimize the cost of communication, and the need to accommodate data security and data ownership policies.

64.1.3 Data Mining and the Role of Data Structures and Algorithms

Research in data mining is motivated by a number of factors. In some cases, the goal is to develop an approach with greater efficiency. For example, a current technique may work well as long as all of the data can be held in main memory, but the size of data sets has grown to the point where this is no longer possible. In other cases, the goal may be to develop an approach that is more flexible. For instance, the nature of the data may be continually changing, and it may be necessary to develop a model of the data that can also change. As an example, network traffic varies in volume and kind, often over relatively short time periods. In yet other cases, the task is to obtain a more accurate model of the data, that is, one that takes into account additional factors that are common in many real world situations.

The development and success of new data mining techniques is heavily dependent on the creation of the proper algorithms and data structures to address the needs such as those just described: efficiency, flexibility, and more accurate models. (This is not to say that system or applications issues are unimportant.) Sometimes, currently existing data structures and algorithms can be directly applied, for example, data access methods can be used to efficiently organize and retrieve data. However, since currently existing data structures and algorithms were typically not designed with data mining tasks in mind, it is frequently the case that some modifications, enhancements, or completely new approaches are needed, that is, new work in data structures and algorithms is needed. We would emphasize, though, that sometimes it is the concepts and viewpoints associated with currently existing algorithms and data structures that are the most useful. Thus, the realization that a problem can be formulated as a particular type of a graph or tree may quickly lead to a solution.

In the following sections, we provide some examples of how data structures play an important role, both conceptually and practically, for classification, association analysis, and clustering.

64.2 Classification

Classification [7,8] is the task of assigning objects to their respective categories. For example, stock analysts are interested in classifying the stocks of publicly-owned companies as *buy*, *hold*, or *sell*, based on the financial outlook of these companies. Stocks classified as *buy* are expected to have stronger future revenue growth than those classified as *sell*. In addition to the practical uses of classification, it also helps us to understand the similarities and differences between objects that belong to different categories.

The data set in a classification problem typically consists of a collection of *records* or data objects. Each record, also known as an *instance* or *example*, is characterized by a tuple (\mathbf{x}, y) , where \mathbf{x} is the set of explanatory variables associated with the object and y is the object's class label. A record is said to be *labeled* if the value of y is known; otherwise, the record is *unlabeled*. Each attribute $x_k \in \mathbf{x}$ can be discrete or continuous. On the other hand, the class label y must be a discrete variable whose value is chosen from a finite set $\{y_1, y_2, \dots, y_c\}$. If y is a continuous variable, then this problem is known as *regression*.

The classification problem can be stated formally as follows:

Classification is the task of learning a function, $f : \mathbf{x} \rightarrow y$, that maps the explanatory variables \mathbf{x} of an object to one of the class labels for y .

f is known as the *target function* or *classification model*.

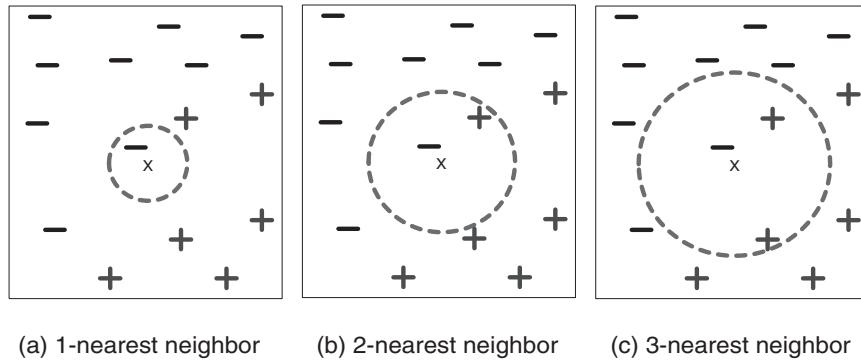

FIGURE 64.3 The 1-, 2- and 3-nearest neighbors of an instance.

(k : number of nearest neighbor, E : training instances, z : unlabeled instance)

- 1: Compute the distance or similarity of z to all the training instances
- 2: Let $E' \subset E$ be the set of k closest training instances to z
- 3: Return the predicted class label for z : $\text{class} \leftarrow \text{Voting}(E')$.

FIGURE 64.4 k -nearest neighbor classification algorithm.

64.2.1 Nearest-Neighbor Classifiers

Typically, the classification framework presented involves a two-step process: (1) an inductive step for constructing classification models from data, and (2) a deductive step for applying the derived model to previously unseen instances. For decision tree induction and rule-based learning systems, the models are constructed immediately after the training set is provided. Such techniques are known as *eager learners* because they intend to learn the model as soon as possible, once the training data is available.

An opposite strategy would be to delay the process of generalizing the training data until it is needed to classify the unseen instances. One way to do this is to find all training examples that are relatively similar to the attributes of the test instance. Such examples are known as the nearest neighbors of the test instance. The test instance can then be classified according to the class labels of its neighbors. This is the central idea behind the *nearest-neighbor classification* scheme [8–11], which is useful for classifying data sets with continuous attributes. A nearest neighbor classifier represents each instance as a data point embedded in a d -dimensional space, where d is the number of continuous attributes. Given a test instance, we can compute its distance to the rest of the data objects (data points) in the training set by using an appropriate distance or similarity measure, for example, the standard Euclidean distance measure.

The k -nearest neighbors of an instance z are defined as the data points having the k smallest distances to z . Figure 64.3 illustrates an example of the 1-, 2- and 3-nearest neighbors of an unknown instance, x , located at the center of the circle. The instance can be assigned to the class label of its nearest neighbors. If the nearest neighbors contain more than one class label, then one takes a majority vote among the class labels of the nearest neighbors.

The nearest data point to the unknown instance shown in Figure 64.3a has a negative class label. Thus, in a 1-nearest neighbor classification scheme, the unknown instance would be assigned to a negative class. If we consider a larger number of nearest neighbors, such as three, the list of nearest neighbors would contain training examples from 2 positive classes and 1 negative class. Using the majority voting scheme, the instance would be classified as a positive class. If the number of instances from both classes are the same, as in the case of the 2-nearest neighbor classification scheme shown in Figure 64.3b, we could choose either one of the classes (or the default class) as the class label.

A summary of the k -nearest neighbor classification algorithm is given in Figure 64.4. Given an unlabeled instance, we need to determine its distance or similarity to all the training instances. This operation can be quite expensive and may require efficient indexing techniques to reduce the amount of computation.

While one can take a majority vote of the nearest neighbors to select the most likely class label, this approach may not be desirable because it assumes that the influence of each nearest neighbor is the same. An alternative approach is to weight the influence of each nearest neighbor according to its distance, so that the influence is weaker if the distance is too large.

64.2.2 Proximity Graphs for Enhancing Nearest Neighbor Classifiers

The nearest neighbor classification scheme, while simple, has a serious problem as currently presented: It is necessary to store all of the data points, and to compute the distance between an object to be classified and all of these stored objects. If the set of

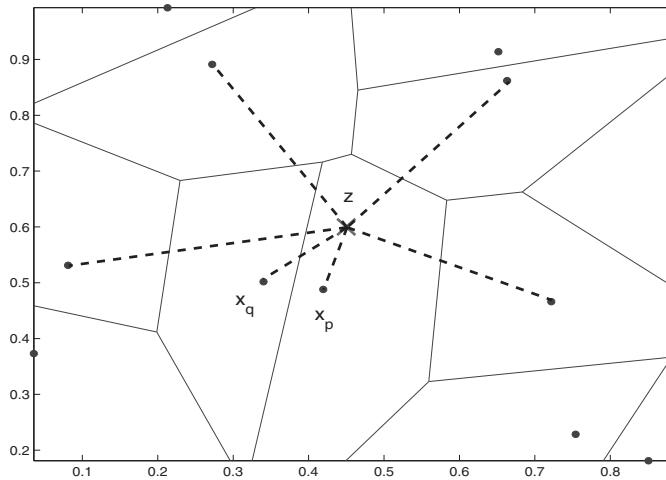

FIGURE 64.5 Voronoi diagram.

original data points is large, then this can be a significant computational burden. Hence, a considerable amount of research has been conducted into strategies to alleviate this problem.

There are two general strategies for addressing the problem just discussed:

Condensing The idea is that we can often eliminate many of the data points without affecting classification performance, or without affecting it very much. For instance, if a data object is in the “middle” of a group of other objects with the same class, then its elimination will likely have no effect on the nearest neighbor classifier.

Editing Often, the classification performance of a nearest neighbor classifier can be enhanced by deleting certain data points. More specifically, if a given object is compared to its nearest neighbors and most of them are of another class (i.e., if the points that would be used to classify the given point are of another class), then deleting the given object will often improve classifier performance.

While various approaches to condensing and editing points to improve the performance of nearest neighbor classifiers have been proposed, there has been a considerable amount of work that approaches this problem from the viewpoint of computational geometry, especially proximity graphs [12]. Proximity graphs include nearest neighbor graphs, minimum spanning trees, relative neighborhood graphs, Gabriel graphs, and the Delaunay triangulation [13]. We can only indicate briefly the usefulness of this approach, and refer the reader to [12] for an in depth discussion.

First, we consider how Voronoi diagrams can be used to eliminate points that add nothing to the classification. (The Voronoi diagram for a set of data points is the set of polygons formed by partitioning all of points in the space into a set of convex regions such that every point in a region is closer to the data point in the same region than to any other data point. [Figure 64.5](#) shows a Voronoi diagram for a number of two-dimensional points.) Specifically, if all the Voronoi neighbors of a point, that is, those points belonging to Voronoi regions that touch the Voronoi region of the given point, have the same class as the given data point, then discarding that point cannot affect the classification performance. The reason for this is that the Voronoi regions of the neighboring points will expand to “occupy” the space once occupied by the Voronoi region of the given point, and thus, classification behavior is unchanged. More sophisticated approaches based on proximity graphs are possible [12].

For editing, that is, discarding points to approve classification performance, proximity graphs can also be useful. In particular, instead of eliminating data points whose k nearest neighbors are of a different class, we build a proximity graph and eliminate those points where a majority of the neighbors in the proximity graph are of a different class. Of course, the results will depend on the type of proximity graph. The Gabriel graph has been found to be the best, but for further discussion, we once again refer the reader to [12], and the extensive list of references that it contains.

In summary, our goal in this section was to illustrate that—for one particular classification scheme, nearest neighbor classification—the rich set of data structures and algorithms of computational geometry, that is, proximity graphs, have made a significant contribution, both practically and theoretically.

64.3 Association Analysis

An important problem in data mining is the discovery of association patterns [14] present in large databases. This problem was originally formulated in the context of *market basket* data, where the goal is to determine whether the occurrence of certain items

TID	Items
1	Bread, Coke, Milk
2	Beer, Bread
3	Beer, Coke, Diaper, Milk
4	Beer, Bread, Diaper, Milk
5	Coke, Diaper, Milk

FIGURE 64.6 Market-basket transactions.

in a transaction can be used to infer the occurrence of other items. If such interesting relationships are found, then they can be put to various profitable uses such as marketing promotions, shelf management, inventory management, etc.

To formalize the problem, let $T = \{t_1, t_2, \dots, t_N\}$ be the set of all transactions and $I = \{i_1, i_2, \dots, i_d\}$ be the set of all items. Any subset of I is known as an *itemset*. The *support count* of an itemset C is defined as the number of transactions in T that contain C , that is,

$$\sigma(C) = |\{t | t \in T, C \subseteq t\}|.$$

An *association rule* is an implication of the form $X \rightarrow Y$, where X and Y are itemsets and $X \cap Y = \emptyset$. The strength of an association rule is given by its *support* (s) and *confidence* (c) measures. The support of the rule is defined as the fraction of transactions in T that contain itemset $X \cup Y$.

$$s(X \rightarrow Y) = \frac{\sigma(X \cup Y)}{|T|}.$$

Confidence, on the other hand, provides an estimate of the conditional probability of finding items of Y in transactions that contain X .

$$c(X \rightarrow Y) = \frac{\sigma(X \cup Y)}{\sigma(X)}$$

For example, consider the market basket transactions shown in Figure 64.6. The support for the rule $\{\text{Diaper}, \text{Milk}\} \rightarrow \{\text{Beer}\}$ is $\sigma(\{\text{Diaper}, \text{Milk}, \text{Beer}\})/5 = 2/5 = 40\%$, whereas its confidence is $\sigma(\{\text{Diaper}, \text{Milk}, \text{Beer}\})/\sigma(\{\text{Diaper}, \text{Milk}\}) = 2/3 = 66\%$.

Support is useful because it reflects the significance of a rule. Rules that have very low support are rarely observed, and thus, are more likely to occur by chance. Confidence is useful because it reflects the reliability of the inference made by each rule. Given an association rule $X \rightarrow Y$, the higher the confidence, the more likely it is to find Y in transactions that contain X . Thus, the goal of association analysis is to automatically discover association rules having relatively high support and high confidence. More specifically, an association rule is considered to be interesting only if its support is greater than or equal to a minimum support threshold, *minsup*, and its confidence is greater than or equal to a minimum confidence threshold, *minconf*.

The association analysis problem is far from trivial because of the exponential number of ways in which items can be grouped together to form a rule. In addition, the rules are constrained by two completely different conditions, stated in terms of the *minsup* and *minconf* thresholds. A standard way for generating association rules is to divide the process into two steps. The first step is to find all itemsets that satisfy the minimum support threshold. Such itemsets are known as *frequent itemsets* in the data mining literature. The second step is to generate high-confidence rules only from those itemsets found to be frequent. The completeness of this two-step approach is guaranteed by the fact that any association rule $X \rightarrow Y$ that satisfies the *minsup* requirement can always be generated from a frequent itemset $X \cup Y$.

Frequent itemset generation is the computationally most expensive step because there are 2^d possible ways to enumerate all itemsets from I . Much research has therefore been devoted to developing efficient algorithms for this task. A key feature of these algorithms lies in their strategy for controlling the exponential complexity of enumerating candidate itemsets. Briefly, the algorithms make use of the anti-monotone property of itemset support, which states that all subsets of a frequent itemset must be frequent. Put another way, if a candidate itemset is found to be infrequent, we can immediately prune the search space spanned by supersets of this itemset. The *Apriori* algorithm, developed by Agrawal et al. [15], pioneered the use of this property to systematically enumerate the candidate itemsets. During each iteration k , it generates only those *candidate* itemsets of length k whose $(k-1)$ -subsets are found to be frequent in the previous iteration. The support counts of these candidates are then determined by scanning the transaction database. After counting their supports, candidate k -itemsets that pass the *minsup* threshold are declared to be frequent.

Well-designed data structures are central to the efficient mining of association rules. The *Apriori* algorithm, for example, employs a hash-tree structure to facilitate the support counting of candidate itemsets. On the other hand, algorithms such as FP-growth [16] and H-Miner [17] employ efficient data structures to provide a compact representation of the transaction database. A brief description of the hash tree and FP-tree data structures is presented next.

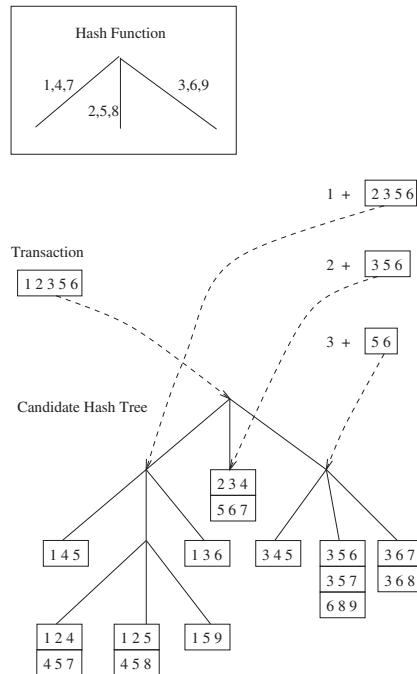

FIGURE 64.7 Hashing a transaction at the root node of a hash tree.

64.3.1 Hash Tree Structure

Apriori is a level-wise algorithm that generates frequent itemsets one level at a time, from itemsets of size-1 up to the longest frequent itemsets. At each level, candidate itemsets are generated by extending the frequent itemsets found at the previous level. Once the candidate itemsets have been enumerated, the transaction database is scanned once to determine their actual support counts. This generate-and-count procedure is repeated until no new frequent itemsets are found.

Support counting of candidate itemsets is widely recognized as the key bottleneck of frequent itemset generation. This is because one has to determine the candidate itemsets contained in each transaction of the database. A naive way for doing this is to simply match each transaction against every candidate itemset. If the candidate is a subset of the transaction, its support count is incremented. This approach can be prohibitively expensive if the number of candidates and number of transactions are large.

In the *Apriori* algorithm, candidate itemsets are hashed into different buckets and stored in a hash tree structure. During support counting, each transaction is also hashed into its appropriate buckets. This way, instead of matching a transaction against all candidate itemsets, the transaction is matched only to those candidates that belong to the same bucket.

Figure 64.7 illustrates an example of a hash tree for storing candidate itemsets of size 3. Each internal node of the hash tree contains a hash function that determines which branch of the current node is to be followed next. The hash function used by the tree is also shown in this figure. Specifically, items 1, 4 and 7 are hashed to the left child of the node; items 2, 5, 8 are hashed to the middle child; and items 3, 6, 9 are hashed to the right child. Candidate itemsets are stored at the leaf nodes of the tree. The hash tree shown in Figure 64.7 contains 15 candidate itemsets, distributed across 9 leaf nodes.

We now illustrate how to enumerate candidate itemsets contained in a transaction. Consider a transaction t that contains five items, $\{1, 2, 3, 5, 6\}$. There are ${}^5C_3 = 10$ distinct itemsets of size 3 contained in this transaction. Some of these itemsets may correspond to the candidate 3-itemsets under investigation, in which case, their support counts are incremented. Other subsets of t that do not correspond to any candidates can be ignored.

Figure 64.8 shows a systematic way for enumerating size-3 itemsets contained in the transaction t by specifying the items one-by-one. It is assumed that items in every 3-itemset are stored in increasing lexicographic order. Because of the ordering constraint, all itemsets of size-3 derived from t must begin with item 1, 2, or 3. No 3-itemset may begin with item 5 or 6 because there are only two items in this transaction that are greater than or equal to 5. This is illustrated by the level 1 structures depicted in Figure 64.8. For example, the structure 1 [2 3 5 6] represents an itemset that begins with 1, followed by two more items chosen from the set {2, 3, 5, 6}.

After identifying the first item, the structures at level 2 denote the various ways to select the second item. For example, the structure 1 2 [3 5 6] corresponds to itemsets with prefix (1 2), followed by either item 3, 5, or 6. Once the first two items have

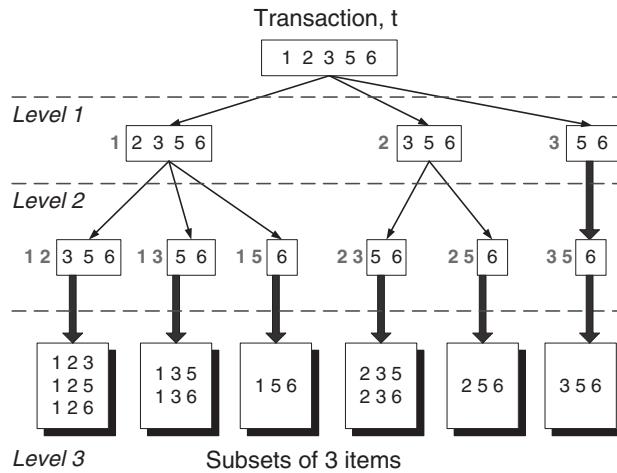

FIGURE 64.8 Enumerating subsets of three items from a transaction t .

been chosen, the structures at level 3 represent the complete set of 3-itemsets derived from transaction t . For example, the three itemsets beginning with the prefix {1 2} are shown in the leftmost box at level 3 of this figure.

The tree-like structure shown in Figure 64.8 is simply meant to demonstrate how subsets of a transaction can be enumerated, that is, by specifying the items in the 3-itemsets one-by-one, from its left-most item to its right-most item. For support counting, we still have to match each subset to its corresponding candidate. If there is a match, then the support count for the corresponding candidate is incremented.

We now describe how a hash tree can be used to determine candidate itemsets contained in the transaction $t = \{1, 2, 3, 5, 6\}$. To do this, the hash tree must be traversed in such a way that all leaf nodes containing candidate itemsets that belong to t are visited. As previously noted, all size-3 candidate itemsets contained in t must begin with item 1, 2, or 3. Therefore, at the root node of the hash tree, we must hash on items 1, 2, and 3 separately. Item 1 is hashed to the left child of the root node; item 2 is hashed to the middle child of the root node; and item 3 is hashed to the right child of the root node. Once we reach a child of the root node, we need to hash on the second item of the level 2 structures given in Figure 64.8. For example, after hashing on item 1 at the root node, we need to hash on items 2, 3, and 5 at level 2. Hashing on items 2 or 5 will lead us to the middle child node while hashing on item 3 will lead us to the right child node, as depicted in Figure 64.9. This process of hashing on items that belong to the transaction continues until we reach the leaf nodes of the hash tree. Once a leaf node is reached, all candidate itemsets stored at the leaf are compared against the transaction. If a candidate belongs to the transaction, its support count is incremented. In this example, 6 out of the 9 leaf nodes are visited and 11 out of the 15 itemsets are matched against the transaction.

64.3.2 FP-Tree Structure

Recently, an interesting algorithm called FP-growth was proposed that takes a radically different approach to discovering frequent itemsets. The algorithm does not subscribe to the generate-and-count paradigm of Apriori. It encodes the database using a compact data structure called an FP-tree and infers frequent itemsets directly from this structure.

First, the algorithm scans the database once to find the frequent singleton items. An order is then imposed on the items based on decreasing support counts. Figure 64.10 illustrates an example of how to construct an FP-tree from a transaction database that contains five items, A, B, C, D, and E. Initially, the FP-tree contains only the root node, which is represented by a null symbol. Next, each transaction is used to create a path from the root node to some node in the FP-tree.

After reading the first transaction, {A, B}, a path is formed from the root node to its child node, labeled as A, and subsequently, to another node labeled as B. Each node in the tree contains the symbol of the item along with a count of the transactions that reach the particular node. In this case, both nodes A and B would have a count equal to one. After reading the second transaction {B,C,D} a new path extending from `null` → B → C → D is created. Again, the nodes along this path have support counts equal to one. When the third transaction is read, the algorithm will discover that this transaction shares a common prefix A with the first transaction. As a result, the path `null` → A → C → D is merged to the existing path `null` → A → B. The support count for node A is incremented to two, while the newly-created nodes, C and D, each have a support count equal to one. This process is repeated until all the transactions have been mapped into one of the paths in the FP-tree. For example, the state of the FP-tree after reading the first ten transactions is shown at the bottom of Figure 64.10.

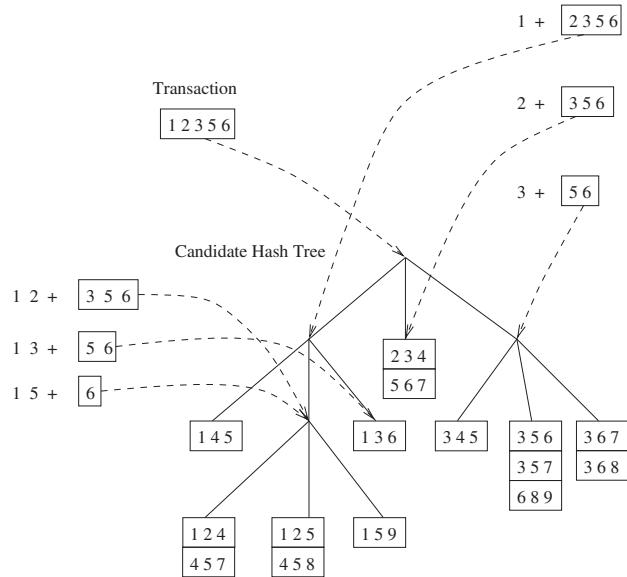

FIGURE 64.9 Subset operation on the left most subtree of the root of a candidate hash tree.

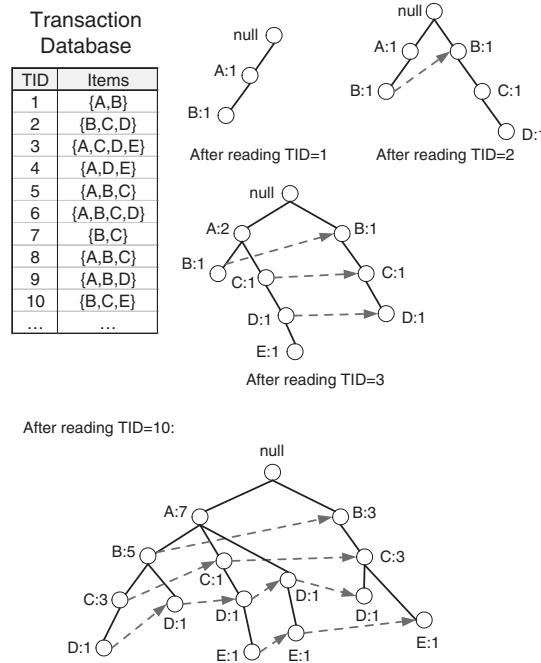

FIGURE 64.10 Construction of an FP-tree.

By looking at the way the tree is constructed, we can see why an FP-tree provides a compact representation of the database. If the database contains many transactions that share common items, then the size of an FP-tree will be considerably smaller than the size of the database. The best-case scenario would be that the database contains the same set of items for all transactions. The resulting FP-tree would contain only a single branch of nodes. The worst-case scenario would be that each transaction contains a unique set of items. In this case, there is no sharing of transactions among the nodes and the size of the FP-tree is the same as the size of the database.

During tree construction, the FP-tree structure also creates a linked-list access mechanism for reaching every individual occurrence of each frequent item used to construct the tree. In the above example, there are five such linked lists, one for each item, A, B, C, D, and E.

```

1: Initialization: Select  $K$  points as the initial centroids.
2: repeat
3:   Form  $K$  clusters by assigning all points to the closest centroid.
4:   Recompute the centroid of each cluster.
5: until The centroids do not change

```

FIGURE 64.11 Basic K-means algorithm.

The algorithm used for generating frequent itemsets from an FP-tree is known as *FP-growth*. Given the FP-tree shown in [Figure 64.10](#), the algorithm divides the problem into several subproblems, where each subproblem involves finding frequent itemsets having a particular suffix. In this example, the algorithm initially looks for frequent itemsets that end in E by following the linked list connecting the nodes for E. After all frequent itemsets ending in E are found, the algorithm looks for frequent itemsets that end in D by following the linked list for D, and so on.

How does FP-growth find all the frequent itemsets ending in E? Recall that an FP-tree stores the support counts of every item along each path, and that these counts reflect the number of transactions that are collapsed onto that particular path. In our example, there are only three occurrences of the node E. By collecting the *prefix paths* of E, we can solve the subproblem of finding frequent itemsets ending in E. The prefix paths of E consist of all paths starting from the root node up to the parent nodes of E. These prefix paths can form a new FP-tree to which the FP-growth algorithm can be recursively applied.

Before creating a new FP-tree from the prefix paths, the support counts of items along each prefix path must be updated. This is because the initial prefix path may include several transactions that do not contain the item E. For this reason, the support count of each item along the prefix path must be adjusted to have the same count as node E for that particular path. After updating the counts along the prefix paths of E, some items may no longer be frequent, and thus, must be removed from further consideration (as far as our new subproblem is concerned). An FP-tree of the prefix paths is then constructed by removing the infrequent items. This recursive process of breaking the problem into smaller subproblems will continue until the subproblem involves only a single item. If the support count of this item is greater than the minimum support threshold, then the label of this item will be returned by the FP-growth algorithm. The returned label is appended as a prefix to the frequent itemset ending in E.

64.4 Clustering

Cluster analysis [18–21] groups data objects based on information found in the data that describes the objects and their relationships. The goal is that the objects in a group be similar (or related) to one another and different from (or unrelated to) the objects in other groups. The greater the similarity (or homogeneity) within a group, and the greater the difference between groups, the “better” or more distinct the clustering.

64.4.1 Hierarchical and Partitional Clustering

The most commonly made distinction between clustering techniques is whether the resulting clusters are nested or unnested or, in more traditional terminology, whether a set of clusters is *hierarchical* or *partitional*. A partitional or unnested set of clusters is simply a division of the set of data objects into non-overlapping subsets (clusters) such that each data object is in exactly one subset, that is, a partition of the data objects. The most common partitional clustering algorithm is K-means, whose operation is described by the psuedo-code in [Figure 64.11](#). (K is a user specified parameter, that is, the number of clusters desired, and a centroid is typically the mean or median of the points in a cluster.)

A hierarchical or nested clustering is a set of nested clusters organized as a hierarchical tree, where the leaves of the tree are singleton clusters of individual data objects, and where the cluster associated with each interior node of the tree is the union of the clusters associated with its child nodes. Typically, hierarchical clustering proceeds in an agglomerative manner, that is, starting with each point as a cluster, we repeatedly merge the closest clusters, until only one cluster remains. A wide variety of methods can be used to define the distance between two clusters, but this distance is typically defined in terms of the distances between pairs of points in different clusters. For instance, the distance between clusters may be the minimum distance between any pair of points, the maximum distance, or the average distance. The algorithm for agglomerative clustering is described by the psuedo-code in [Figure 64.12](#).

The tree that represents a hierarchical clustering is called a *dendrogram*, a term that comes from biological taxonomy. [Figure 64.13](#) shows six points and the hierarchical clustering that is produced by the MIN clustering technique. This approach creates a hierarchical clustering by starting with the individual points as clusters, and then successively merges pairs of clusters with the minimum distance, that is, that have the closest pair of points.

- 1: Compute the pairwise distance matrix.
- 2: **repeat**
- 3: Merge the closest two clusters.
- 4: Update the distance matrix to reflect the distance between the new cluster and the original clusters.
- 5: **until** Only one cluster remains

FIGURE 64.12 Basic agglomerative hierarchical clustering algorithm.

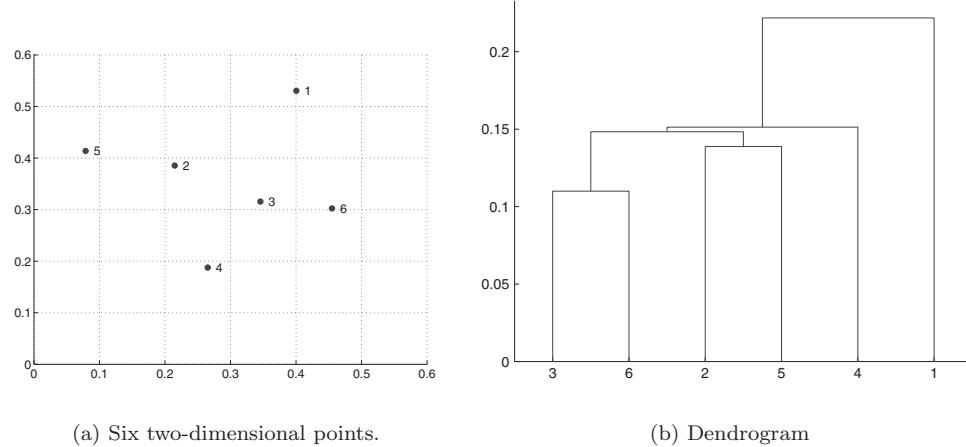

FIGURE 64.13 A hierarchical clustering of six points.

64.4.2 Nearest Neighbor Search and Multi-Dimensional Access Methods

In both the K-means and agglomerative hierarchical clustering algorithms, the time required is heavily dependent on the amount of time that it takes to find the the distance between sets of points—step 3 in both algorithms. This is true of most other clustering schemes as well, and thus, efficient implementations of clustering techniques often require considerations of nearest-neighbor search and the related area of multi-dimensional access methods. In the remainder of this section, we discuss these areas and their relevance to cluster analysis.

We begin by considering a general situation. Given a set of objects or data points, including possibly complicated data such as images, text strings, DNA sequences, polygons, etc., two issues are key to efficiently utilizing this data:

1. **How can items be located efficiently?** While a “representative” feature vector is commonly used to “index” these objects, these data points will normally be very sparse in the space, and thus, it is not feasible to use an array to store the data. Also, many sets of data do not have any features that constitute a “key” that would allow the data to be accessed using standard and efficient database techniques.
2. **How can similarity queries be efficiently conducted?** Many applications, including clustering, require the nearest neighbor (or the k nearest neighbors) of a point. For instance, the clustering techniques DBSCAN [22] and Chameleon [23] will have a time complexity of $O(n^2)$ unless they can utilize data structures and algorithms that allow the nearest neighbors of a point to be located efficiently. As a non-clustering example of an application of similarity queries, a user may want to find all the pictures similar to a particular photograph in a database of photographs.

Techniques for nearest-neighbor search are often discussed in papers describing multi-dimensional access methods or spatial access methods, although strictly speaking the topic of multi-dimensional access methods is broader than nearest-neighbor search since it addresses all of the many different types of queries and operations that a user might want to perform on multi-dimensional data. A large amount of work has been done in the area of nearest neighbor search and multi-dimensional access methods. Examples of such work include the kdb tree [24,25], the R [26] tree, the R* tree [27], the SS-tree [28], the SR-tree [29], the X-tree [30], the GNAT tree [31], the M-tree [32], the TV tree [33], the hB tree [34], the “pyramid technique” [35], and the “hybrid” tree [36]. A good survey of nearest-neighbor search, albeit from the slightly more general perspective of multi-dimensional access methods is given by [37].

As indicated by the prevalence of the word “tree” in the preceding references, a common approach for nearest neighbor search is to create tree-based structures, such that the “closeness” of the data increases as the tree is traversed from top to bottom. Thus,

```

1: Add the children of the root node to a search queue
2: while the search queue is not empty do
3:   Take a node off the search queue
4:   if that node and its descendants are not ‘close enough’ to be considered for the search then
5:     Discard the subtree represented by this node
6:   else
7:     if the node is not a leaf node, i.e., a data point then
8:       Add the children of this node to a search queue
9:     else {if the node is a leaf node}
10:      add the node to a list of possible solutions
11:    end if
12:  end if
13: end while
14: Sort the list of possible solutions by distance from the query point and return the k-nearest neighbors

```

FIGURE 64.14 Basic algorithm for a nearest neighbor query.

the nodes towards the bottom of the tree and their children can often be regarded as representing “clusters” of data that are relatively cohesive. In the reverse directions, we also view clustering as being potentially useful for finding nearest neighbors. Indeed, one of the simplest techniques for generating a nearest neighbor tree is to cluster the data into a set of clusters and then, recursively break each cluster into subclusters until the subclusters consist of individual points. The resulting cluster tree tree consists of the clusters generated along the way. Regardless of how a nearest neighbor search tree is obtained, the general approach for performing a k -nearest-neighbor query is given by the algorithm in Figure 64.14.

This seems fairly straightforward and, thus it seems as though nearest neighbor trees should be useful for clustering data, or conversely, that clustering would be a practical way to find nearest neighbors based on the results of clustering. However, there are some problems.

Goal Mismatch One of the goals of many nearest-neighbor tree techniques is to serve as efficient secondary storage based access methods for non-traditional databases, for example, spatial databases, multimedia databases, document databases, etc. Because of requirements related to page size and efficient page utilization, “natural” clusters may be split across pages or nodes. Nonetheless, data is normally highly “clustered” and this can be used for actual clustering as shown in [38], which uses an R* tree to improve the efficiency of a clustering algorithm introduced in [39].

Problems with High-dimensional Data Because of the nature of nearest-neighbor trees, the tree search involved is a branch-and-bound technique and needs to search large parts of the tree, that is, at any particular level, many children and their descendants may need to be examined. To see this, consider a point and all points that are within a given distance of it. This hyper-sphere (or hyper-rectangle in the case of multi-dimensional range queries) may very well cut across a number of nodes (clusters)—particularly if the point is on the edge of a cluster and/or the query distance being considered is greater than the distance between clusters. More specifically, it is difficult for the algorithms that construct nearest neighbor trees to avoid a significant amount of overlap in the volumes represented by different nodes in the tree. In [30], it has been shown that the degree of overlap in a frequently used nearest neighbor tree, the R* tree, approaches 100% as the dimensionality of the vectors exceeds 5. Even in two dimensions the overlap was about 40%. Other nearest neighbor search techniques suffer from similar problems.

Furthermore, in [40] it was demonstrated that the concept of “nearest neighbor” is not meaningful in many situations, since the minimum and maximum distances of a point to its neighbors tend to be very similar in high dimensional space. Thus, unless there is significant clustering in the data and the query ranges stay within individual clusters, the points returned by nearest neighbor queries are not much closer to the query point than are the points that are not returned. In this latter case, the nearest neighbor query is ‘unstable’, to use the terminology of [40]. Recently, for example, in [35], there has been some work on developing techniques that avoid this problem. Nonetheless, in some cases, a linear scan can be more efficient at finding nearest neighbors than more sophisticated techniques.

Outliers Typically, outliers are not discarded, that is, all data points are stored. However, if some of the data points do not fit into clusters particularly well, then the presence of outliers can have deleterious effects on the lookups of other data points.

To summarize, there is significant potential for developments in the areas of nearest neighbor search and multidimensional access methods to make a contribution to cluster analysis. The contribution to efficiency is obvious, but the notions of distance (or similarity) are central to both areas, and thus, there is also the possibility of conceptual contributions as well. However,

currently, most clustering methods that utilize nearest neighbor search or multidimensional access methods are interested only in the efficiency aspects [38,41,42].

64.5 Conclusion

In this chapter we have provided some examples to indicate the role that data structures play in data mining. For classification, we indicated how proximity graphs can play an important role in understanding and improving the performance of nearest neighbor classifiers. For association analysis, we showed how data structures are currently used to address the exponential complexity of the problem. For clustering, we explored its connection to nearest neighbor search and multi-dimensional access methods—a connection that has only been modestly exploited.

Data mining is a rapidly evolving field, with new problems continually arising, and old problems being looked at in the light of new developments. These developments pose new challenges in the areas of data structures and algorithms. Some of the most promising areas in current data mining research include multi-relational data mining [43–45], mining streams of data [46], privacy preserving data mining [47], and mining data with complicated structures or behaviors, for example, graphs [45,48] and link analysis [49,50].

65.1 Introduction

Computational geometry deals with the design and analysis of algorithms and data structures for problems involving spatial data. The questions that are studied range from basic problems such as line-segment intersection (“Compute all intersection points in a given set of line segments in the plane.”) to quite involved problems such as motion-planning (“Compute a collision-free path for a robot in workspace from a given start position to a given goal position.”) Because spatial data plays an important role in many areas within and outside of computer science—CAD/CAM, computer graphics and virtual reality, and geography are just a few examples—computational geometry has a broad range of applications. Computational geometry emerged from the general algorithms area in the late 1970s. It experienced a rapid growth in the 1980s and by now is a recognized discipline with its own conferences and journals and many researchers working in the area. It is a beautiful field with connections to other areas of algorithms research, to application areas like the ones mentioned earlier, and to areas of mathematics such as combinatorial geometry.

To design an efficient geometric algorithm or data structure, one usually needs two ingredients: a toolbox of algorithmic techniques and geometric data structures and a thorough understanding of the geometric properties of the problem at hand. As an example, consider the classic *post-office problem*, where we want to preprocess a set S of n points in the plane—the points in S are usually called *sites*—for the following queries: report the site in S that is closest to a query point q . A possible approach is to subdivide the plane into n regions, one for each site, such that the region of a site $s \in S$ consists of exactly those points $q \in \mathbb{R}^2$ for which s is the closest site. This subdivision is called the Voronoi diagram of S . A query with a point q can now be answered by locating the region in which q lies, and reporting the site defining that region. To make this idea work, one needs an efficient data structure for point location. But one also needs to understand the geometry: What does the Voronoi diagram look like? What is its complexity? How can we construct it efficiently?

In Part IV, many data structures for spatial data were already discussed. Hence, in this chapter we will focus on the second ingredient: we will discuss a number of basic geometric concepts. In particular, we will discuss arrangements in Section 65.2, convex hulls in Section 65.3, Voronoi diagrams in Section 65.4, and triangulations in Section 65.5.

More information on computational geometry can be found in various sources: there are several general textbooks on computational geometry [1–4], as well as more specialized books, for example, on arrangements [5,6] and Voronoi diagrams [7]. Finally, there are two handbooks that are devoted solely to (discrete and) computational geometry [8,9].

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

65.2 Arrangements

The arrangement $\mathcal{A}(S)$ defined by a finite collection S of curves in the plane is the subdivision of the plane into open cells of dimensions 2 (the *faces*), 1 (the *edges*), and 0 (the *vertices*), induced by S —see [Figure 65.1](#) for an example. This definition generalizes readily to higher dimensions: the arrangement defined by a set S of geometric objects in \mathbb{R}^d such as hyperplanes or surfaces, is the decomposition of \mathbb{R}^d into open cells of dimensions 0, …, d induced by S . The cells of dimension k are usually called k -*cells*. The 0-cells are called *vertices*, the 1-cells are called *edges*, the 2-cells are called *faces*, the $(d - 1)$ -cells are called *facets*, and the d -cells are sometimes just called *cells*.

Arrangements have turned out to form a fundamental concept underlying many geometric problems and the efficiency of geometric algorithms is often closely related to the combinatorial complexity of (certain parts of) some arrangement. Moreover, to solve a certain problem geometric algorithms often rely on some decomposition of the arrangement underlying the problem. Hence, the following subsections give some more information on the complexity and the decomposition of arrangements.

65.2.1 Substructures and Complexity

Let H be a collection of n hyperplanes in \mathbb{R}^d . As stated earlier, the arrangement $\mathcal{A}(H)$ is the decomposition of \mathbb{R}^d into open cells of dimensions 0, …, d induced by H . The *combinatorial complexity* of $\mathcal{A}(H)$ is defined to be the total number of cells of the various dimensions. This definition immediately carries over to arrangements induced by other objects, such as segments in the plane, or surfaces in \mathbb{R}^d . For example, the complexity of the arrangement in [Figure 65.1](#) is 58, since it consists of 27 vertices, 27 edges, and 4 faces (one of which is the unbounded face).

It is easy to see that the maximum complexity of an arrangement of n lines in the plane is $\Theta(n^2)$: there can be at most $n(n - 1)/2$ vertices, at most n^2 edges, and at most $n^2/2 + n/2 + 1$ faces. Also for an arrangement of curves the maximum complexity is $\Theta(n^2)$, provided that any pair of curves intersect at most s times, for a constant s . More generally, the maximum complexity of an arrangement of n hyperplanes in \mathbb{R}^d is $\Theta(n^d)$. The same bound holds for well-behaved surfaces (such as algebraic surfaces of constant maximum degree) or well-behaved surface patches in \mathbb{R}^d .

Single cells. It becomes more challenging to bound the complexity when we consider only a part of an arrangement. For example, what is the maximum complexity of a *single cell*, that is, the maximum number of i -cells, for $i < d$, on the boundary of any given d -cell? For lines in the plane this is still rather easy—the maximum complexity is $\Theta(n)$, since any line can contribute at most one edge to a given face—but the question is already quite hard for arrangements of line segments in the plane. Here it turns out that the maximum complexity can be $\Theta(n\alpha(n))$, where $\alpha(n)$ is the extremely slowly growing functional inverse of Ackermann's function. More generally, for Jordan curves where each pair intersects in at most s points, the maximum complexity is $\Theta(\lambda_{s+2}(n))$, where $\lambda_{s+2}(n)$ is the maximum length of a Davenport-Schinzel sequence of order $s + 2$ on n symbols. The function $\lambda_{s+2}(n)$ is only slightly super-linear for any constant s . In higher dimensions, tight bounds are known for hyperplanes: the famous *Upper Bound Theorem* states that the maximum complexity of a single cell is $\Theta(n^{\lfloor d/2 \rfloor})$. For most other objects, the known upper and lower bounds are close but not tight—see [Table 65.1](#).

Lower envelopes. Another important substructure is the *lower envelope*. Intuitively, the lower envelope of a set of segments in the plane is what one would see when looking at the segments from below—see [Figure 65.2](#). More formally, if we view the segments as graphs of partially defined (linear) functions, then the lower envelope is the point-wise minimum of these functions. Similarly, the *upper envelope* is defined as the point-wise maximum of the functions. The definition readily extends to x -monotone curves in the plane, to planes, triangles, or xy -monotone surface patches in \mathbb{R}^3 , etc.

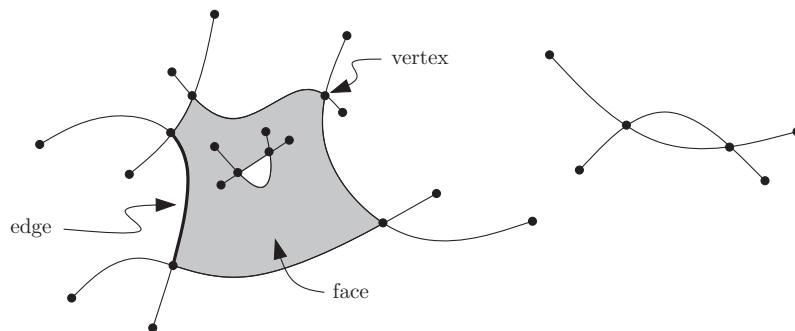

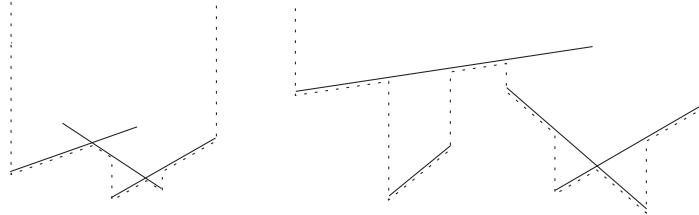

FIGURE 65.1 An arrangement of curves in the plane.

TABLE 65.1 Maximum Complexity of Single Cells and Envelopes in Arrangements

		Single cell	Upper envelope	Reference
$d = 2$	Lines	$\Theta(n)$	$\Theta(n)$	Trivial
	Segments	$\Theta(n\alpha(n))$	$\Theta(n\alpha(n))$	[10]
	Circles	$\Theta(n)$	$\Theta(n)$	Linearization
	Jordan arcs	$\Theta(\lambda_{s+2}(n))$	$\Theta(\lambda_{s+2}(n))$	[11]
$d = 3$	Planes	$\Theta(n)$	$\Theta(n)$	Euler's formula
	Triangles	$\Omega(n^2\alpha(n)), O(n^2 \log n)$	$\Theta(n^2\alpha(n))$	[12], [13]
	Spheres	$\Theta(n^2)$	$\Theta(n^2)$	Linearization
	Surfaces	$\Omega(n\lambda_q(n)), O(n^{2+\varepsilon})$	$\Omega(n\lambda_q(n)), O(n^{2+\varepsilon})$	[14]
$d > 3$	Hyperplanes	$\Theta(n^{\lfloor d/2 \rfloor})$	$\Theta(n^{\lfloor d/2 \rfloor})$	Upper Bound Thm [15]
	$(d-1)$ -simplices	$\Omega(n^{d-1}\alpha(n)), O(n^{d-1} \log n)$	$\Theta(n^{d-1}\alpha(n))$	[12], [13]
	$(d-1)$ -spheres	$\Theta(n^{\lceil d/2 \rceil})$	$\Theta(n^{\lceil d/2 \rceil})$	Linearization
	Surfaces	$\Omega(n^{d-2}\lambda_q(n)), O(n^{d-1+\varepsilon})$	$O(n^{d-1+\varepsilon})$	[16], [17]

The parameter s is the maximum number of points in which any two curves meet; the parameter q is a similar parameter for higher dimensional surfaces. The function $\lambda_t(n)$ is the maximum length of a Davenport-Schinzel sequence [6] of order t on n symbols, and is only slightly super-linear for any constant t . Bounds of the form $O(n^{d-1+\varepsilon})$ hold for any constant $\varepsilon > 0$.

**FIGURE 65.2** The lower envelope of a set of segments in the plane.

Envelopes are closely related to single cells. The lower envelope of a set of lines in the plane, for instance, is the boundary of the single cell in the arrangement that is below all the lines. The vertices of the lower envelope of a set of segments in the plane are also vertices of the unbounded cell defined by those segments, but here the reverse is not true: vertices of the unbounded cell that are above other segments are not on the lower envelope. Nevertheless, the worst-case complexities of lower envelopes and single cells are usually very similar—see Table 65.1.

Other substructures. More types of substructures have been studied than single cells and envelopes: zones, levels, multiple cells, etc. The interested reader may consult the Chapter 21 of the *CRC Handbook of Discrete and Computational Geometry* [8], or the books by Edelsbrunner [5] or Sharir and Agarwal [6].

65.2.2 Decomposition

Full arrangements, or substructures in arrangements, are by themselves not convenient to work with, because their cells can be quite complex. Thus it is useful to further decompose the cells of interest into constant-complexity subcells: triangles or trapezoids in 2D, and simplices or trapezoid-like cells in higher dimensions. There are several ways of doing this.

Bottom-vertex triangulations. For arrangements of hyperplanes, the so-called *bottom-vertex triangulation* is often used. This decomposition is obtained as follows. Consider a bounded face f in a planar arrangement of lines. We can decompose f into triangles by drawing a line segment from the bottommost vertex v of f to all other vertices of f , except the vertices that are already adjacent to v —see Figure 65.3a. Note that this easy method for triangulating f is applicable since f is always convex. To decompose the whole arrangement of lines (or some substructure in it) we simply decompose each face in this manner.*

To decompose a d -cell C in a higher-dimensional arrangement of hyperplanes, we proceed inductively as follows. We first decompose each $(d-1)$ -cell on the boundary of C , and then extend each $(d-1)$ -simplex in this boundary decomposition into

* Unbounded faces require a bit of care, but they can be handled in a similar way.

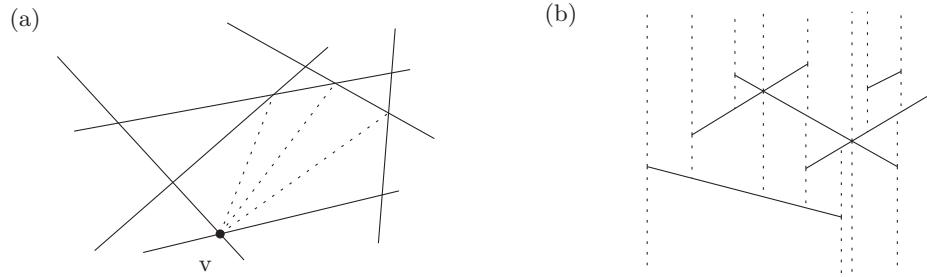

FIGURE 65.3 (a) The bottom-vertex triangulation of a face in a planar arrangement. (b) The vertical decomposition of a planar arrangement of line segments.

a d -simplex by connecting each of its vertices to the bottommost vertex of C . Again, this can readily be used to decompose any subset of cells in an arrangement of hyperplanes.

The total number of simplices in a bottom-vertex decomposition is linear in the total complexity of the cells being decomposed.

Vertical decompositions. The bottom-vertex triangulation requires the cells to be convex, so it does not work for arrangements of segments or for arrangements of surfaces. For such arrangements one often uses the *vertical decomposition* (or: *trapezoidal decomposition*). For an arrangement of line segments or curves in the plane, this decomposition is defined as follows. Each vertex of the arrangement—this can be a segment endpoint or an intersection point—has a vertical connection to the segment immediately above it, and to the segment immediately below it. If there is no segment below or above a vertex, then the connection extends to infinity. This decomposes each cell into trapezoids: subcells that are bounded by at most two vertical connections and by at most two segments—see Figure 65.3b. This definition can be generalized to higher dimensions as follows. Suppose we wish to decompose the arrangement $\mathcal{A}(S)$ induced by a collection S of surfaces in \mathbb{R}^d , where each surface is vertically monotone (i.e., any line parallel to the x_d -axis intersects the surface in at most one point). Each point of any $(d-2)$ -dimensional cell of $\mathcal{A}(S)$ is connected by a vertical segment to the surface immediately above it and to the surface immediately below it. In other words, from each $(d-2)$ -cell we extend a vertical wall upward and downward. These walls together decompose the cells into subcells bounded by vertical walls and by at most two surfaces from S —one from above and one from below. These subcells are vertically monotone, but do not yet have constant complexity. Hence, we recursively decompose the bottom of the cell, and then extend this decomposition vertically upward to obtain a decomposition of the entire cell.

The vertical decomposition can be used for most arrangements (or substructures in them). In the plane, the maximum complexity of the vertical decomposition is linear in the total complexity of the decomposed cells. However, in higher dimensions this is no longer true. In \mathbb{R}^3 , for instance, the vertical decomposition of an arrangement of n disjoint triangles can consist of $\Theta(n^2)$ subcells, even though in this case the total complexity of the arrangement is obviously linear. Unfortunately, this is unavoidable, as there are collections of disjoint triangles in \mathbb{R}^3 for which any decomposition into convex subcells must have $\Omega(n^2)$ subcells. For n intersecting triangles, the vertical decomposition has complexity $O(n^2\alpha(n)\log n + K)$, where K is the complexity of the arrangement of triangles [12]. More information about the complexity of vertical decompositions in various settings can be found in Halperin's survey on arrangements [8, Chapter 21]. In many cases, vertical decompositions can be constructed in time proportional to their complexity, with perhaps a small (logarithmic or $O(n^\epsilon)$) multiplicative factor.

65.2.3 Duality

Consider the transformation in the plane that maps the point $p = (p_x, p_y)$ to the line $p^*: y = p_x x - p_y$, and the line $\ell: y = ax + b$ to the point $\ell^* = (a, -b)$. Such a transformation that maps points to lines and vice versa is called a *duality transform*. Often the term *primal plane* is used for the plane in which the original objects live, and the term *dual plane* is used for the plane in which their images live. The duality transform defined above has a few easy-to-verify properties:

1. It is *incidence preserving*: if a point p lies on a line ℓ , then the point ℓ^* dual to ℓ lies on the line p^* dual to p .
2. It is *order preserving*: if a point p lies above a line ℓ , then ℓ^* lies above p^* .

These properties imply several others. For example, three points on a line become three lines through a point under the duality transform—see Figure 65.4. Another property is that for any point p we have $(p^*)^* = p$. Notice that the duality transform above is not defined for vertical lines. This technicality is usually not a problem, as vertical lines can often be handled separately.

This duality transform is so simple that it does not seem very interesting at first sight. However, it turns out to be extremely useful. As an example, consider the following problem. We are given a set P of n points in the plane, which we wish to preprocess for *strip-emptiness* queries: given a query strip—a strip is the region between two parallel lines—decide whether that strip is empty

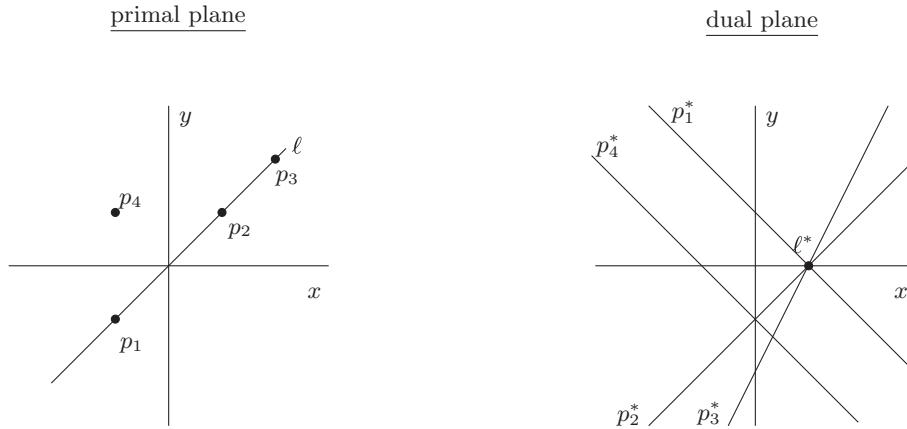

FIGURE 65.4 Illustration of the duality transform.

or if it contains one or more points from P . If we know about duality, and we know about data structures for point location, then this problem is easy to solve: we take the duals of the points in P to obtain a set P^* of lines in the plane, and we preprocess the arrangement $\mathcal{A}(P^*)$ induced by P^* for logarithmic-time point location. To decide whether the strip bounded by lines ℓ_1 and ℓ_2 is empty, we perform point locations with ℓ_1^* and ℓ_2^* in $\mathcal{A}(P^*)$; the strip is empty if and only if ℓ_1^* and ℓ_2^* lie in the same face of the arrangement. (This does not work if ℓ_1 and ℓ_2 are vertical, since then their duals are undefined. But for this case we can simply build one extra data structure, which is a balanced binary search tree on the x -coordinates of the points.)

In principle, of course, we could also have arrived at this solution without using duality. After all, duality does not add any new information: it is just a different way of looking at things. Hence, every algorithm or data structure that works in the dual plane can also be interpreted as working in the primal plane. But some things are simply more easy to see in the dual plane. For example, a face in the arrangement $\mathcal{A}(P^*)$ in the dual plane is much more visible than the collection of all lines in the primal plane dividing P into two subsets in a certain way. So without duality, we would not have realized that we could solve the strip-emptiness problem with a known data structure, and we would probably not have been able to develop that structure ourselves either.

This is just one example of the use of duality. There are many more problems where duality is quite useful. In fact, we will see another example in the next section, when we study convex hulls.

65.3 Convex Hulls

A set $A \subset \mathbb{R}^d$ is *convex* if for any two points $p, q \in A$ the segment \overline{pq} is completely contained in A . The *convex hull* of a set S of objects is the smallest convex set that contains all objects in S , that is, the most tightly fitting convex bounding volume for S . For example, if S is a set of objects in the plane, we can obtain the convex hull by taking a large rubber band around the objects and then releasing the band; the band will snap around the objects and the resulting shape is the convex hull. More formally, we can define $\mathcal{CH}(S)$ as the intersection of all convex sets containing all objects in S :

$$\mathcal{CH}(S) := \bigcap \{A : A \text{ is convex, and } o \subset A \text{ for all } o \in S\}.$$

We denote the convex hull of the objects in S by $\mathcal{CH}(S)$.

It is easy to see that the convex hull of a set of line segments in the plane is the same as the convex hull of the endpoints of the segments. More generally, the convex hull of a set of bounded polygonal objects in \mathbb{R}^d is the same as the convex hull of the vertices of the objects. Therefore we will restrict our discussion to convex hulls of sets of points. Table 65.2 gives an overview of the results on the complexity and construction of convex hulls discussed below.

65.3.1 Complexity

Let P be a set of n points in \mathbb{R}^d . The *convex hull* of P , denoted by $\mathcal{CH}(P)$, is a convex polytope whose vertices are a subset of the points in P . The complexity of a polytope is defined as the total number of k -facets[†] (i.e., k -dimensional features) on the

[†] In the previous section we used the term k -cells for the k -dimensional features in an arrangement, but since we are dealing here with a single polytope we prefer the term k -facet.

TABLE 65.2 Maximum Complexity of the Convex Hull of a Set of n Points, and the Time Needed to Construct the Convex Hull

	Complexity	Construction	Reference
$d = 2$, worst case	$\Theta(n)$	$O(n \log n)$	[1,18]
$d = 3$, worst case	$\Theta(n)$	$O(n \log n)$	[19–22]
$d > 3$, worst case	$\Theta(n^{\lfloor d/2 \rfloor})$	$O(n^{\lfloor d/2 \rfloor})$	[19,20,22,23]
$d \geq 2$, uniform distr.	$\Theta(\log^{d-1} n)$	$O(n)$	[24]

The bounds on uniform distribution refer to points drawn uniformly at random from a hypercube or some other convex polytope.

boundary of the polytope, for $k = 0, 1, \dots, d - 1$: the complexity of a planar polygon is the total number of vertices and edges, the complexity of a 3-dimensional polytope is the total number of vertices, edges, and faces, and so on.

Because the vertices of $\mathcal{CH}(P)$ are a subset of the points in P , the number of vertices of $\mathcal{CH}(P)$ is at most n . In the plane this means that the total complexity of the convex hull is $O(n)$, because the number of edges of a planar polygon is equal to the number of vertices. In higher dimensions this is no longer true: the number of k -facets ($k > 0$) of a polytope can be larger than the number of vertices. How large can this number be in the worst case? In \mathbb{R}^3 , the total complexity is still $O(n)$. This follows from Euler's formula, which states that for a convex polytope in \mathbb{R}^3 with V vertices, E edges, and F faces it holds that $V - E + F = 2$. In higher dimensions, the complexity can be significantly higher: the worst-case complexity of a convex polytope with n vertices in \mathbb{R}^d is $\Theta(n^{\lfloor d/2 \rfloor})$.

In fact, the bound on the complexity of the convex hull immediately follows from the results of the previous section if we apply duality. To see this, consider a set P of n points in the plane. For simplicity, let us suppose that $\mathcal{CH}(P)$ does not have any vertical edges and that no three points in P are collinear. Define the *upper hull* of P , denoted by $\mathcal{UH}(P)$, as the set of edges of $\mathcal{CH}(P)$ that bound $\mathcal{CH}(P)$ from above. Let P^* be the set of lines that are the duals of the points in P . A pair $p, q \in P$ defines an edge of $\mathcal{UH}(P)$ if and only if all other points $r \in P$ lie below the line through p and q . In the dual this means that all lines $r^* \in P^*$ lie above the intersection point $p^* \cap q^*$. In other words, $p^* \cap q^*$ is a vertex on the lower envelope $\mathcal{LE}(P^*)$ of the lines in P^* . Furthermore, a point $p \in P$ is a vertex of $\mathcal{UH}(P)$ if and only if its dual p^* defines an edge of $\mathcal{LE}(P^*)$. Thus there is a one-to-one correspondence between the vertices (or, edges) of $\mathcal{UH}(P)$, and the edges (or, vertices) of $\mathcal{LE}(P^*)$. In higher dimensions a similar statement is true: there is a one-to-one correspondence between the k -facets of the upper hull of P and the $(d - k - 1)$ -facets of the lower envelope of P^* . The bound on the complexity of the convex hull of a set of n points in \mathbb{R}^d therefore follows from the $\Theta(n^{\lfloor d/2 \rfloor})$ bound on the complexity of the lower envelope of a set of n hyperplanes \mathbb{R}^d .

The $\Theta(n^{\lfloor d/2 \rfloor})$ bound implies that the complexity of the convex hull can be quite high when the dimension gets large. Fortunately this is not the case if the points in P are distributed uniformly: in that case only few of the points in P are expected to show up as a vertex on the convex hull. More precisely, the expected complexity of the convex hull of a set P that is uniformly distributed in the unit hypercube is $O(\log^{d-1} n)$ [24,25].

65.3.2 Construction

We now turn our attention to algorithms for computing the convex hull of a set P of n points in \mathbb{R}^d . In the previous subsection we have shown that there is a correspondence between the upper hull of P and the lower envelope of P^* , where P^* is the set of hyperplanes dual to the points in P . It follows that any algorithm that can compute the convex hull of a set of points in \mathbb{R}^d can also be used to compute the intersection of a set of half-spaces in \mathbb{R}^d , and vice versa.

First consider the planar case. By a reduction from sorting, one can show that $\Omega(n \log n)$ is a lower bound on the worst-case running time of any convex-hull algorithm. There are many different algorithms that achieve $O(n \log n)$ running time and are thus optimal in the worst case. One of the best known algorithms is called *Graham's scan* [1,18]. It treats the points from left to right, and maintains the upper hull of all the points encountered so far. To handle a point p_i , it is first added to the end of the current upper hull. The next step is to delete the points that should no longer be part of the hull. They always form a consecutive portion at the right end of the old hull, and can be identified easily—see Figure 65.5.

After these points have been deleted, the next point is handled. Graham's scan runs in linear time, after the points have been sorted from left to right. This is optimal in the worst case.

The $\Omega(n \log n)$ lower bound does not hold if only few points show up on the convex hull. Indeed, in this case it is possible to do better: Kirkpatrick and Seidel [26], and later Chan [27], gave output-sensitive algorithms that compute the convex hull in $O(n \log k)$ time, where k is the number of vertices of the hull.

In \mathbb{R}^3 , the worst-case complexity of the convex hull is still linear, and it can be computed in $O(n \log n)$ time, either by a deterministic divide-and-conquer algorithm [21] or by a simpler randomized algorithm [19,20,22]. In dimensions $d > 3$, the convex

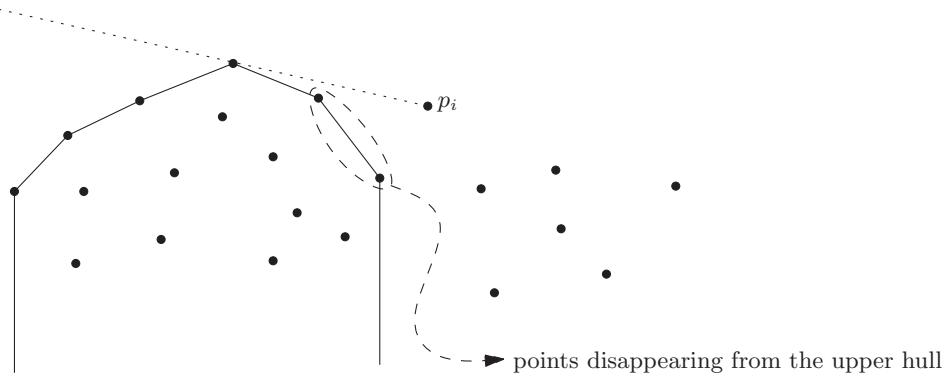

FIGURE 65.5 Constructing the upper hull.

hull can be computed in $\Theta(n^{\lfloor d/2 \rfloor})$ time [23]. This is the same as the worst-case complexity of the hull, and therefore optimal. Again, the simplest algorithms that achieve this bound are randomized [19,20,22]. There is also an output-sensitive algorithm by Chan [27], which computes the convex hull in $O(n \log k + (nk)^{1-1/(\lfloor d/2 \rfloor + 1)} \log^{O(1)} n)$ time, where k is its complexity.

As remarked earlier, the expected complexity of the convex hull of a set of n uniformly distributed points is much smaller than the worst-case complexity. This means that if we use an output-sensitive algorithm to compute the convex hull, its expected running time will be better than its worst-case running time. One can do even better, however, by using specialized algorithms. For example, Dwyer [24] has shown that the convex hull of points distributed uniformly in, for example, the unit hypercube can be computed in linear expected time.

65.3.3 Dynamic Convex Hulls

In some applications the set P changes over time: new points are inserted into P , and some existing points are deleted. The convex hull can change drastically after an update: the insertion of a single point can cause $\Theta(n)$ points to disappear from the convex hull, and the deletion of a single point can cause $\Theta(n)$ points to appear on the convex hull. Surprisingly, it is nevertheless possible to store the convex hull of a planar point set in such a way that any update can be processed in $O(\log^2 n)$ in the worst case, as shown by Overmars and van Leeuwen [28]. The key to their result is to not only store the convex hull of the whole set, but also information about the convex hull of certain subsets. The structure of Overmars and van Leeuwen roughly works as follows. Suppose we wish to maintain $\mathcal{UH}(P)$, the upper hull of P ; maintenance of the lower hull can be done similarly. The structure to maintain $\mathcal{UH}(P)$ is a balanced binary tree \mathcal{T} , whose leaves store the points from P sorted by x -coordinate. The idea is that each internal node v stores the upper hull of all the points in the subtree rooted at v . Instead of storing the complete upper hull at each node v , however, we only store those parts that are not already on the upper hull of nodes higher up in the tree. In other words, the point corresponding to a leaf μ is stored at the highest ancestor of μ where it is on the upper hull—see Figure 65.6 for an illustration.

Note that the root still stores the upper hull of the entire set P . Because a point is stored in only one upper hull, the structure uses $O(n)$ storage. Overmars and van Leeuwen show how to update the structure in $O(\log^2 n)$ time in the worst case.

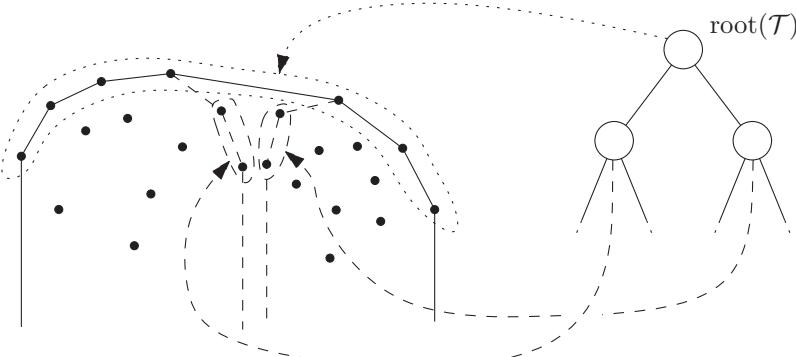

FIGURE 65.6 The Overmars-van Leeuwen structure to maintain the convex hull.

Although the result by Overmars and van Leeuwen is more than 20 years old by now, it still has not been improved in its full generality. Nevertheless, there have been several advances in special cases. For example, for the semi-dynamic case (only insertions, or only deletions), there are structures with $O(\log n)$ update time [14,29]. Furthermore, $O(\log n)$ update time can be achieved in the off-line setting, where the sequence of insertions and deletions is known in advance [30]. Improvements are also possible if one does not need to maintain the convex hull explicitly. For example, in some applications the reason for maintaining the convex hull is to be able to find the point that is extreme in a query direction, or the intersection of the convex hull with a query line. Such queries can be answered in logarithmic time if the convex hull vertices are stored in order in a balanced binary tree, but it is not necessary to know all the convex hull vertices explicitly to answer such queries. This observation was used by Chan [31], who described a fully dynamic structure that can answer such queries in $O(\log n)$ time and that can be updated in $O(\log^{1+\varepsilon} n)$ time. This result was recently improved by Brodal and Jacob [32], who announced a structure that uses $O(n)$ storage, has $O(\log n)$ update time, and can answer queries in $O(\log n)$ time. Neither Chan's structure nor the structure of Brodal and Jakob, however, can report the convex hull in time linear in its complexity, and the update times are amortized.

65.4 Voronoi Diagrams

Recall the *post-office problem* mentioned in the introduction. Here we want to preprocess a set S of n points, referred to as *sites*, in the plane such that we can answer the query: which site in S is closest to a given query point q ? In order to solve this problem we can divide the plane into regions according to the nearest-neighbor rule: each site s gets assigned the region which is closest to s . This subdivision, which compactly captures the distance information inherent in a given configuration, is called the *Voronoi diagram* of S —see Figure 65.7a.

More formally, the Voronoi diagram of a set of sites $S = \{s_1, \dots, s_n\}$ in \mathbb{R}^d , which we refer to as $\text{Vor}(S)$, partitions space into n regions—one for each site—such that the region for a site s_i consists of all points that are closer to s_i than to any other site $s_j \in S$. The set of points that are closest to a particular site s_i forms the so-called *Voronoi cell* of s_i , and is denoted by $V(s_i)$. Thus, when S is a set of sites in the plane we have

$$V(s_i) = \{p \in \mathbb{R}^2 : \text{dist}(p, s_i) < \text{dist}(p, s_j) \text{ for all } j \neq i\},$$

where $\text{dist}(\cdot, \cdot)$ denotes the Euclidean distance.

Now consider the dual graph of the Voronoi diagram, that is, the graph that has a node for every Voronoi cell and an arc between any two Voronoi cells that share a common edge—see Figure 65.7b. (Observe that the concept of dual graph used here has nothing to do with the duality transform discussed in Section 65.2.3.) Suppose we embed this graph in the plane, by using the site s_i to represent the node corresponding to the cell $V(s_i)$ and by drawing the edges as straight line segments, as in Figure 65.7c. Somewhat surprisingly perhaps, this graph is always planar. Moreover, it is actually a triangulation of the point set S , assuming that no four points in S are co-circular. More details on this special triangulation, which is called the *Delaunay triangulation*, will be given in Section 65.5.1.

There exists a fascinating connection between Voronoi diagrams in \mathbb{R}^d and half-space intersections in \mathbb{R}^{d+1} . Assume for simplicity that $d = 2$, and consider the transformation that maps a site $s = (s_x, s_y)$ in \mathbb{R}^2 to the non-vertical plane $h(s) : z = 2s_x x + 2s_y y - (s_x^2 + s_y^2)$ in \mathbb{R}^3 . Geometrically, $h(s)$ is the plane tangent to the unit paraboloid $z = x^2 + y^2$ at the point vertically above $(s_x, s_y, 0)$. Let $H(S)$ be the set of planes that are the image of a set of point sites S in the plane. Let \mathcal{S} denote the convex polyhedron that is formed by the intersection of the positive half-spaces defined by the planes in $H(S)$, that is, $\mathcal{S} = \bigcap_{h \in H(S)} h^+$,

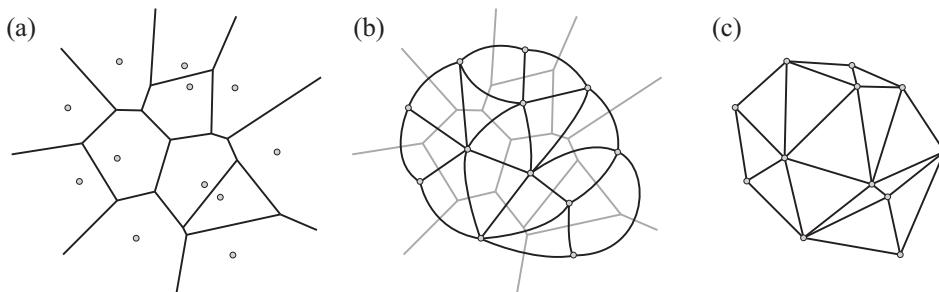

FIGURE 65.7 (a) The Voronoi diagram of a set of points. (b) The dual graph of the Voronoi diagram. (c) The Delaunay triangulation of the points.

where h^+ denotes the half-space above h . Surprisingly, the projection of the edges and vertices of \mathcal{S} vertically downward on the xy -plane is exactly the Voronoi diagram of S .

The Voronoi diagram can be defined for various sets of sites, for example points, line segments, circles, or circular arcs, and for various metrics. Sections 65.4.1 and 65.4.2 discuss the complexity and construction algorithms of Voronoi diagrams for the usual case of point sites in \mathbb{R}^d , while Section 65.4.3 describes some of the possible variations. Additional details and proofs of the material presented in this section can be found in References 33–35.

65.4.1 Complexity

Let S be a set of n points in \mathbb{R}^d . The Voronoi diagram of S is a cell complex in \mathbb{R}^d . If $d = 2$ then the Voronoi cell of a site is the interior of a convex, possibly infinite polygon. Its boundary consists of *Voronoi edges*, which are equidistant from two sites, and *Voronoi vertices*, which are equidistant from at least three sites. The Voronoi diagram of $n \geq 3$ sites has at most $2n - 5$ vertices and at most $3n - 6$ edges, which implies that the Delaunay triangulation has at most $2n - 5$ triangles and $3n - 6$ edges. What is the complexity of the Voronoi diagram in $d \geq 3$? Here the connection between Voronoi diagrams in \mathbb{R}^d and intersections of half-spaces in \mathbb{R}^{d+1} comes in handy: we know from the Upper Bound Theorem that the intersection of n half-spaces in \mathbb{R}^{d+1} has complexity $O(n^{\lfloor(d+1)/2\rfloor}) = O(n^{\lceil d/2 \rceil})$. This bound is tight, so the maximum complexity of the Voronoi diagram—and of the Delaunay triangulation, for that matter—in \mathbb{R}^d is $\Theta(n^{\lceil d/2 \rceil})$.

65.4.2 Construction

In this section we present several algorithms to compute the Voronoi diagram or its dual, the Delaunay triangulation, for point sites in \mathbb{R}^d . Several of these algorithms can be generalized to work with metrics other than the Euclidean, and to sites other than points. Since the Voronoi diagram in the plane has only linear complexity one might be tempted to search for a linear time construction algorithm. However the problem of sorting n real numbers is reducible to the problem of computing Voronoi diagrams and, hence, any algorithm for computing the Voronoi diagram must take $\Omega(n \log n)$ time in the worst case.

Two data structures that are particularly well suited to working with planar subdivisions like the Voronoi diagram are the *doubly-connected edge list* (DCEL) by Muller and Preparata [36] and the *quad-edge structure* by Guibas and Stolfi [37]. Both structures require $O(n)$ space, where n is the complexity of the subdivision, and allow to efficiently traverse the edges adjacent to a vertex and the edges bounding a face. In both structures, one can easily obtain in $O(n)$ time a structure for the Voronoi diagram from a structure for the Delaunay triangulation, and vice versa. In fact, the quad-edge structure, as well as a variant of the DCEL [1], are representations of a planar subdivision and its dual at the same time, so there is nothing to convert (except, perhaps, that one may wish to explicitly compute the coordinates of the vertices in the Voronoi diagram, if the quad-edge structure or DCEL describes the Delaunay triangulation).

Divide-and-conquer. The first deterministic worst-case optimal algorithm to compute the Voronoi diagram was given by Shamos and Hoey [38]. Their divide-and-conquer algorithm splits the set S of point sites by a dividing line into subsets L and R of approximately the same size. The Voronoi diagrams $\text{Vor}(L)$ and $\text{Vor}(R)$ are computed recursively and then merged into $\text{Vor}(S)$ in linear time. This algorithm constructs the Voronoi diagram of a set of n points in the plane in $O(n \log n)$ time and linear space.

Plane Sweep. The strategy of a sweep line algorithm is to move a line, called the *sweep line*, from top to bottom over the plane. While the sweep is performed, information is maintained regarding the structure one wants to compute. It is tempting to apply the same approach to Voronoi diagrams, by keeping track of the Voronoi edges that are currently intersected by the sweep line. It is problematic, however, to discover a new Voronoi region in time: when the sweep line reaches a new site, then the line has actually been intersecting the Voronoi edges of its region for a while. Fortune [39] was the first to find a way around this problem. *Fortune's algorithm* applies the plane sweep paradigm in a slightly different fashion: instead of maintaining the intersection of the sweep line with the Voronoi diagram, it maintains information of the part of the Voronoi diagram of the sites above the line that can not be changed by sites below it. This algorithm provides an alternative way of computing the Voronoi diagram of n points in the plane in $O(n \log n)$ time and linear space.

Randomized incremental construction. A natural idea is to construct the Voronoi diagram by *incremental insertion*, that is, to obtain $\text{Vor}(S)$ from $\text{Vor}(S \setminus \{s\})$ by inserting the site s . Insertion of a site means integrating its Voronoi region into the diagram constructed so far. Unfortunately the region of s can have up to $n - 1$ edges, for $|S| = n$, which may lead to a running time of $O(n^2)$. The insertion process is probably better described and implemented in the dual environment, for the Delaunay triangulation DT : construct $DT_i = DT(\{s_1, \dots, s_i\})$ by inserting s_i into DT_{i-1} . The advantage of this approach over a direct construction of $\text{Vor}(S)$ is that Voronoi vertices that appear only in intermediate diagrams but not in the final one need not be computed or stored. DT_i is constructed by exchanging edges, using edge flips [40], until all edges invalidated by s_i have been removed. Still, the worst-case

running time of this algorithm can be quadratic. However, if we insert the sites in *random order*, and the algorithm is implemented carefully, then one can prove that the expected running time is $O(n \log n)$, and that the expected amount of storage is $O(n)$.

Other approaches. Finally, recall the connection between Delaunay triangulations and convex hulls. Since there exist $O(n \log n)$ algorithms to compute the convex hull of points in \mathbb{R}^3 (see Section 65.3) we therefore have yet another optimal algorithm for the computation of Voronoi diagrams.

65.4.3 Variations

In this section we present some of the common variations on Voronoi diagrams. The first is the *order- k Voronoi diagram* of a set S of n sites, which partitions \mathbb{R}^d on the basis of the first k closest point sites. In other words, each cell in the order- k Voronoi diagram of a set S of sites in the plane corresponds to a k -tuple of sites from S and consists of those points in the plane for which that k -tuple are the k closest sites. One might fear that the order- k Voronoi diagram has $\Theta(n^k)$ cells, but this is not the case. In two dimensions, for example, its complexity is $O(k(n - k))$, and it can be computed in $O(k(n - k) \log n + n \log^3 n)$ expected time [41].

The *furthest-site Voronoi diagram* partitions \mathbb{R}^d according to the furthest site, or equivalently, according to the closest $n - 1$ of n sites. The furthest-site Voronoi diagram can be computed in $O(n \log n)$ time in two dimensions, and in $O(n^{[d/2]})$ in dimension $d \geq 3$.

One can also consider different distance functions than the Euclidean distance. For example, one can alter the distance function by the addition of *additive* or *multiplicative weights*. In this case every point site s_i is associated with a weight w_i and the distance function $d(s_i, x)$ between a point x and a site s_i becomes $d(s_i, x) = w_i + \text{dist}(s_i, x)$ (additive weights) or $d(s_i, x) = w_i \cdot \text{dist}(s_i, x)$ where $\text{dist}(s_i, x)$ denotes the Euclidean distance between s_i and x . The Voronoi diagram for point sites in 2 dimensions with additive weights can be computed in $O(n \log n)$ time, for multiplicative weights the time increases to $O(n^2)$ time.

Finally the *power diagram*, or *Laguerre diagram*, is another Voronoi diagram for point sites s_i that are associated with weights w_i . Here the distance function is the *power distance* introduced by Aurenhammer [42], where the distance from a point x to a site s_i is measured along a line tangent to the sphere of radius $\sqrt{w_i}$ centered at s_i , that is, $d(s_i, x) = \sqrt{\text{dist}(s_i, x)^2 - w_i}$. The power diagram can be computed in $O(n \log n)$ time in two dimensions.

65.5 Triangulations

In geometric data processing, structures that partition the geometric input, as well as connectivity structures for geometric objects, play an important role. Versatile tools in this context are *triangular meshes*, often called *triangulations*. A triangulation of a geometric domain such as a polygon in \mathbb{R}^2 or a polyhedron in \mathbb{R}^3 is a partition into simplices that meet only at shared faces. A triangulation of a point set S is a triangulation of the convex hull of S , such that the vertices in the triangulation are exactly the points in S .

In the following sections, we first discuss the most famous of all triangulations, the Delaunay triangulation. We then address triangulations of polygons and polyhedra in \mathbb{R}^3 . Finally we describe a recent generalization of triangulations: the pseudo-triangulation.

65.5.1 Delaunay Triangulation

In this section we provide additional detail on the Delaunay triangulation of a set $S = \{s_1, \dots, s_n\}$ of points in \mathbb{R}^d , which was introduced in Section 65.4. There we defined the Delaunay triangulation as the dual of the Voronoi diagram. In the plane, for instance, the Delaunay triangulation has an edge between sites s_i and s_j if and only if the Voronoi cells of s_i and s_j share a boundary edge. In higher dimensions, there is an edge between s_i and s_j if their Voronoi cells share a $(d - 1)$ -facet. The Delaunay triangulation can also be defined directly. If we restrict ourselves for the moment to a set S of points in \mathbb{R}^2 then the Delaunay triangulation of S , $DT(S)$, is defined by the *empty-circle condition*: a triangle Δ defined by three points s_i, s_j , and s_k is part of $DT(S)$ if and only if Δ 's circumcircle neither encloses nor passes through any other points of S . More generally, $d + 1$ points in \mathbb{R}^d define a simplex in the Delaunay triangulation if and only if its circumscribed sphere neither encloses nor passes through any other points of S . If no $d + 1$ points of S are co-spherical then $DT(S)$ is indeed a triangulation. If $d + 2$ or more points are co-spherical, then $DT(S)$ can contain cells with more than $d + 1$ sides. Fortunately, such cells can easily be further decomposed in simplices—with a bottom-vertex triangulation, for example—so such degeneracies are not a real problem. To simplify the description, we from now on assume that these degeneracies do not occur.

In the previous section we have seen a close connection between Voronoi diagrams in \mathbb{R}^d and intersections of half-spaces in \mathbb{R}^{d+1} . Similarly, there is a close connection between the Delaunay triangulation in \mathbb{R}^d and convex hulls in \mathbb{R}^{d+1} . Let's again restrict ourselves to the case $d = 2$. Consider the transformation that maps a site $s = (s_x, s_y)$ in \mathbb{R}^2 onto the point $\lambda(s_x, s_y) = (s_x, s_y, s_x^2 + s_y^2)$

in \mathbb{R}^3 . In other words, s is “lifted” vertically onto the unit paraboloid to obtain $\lambda(s)$. Let $\lambda(S)$ be the set of lifted sites. Then if we project the lower convex hull of $\lambda(S)$ —the part of the convex hull consisting of the facets facing downward—back onto the xy -plane, we get the Delaunay triangulation of S .

The Delaunay triangulation is the “best” triangulation with respect to many optimality criteria. The Delaunay triangulation:

- Minimizes the maximum radius of a circumcircle;
- Maximizes the minimum angle;
- Maximizes the sum of inscribed circle radii;
- Minimizes the “potential energy” of a piecewise-linear interpolating surface.

Also, the distance between any two vertices of the Delaunay triangulation along the triangulation edges is at most 2.42 times their Euclidean distance, that is, the *dilation* of the Delaunay triangulation is 2.42. Finally, the Delaunay triangulation contains as a subgraph many other interesting graphs:

$$EMST \subseteq RNG \subseteq GG \subseteq DT$$

where $EMST$ is the Euclidean minimum spanning tree, RNG is the relative neighborhood graph, and GG is the Gabriel graph (see Reference 4 for details on these graphs).

Since the Delaunay triangulation is the dual of the Voronoi diagram, any algorithm presented in Section 65.4.2 can be used to efficiently compute the Delaunay triangulation. We therefore refrain from presenting any additional algorithms at this point.

65.5.2 Polygons

Triangulating a simple polygon P is not only an interesting problem in its own right, but it is also an important preprocessing step for many algorithms. For example, many shortest-path and visibility problems on a polygon P can be solved in linear time if a triangulation of P is given [43]. It is fairly easy to show that any polygon can indeed be decomposed into triangles by adding a number of diagonals and, moreover, that the number of triangles in any triangulation of a simple polygon with n vertices is $n - 2$.

There are many algorithms to compute a triangulation of a simple polygon. Most of them run in $O(n \log n)$ time. Whether it is possible to triangulate a polygon in linear time was a prominent open problem for several years until Chazelle [44], after a series of interim results, devised a linear-time algorithm. Unfortunately, his algorithm is more of theoretical than of practical interest, so it is probably advisable to use a deterministic algorithm with $O(n \log n)$ running time, such as the one described below, or one of the slightly faster randomized approaches with a time complexity of $O(n \log^* n)$ [20].

In the remainder of this section we sketch a deterministic algorithm that triangulates a simple polygon P with n vertices in $O(n \log n)$ time. We say that a polygon P is *monotone* with respect to a line ℓ if the intersection of any line ℓ' perpendicular to ℓ with P is connected. A polygon that is monotone with respect to the x -axis is called *x -monotone*. Now the basic idea is to decompose P into monotone polygons and then to triangulate each of these monotone polygons in linear time.

There are several methods to decompose a simple polygon into x -monotone polygons in $O(n \log n)$ time. One approach is to sweep over P twice, from left to right and then from right to left, and to add appropriate edges to vertices that did not previously have at least one edge extending to the left and at least one edge extending to the right. A more detailed description of this or related approaches can be found in References 1,8.

Triangulating a monotone polygon. Now suppose we are given an x -monotone polygon P —see Figure 65.8. We consider its vertices p_1, \dots, p_n from left to right and use a stack to store the vertices of the not-yet-triangulated part of the polygon (which necessarily form a reflex chain) to the left of our current vertex p_i . If p_i is adjacent to p_{i-1} , as in see Figure 65.8a, then we pop vertices from the stack and connect them to p_i until the stack (including p_i) forms a reflex chain again. In particular that might mean that we simply add p_i to the stack. If p_i is adjacent to the leftmost vertex on the stack, which could be p_{i-1} , as in see Figure 65.8b, then we connect p_i to each vertex of the stack and clear the stack of all vertices except p_i and p_{i-1} . This algorithm triangulates P in linear time.

65.5.3 Polyhedra

In this section we briefly discuss triangulations (or *tetrahedralizations*) of three-dimensional polyhedra. A polyhedron P is a connected solid with a piecewise linear boundary (i.e., its boundary is composed of polygons). We assume P to be non-degenerate: A sufficiently small ball around any point of the boundary of P contains a connected component of the interior as well as the exterior of P . The number of vertices, edges, and faces of a non-degenerate tetrahedron are linearly related.

Three dimensions unfortunately do not behave as nicely as two. Two triangulations of the same input data may contain quite different numbers of tetrahedra. For example, a triangulation of a convex polyhedron with n vertices may contain between $n - 3$

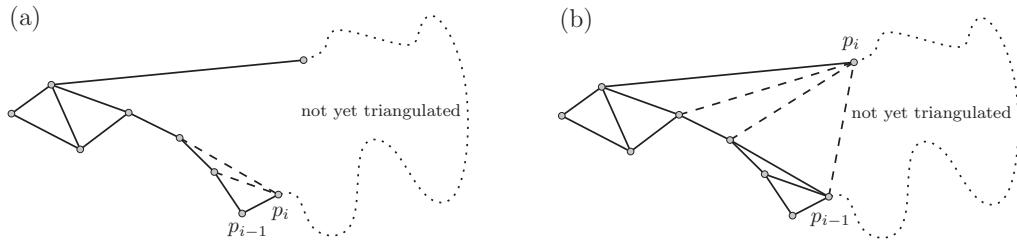

FIGURE 65.8 Triangulating an x -monotone polygon.

and $\binom{n-2}{2}$ tetrahedra. Furthermore, some non-convex polyhedra can not be triangulated at all without the use of additional (so-called *Steiner*) points. The most famous example is *Schönhardt's* polyhedron. Finally, it is NP-complete to determine whether a polyhedron can be triangulated without Steiner points and to test whether k Steiner points are sufficient [45].

Chazelle [46] constructed a polyhedron with n vertices that requires $\Omega(n^2)$ Steiner points. On the other hand, any polyhedron can be triangulated with $O(n^2)$ tetrahedra, matching his lower bound. If one pays special attention to the reflex vertices of the input polyhedron P , then it is even possible to triangulate P using only $O(n + r^2)$ tetrahedra, where r is the number of reflex edges of P [47].

65.5.4 Pseudo-Triangulations

In recent years a relaxation of triangulations, called *pseudo-triangulations*, has received considerable attention. Here, faces are bounded by three concave chains, rather than by three line segments. More formally, a pseudo-triangle is a planar polygon that has exactly three convex vertices with internal angles less than π , all other vertices are concave. Note that every triangle is a pseudo-triangle as well. The three convex vertices of a pseudo-triangle are called its *corners*. Three concave chains, called *sides*, join the three corners. A pseudo-triangulation for a set S of points in the plane is a partition of the convex hull of S into pseudo-triangles whose vertex set is exactly S —see Figure 65.9. Pseudo-triangulations, also called *geodesic triangulations*, were originally studied for convex sets and for simple polygons in the plane because of their applications to visibility [48,49] and ray shooting [50,51]. But in the last few years they also found application in robot motion planning [52] and kinetic collision detection [53,54].

Of particular interest are the so-called *minimum pseudo-triangulations*, which have the minimum number of pseudo-triangular faces among all possible pseudo-triangulations of a given domain. They were introduced by Streinu [52], who established that every minimum pseudo-triangulation of a set S of n points consists of exactly $n - 2$ pseudo-triangles (here we do not count the outer face). Note that such a statement cannot be made for ordinary triangulations: there the number of triangles depends on the number of points that show up on the convex hull of S . Minimum pseudo-triangulations are also referred to as *pointed pseudo-triangulations*. The name stems from the fact that every vertex v of a minimum pseudo-triangulation has an incident region whose angle at v is greater than π . The converse is also true (and can be easily established via Euler's relation): If every vertex of a pseudo-triangulation is *pointed*—it has an incident angle greater than π —then this pseudo-triangulation has exactly $n - 2$ pseudo-triangles and is therefore minimum. A pseudo-triangulation is called *minimal* (as opposed to minimum) if the union of any two faces is not a pseudo-triangle. In general, all minimum pseudo-triangulations are also minimal, but the opposite is not necessarily true—see Figure 65.9a for an example of a minimal but not minimum pseudo-triangulation.

The great variety of applications in which pseudo-triangulations are successfully employed prompted a growing interest in their geometric and combinatoric properties, which often deviate substantially from those of ordinary triangulations. An example of a nice property of pseudo-triangulations is that every point set in the plane admits a pseudo-triangulation of maximum vertex

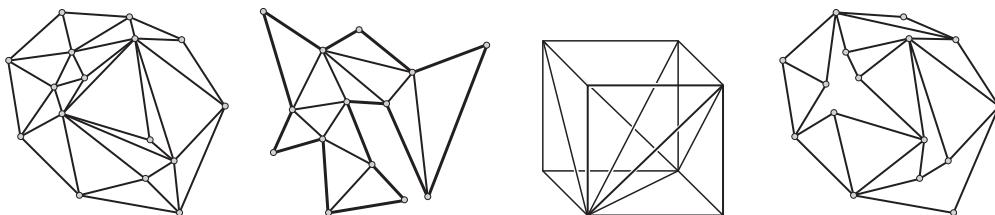

FIGURE 65.9 Triangulations of a point set, a simple polygon, and a polyhedron; a pseudotriangulation of a point set.

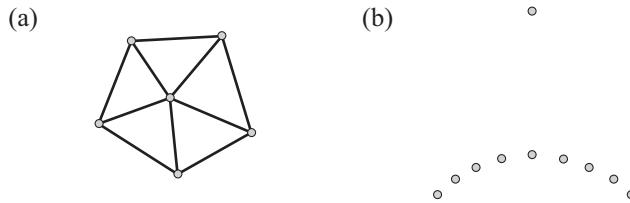

FIGURE 65.10 (a) A minimal but not minimum pseudo-triangulation. (b) A point set for which every triangulation has a vertex of high degree.

degree 5 [55]. (This bound is tight.) Again, this is not the case for ordinary triangulations: any ordinary triangulation of the point set depicted in Figure 65.10b, contains a vertex of degree $n - 1$.

Up to now there are unfortunately no extensions of pseudo-triangulations to dimensions higher than two which retain a significant subset of their useful planar properties.

66.1 Introduction

Proximity and location are fundamental concepts in geometric computation. The term *proximity* refers informally to the quality of being close to some point or object. Typical problems in this area involve computing geometric structures based on proximity, such as the Voronoi diagram, Delaunay triangulation and related graph structures such as the relative neighborhood graph. Another class of problems are retrieval problems based on proximity. These include nearest neighbor searching and the related concept of range searching. (See [Chapter 19](#) for a discussion of data structures for range searching.) Instances of proximity structures and proximity searching arise in many fields of applications and in many dimensions. These applications include object classification in pattern recognition, document analysis, data compression, and data mining.

The term *location* refers to the position of a point relative to a geometric subdivision or a given set of disjoint geometric objects. The best known example is the point location problem, in which a subdivision of space into disjoint regions is given, and the problem is to identify which region contains a given query point. This problem is widely used in areas such as computer graphics, geographic information systems, and robotics. Point location is also used as a method for proximity searching, when applied in conjunction with Voronoi diagrams.

In this chapter we will present a number of geometric data structures that arise in the context of proximity and location. The area is so vast that our presentation will be limited to a relatively few relevant results. We will discuss data structures for answering point location queries first. After this we will introduce proximity structures, including Voronoi diagrams and Delaunay triangulations. Our presentation of these topics will be primarily restricted to the plane. Finally, we will present results on multidimensional nearest neighbor searching.

66.2 Point Location

The planar *point location* problem is one of the most fundamental query problems in computational geometry. Consider a *planar straight line graph* S . (See [Chapter 18](#) for details.) This is an undirected graph, drawn in the plane, whose edges are straight

* This chapter has been reprinted from first edition of this Handbook, without any content updates.

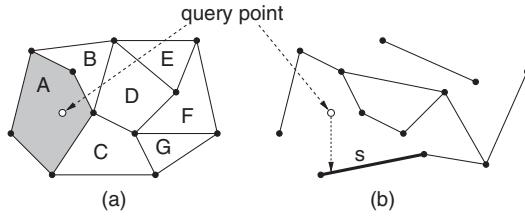

FIGURE 66.1 Illustration of (a) point location and (b) vertical ray shooting queries.

line segments that have pairwise disjoint interiors. The edges of S subdivide the plane into (possibly unbounded) polygonal regions, called *faces*. Henceforth, such a structure will be referred to as a *polyangular subdivision*. Throughout, we let n denote the *combinatorial complexity* of S , that is, the total number of vertices, edges and faces. (We shall occasionally abuse notation and use n to refer to the specific number of vertices, edges, or faces of S .) A planar subdivision is a special case of the more general topological concept of a *cell complex* [1], in which vertices, edges, and generally faces of various dimensions are joined together so that the intersection of any two faces is either empty or is a face of lower dimension.

The *point location problem* is to preprocess a polyangular subdivision S in the plane into a data structure so that, given any query point q , the polyangular face of the subdivision containing q can be reported quickly. (In Figure 66.1a, face A would be reported.) This problem is a natural generalization of the binary search problem in 1-dimensional space, where the faces of the subdivision correspond to the intervals between the 1-dimensional key values. By analogy with the 1-dimensional case, the goal is to preprocess a subdivision into a data structure of size $O(n)$ so that point location queries can be answered in $O(\log n)$ time.

A slightly more general formulation of the problem, which is applicable even when the input is not a subdivision is called *vertical ray shooting*. A set S of line segments is given with pairwise disjoint interiors. Given a query point q , the problem is to determine the line segment of S that lies vertically below q . (In Figure 66.1b, the segment s would be reported.) If the ray hits no segment, a special value is returned. When S is a polyangular subdivision, point location can be reduced to vertical ray shooting by associating each edge of S with the face that lies immediately above it.

66.2.1 Kirkpatrick's Algorithm

Kirkpatrick was the first to present a simple point location data structure that is asymptotically optimal [2]. It answers queries in $O(\log n)$ time using $O(n)$ space. Although this is not the most practical approach to point location, it is quite easy to understand.

Kirkpatrick starts with the assumption that the planar subdivision has been refined (through the addition of $O(n)$ new edges and vertices) so that it is a triangulation whose external face is a triangle. Let T_0 denote this initial triangulation subdivision. Kirkpatrick's method generates a finite sequence of increasingly coarser triangulations, $\langle T_0, T_1, T_2, \dots, T_m \rangle$, where T_m consists of the single triangle forming the outer face of the original triangulation. This sequence satisfies the following constraints: (a) each triangle of T_{i+1} intersects a constant number of triangles of T_i , and (b) the number of vertices of T_{i+1} is smaller than the number of vertices of T_i by a constant fraction. (See Figure 66.2.)

The data structure itself is a rooted DAG (directed acyclic graph), where the root of the structure corresponds to the single triangle of T_m , and the leaves correspond to the triangles of T_0 . The interior nodes of the DAG correspond to the triangles of each of the triangulations. A directed edge connects each triangle in T_{i+1} with each triangle in T_i that it overlaps.

Given a query point q , the point location query proceeds level-by-level through the DAG, visiting the nodes corresponding to the triangles that contain q . By property (a), each triangle in T_{i+1} overlaps a constant number of triangles of T_i , which implies that it is possible to descend one level in the data structure in $O(1)$ time. It follows that the running time is proportional to the

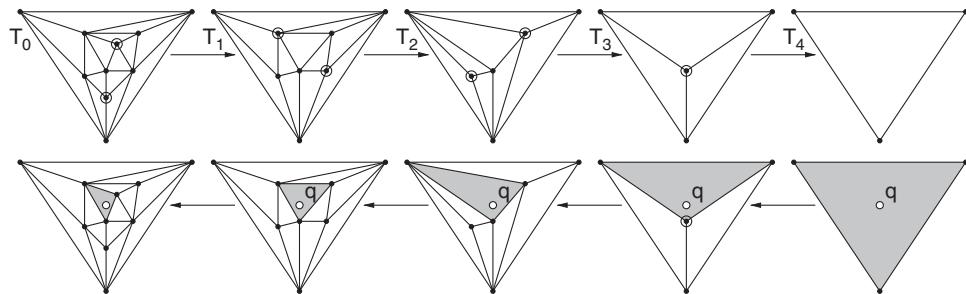

FIGURE 66.2 The sequence of triangulations generated in the construction of Kirkpatrick's structure (above) and the triangles visited in answering a point location query (below).

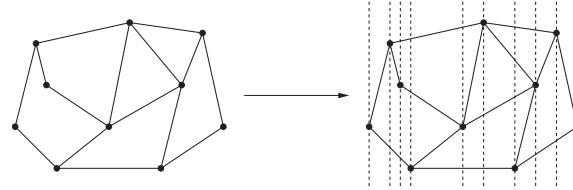

FIGURE 66.3 Slab refinement of a subdivision.

number of levels in the tree. By property (b), the number of vertices decreases at each level by a fixed constant fraction, and hence, the number of levels is $O(\log n)$. Thus the overall query time is $O(\log n)$.

Kirkpatrick showed how to build the data structure by constructing a sequence of triangulations satisfying the above properties. Kirkpatrick's approach is to compute an *independent set* of vertices (that is, a set of mutually nonadjacent vertices) in T_i where each vertex of the independent set has constant degree. (An example is shown at the top of Figure 66.2. The vertices of the independent set are highlighted.) The three vertices of the outer face are not included. Kirkpatrick showed that there exists such a set whose size is a constant fraction of the total number of vertices, and it can be computed in linear time. These vertices are removed along with any incident edges, and the resulting “holes” are then retriangulated. Kirkpatrick showed that the two properties hold for the resulting sequence of triangulations.

66.2.2 Slab-Based Methods and Persistent Trees

Many point location methods operate by refining the given subdivision to form one that is better structured, and hence, easier to search. One approach for generating such a refinement is to draw a vertical line through each vertex of the subdivision. These lines partition the plane into a collection of $O(n)$ *vertical slabs*, such that there is no vertex within each slab. As a result, the intersection of the subdivision with each slab consists of a set of line segments, which cut clear through the slab. These segments thus partition the slab into a collection of disjoint trapezoids with vertical sides. (See Figure 66.3.)

Point location queries can be answered in $O(\log n)$ time by applying two binary searches. The first search accesses the query point's x coordinate to determine the slab containing the query point. The second binary search tests whether the query point lies above or below individual lines of the slab, in order to determine which trapezoid contains the query point. Since each slab can be intersected by at most n lines, this second search can be done in $O(\log n)$ time as well.

A straightforward implementation of this method is not space efficient, since there are $\Omega(n)$ slabs,^{*} each having up to $\Omega(n)$ intersecting segments, for a total of $\Omega(n^2)$ space. However, adjacent slabs are very similar, since the only segments that change are those that are incident to the vertices lying on the slab boundary. Sarnak and Tarjan [4] exploited this idea to produce an optimal point location data structure. To understand their algorithm, imagine sweeping a line segment continuously from left to right. Consider the sorted order of subdivision line segments intersecting this sweep line. Whenever the sweep line encounters a vertex of the subdivision, the edges incident to this vertex lying to the left of the vertex are removed from the sweep-line order and incident edges to the right of the vertex are inserted. Since every edge is inserted once and deleted once in this process, the total number of changes over the entire sweep process is $O(n)$.

Sarnak and Tarjan proposed maintaining a persistent variant of the search tree. A *persistent search tree* is a dynamic search tree (supporting insertion and deletion) which can answer queries not only to the current tree, but to any of the previous versions in the history of the tree's lifetime as well. (See Chapter 33.) In this context, the history of changes to the search tree is maintained in a left to right sweep of the plane. The persistent search tree supports queries to any of these trees, that is, in any of the slabs, in $O(\log n)$ time. The clever aspect of Sarnak and Tarjan's tree is that it can be stored in $O(n)$ total space (as opposed to $O(n^2)$ space, which would result by generating $O(n)$ copies of the tree). This is done by a method called *limited node copying*. Thus, this provides an asymptotically optimal point location algorithm. A similar approach was discovered independently by Cole [5].

66.2.3 Separating Chains and Fractional Cascading

Slab methods use vertical lines to help organize the search. An alternative approach, first suggested by Lee and Preparata [6], is to use a divide-and-conquer approach based on a hierarchy of monotone polygon chains, called *separating chains*. A simple polygon is said to be *x-monotone* if the intersection of the interior of the polygon with a vertical line is connected. An *x-monotone subdivision* is one in which all the faces are *x-monotone*. The separating chain method requires that the input be an *x-monotone subdivision*. Fortunately, it is possible to convert any polygonal subdivision in the plane into an *x-monotone subdivision* in

* For readers unfamiliar with this notation, $\Omega(f(n))$ is analogous to the notation $O(f(n))$, but it provides an asymptotic lower bound rather than an upper bound. The notation $\Theta(f(n))$ means that both upper and lower bounds apply [3].

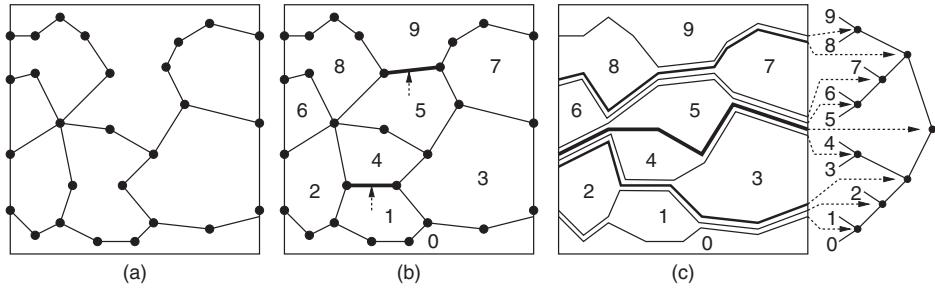

FIGURE 66.4 Point location by separating chains: (a) the original subdivision, (b) the addition of one or more edges to make the subdivision x -monotone, (c) decomposition of the subdivision into a hierarchy of separating chains.

$O(n \log n)$ time, through the addition of $O(n)$ new edges. (See e.g., [6–8].) For example, Figure 66.4a shows a subdivision that is not x -monotone, but the addition of two edges suffice to produce an x -monotone subdivision shown in Figure 66.4b.

Consider an x -monotone subdivision with n faces. It is possible to order the faces f_0, f_1, \dots, f_{n-1} such that if $i < j$, then every vertical line that intersects both of these faces intersects f_i below f_j . (See Figure 66.4b.) For each i , $0 < i < n$, define the i th separating chain to be the x -monotone polygonal chain separating faces whose indices are less than i from those that are greater than or equal to i .

Observe that, given a chain with m edges, it is possible to determine whether a given query point lies above or below the chain in $O(\log m)$ time, by first performing a binary search on the x -coordinates of the chain, in order to find which chain edge overlaps the query point, and then determining whether the query point lies above or below this edge in $O(1)$ time. The separating chain method works intuitively by performing a binary search on these chains. The binary search can be visualized as a binary tree imposed on the chains, as shown in Figure 66.4c.

Although many chains traverse the same edge, it suffices to store each edge only once in the structure, namely with the chain associated with the highest node in the binary tree. This is because once a discrimination of the query point is made with respect to such an edge, its relation is implicitly known for all other chains that share the same edge. It follows that the total space is $O(n)$.

As mentioned above, at each chain the search takes logarithmic time to determine whether the query point is above or below the chain. Since there are $\Omega(n)$ chains, this would lead to an $\Omega(\log^2 n)$ algorithm [6]. There is a clever way to reduce the search time to $O(\log n)$, through the use of a simple and powerful method called *fractional cascading* [9,10]. Intuitively, fractional cascading seeks to replace a sequence of independent binary searches with a more efficient sequence of coordinated searches. After searching through a parent's chain, it is known which edge of this chain the query point overlaps. Thus, it is not necessary to search the entire range of x -coordinates for the child's chain, just the sublist of x -coordinates that overlap this interval.

However, in general, the number of edges of the child's chain that overlaps this interval may be as large as $\Omega(n)$, and so this observation would seem to be of no help. In fractional cascading, this situation is remedied by augmenting each list. Starting with the leaf level, the x -coordinate of every fourth vertex is passed up from each child's sorted list of x -coordinates and inserted into its parent's list. This is repeated from the parent to the grandparent, and so on. After doing this, once the edge of the parent's chain that overlaps the query point has been determined, there can be at most four edges of the child's chain that overlap this interval. (e.g., in Figure 66.5 the edge \overline{pq} is overlapped by eight edges at the next lower level. After cascading, it is broken into three subedges, each of which overlaps at most four edges at the next level.) Thus, the overlapping edge in the child's chain can be found in $O(1)$ time. The root requires $O(\log n)$ time, and each of the subsequent $O(\log n)$ searches can be performed in $O(1)$ additional time. It can be shown that this augmentation of the lists increases the total size of all the lists by at most a constant factor, and hence the total space is still $O(n)$.

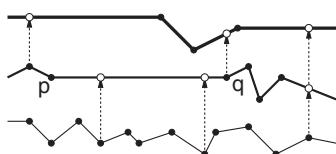

FIGURE 66.5 Example of fractional cascading. Every fourth vertex is sampled from each chain and inserted in its parent's chain.

66.2.4 Trapezoidal Maps and the History Graph

Next we describe a randomized approach for point location. It is quite simple and practical. Let us assume that the planar subdivision is presented simply as a set of n line segments $S = \{s_1, s_2, \dots, s_n\}$ with pairwise disjoint interiors. The algorithm answers vertical ray-shooting queries as described earlier. This approach was developed by Mulmuley [11]. Also see Seidel [12].

The algorithm is based on a structure called a *trapezoidal map* (or *trapezoidal decomposition*). First, assume that the entire domain of interest is enclosed in a large rectangle. Imagine shooting a bullet vertically upwards and downwards from each vertex in the polygonal subdivision until it hits another segment of S . To simplify the presentation, we shall assume that the x -coordinates of no two vertices are identical. The segments of S together with the resulting bullet paths subdivide the plane into $O(n)$ trapezoidal cells with vertical sides, which may degenerate to triangles. (See Figure 66.6a.)

For the purposes of point location, the trapezoidal map is created by a process called a *randomized incremental construction*. The process starts with the initial bounding rectangle (i.e., one trapezoid) and then the segments of S are inserted one by one in random order. As each segment is added, the trapezoidal map is updated by “walking” the segment through the subdivision, and updating the map by shooting new bullet paths through the segments endpoints and trimming existing paths that hit the new segment. See References 7,11,12 for further details. The number of changes in the diagram with each insertion is proportional to the number of vertical segments crossed by the newly added segment, which in the worst case may be as high as $\Omega(n)$. It can be shown, however, that on average each insertion of a new segment results in $O(1)$ changes. This is true irrespective of the distribution of the segments, and the expectation is taken over all possible insertion orders.

The point location data structure is based on a rooted directed acyclic graph, or DAG, called the *history DAG*. Each node has either two outgoing edges (internal nodes) or none (leaves). Leaves correspond one-to-one with the cells of the trapezoidal map. There are two types of internal nodes, *x-nodes* and *y-nodes*. Each *x-node* contains the x -coordinate x_0 of an endpoint of one of the segments, and its two children correspond to the points lying to the left and to the right of the vertical line $x = x_0$. Each *y-node* contains a pointer to a line segment of the subdivision. The left and right children correspond to whether the query point is above or below the line containing this segment, respectively. (In Figure 66.7, *x-nodes* are shown as circles, *y-nodes* as hexagons, and leaves as squares.)

As with Kirkpatrick’s algorithm, the construction of the point location data structure encodes the history of the randomized incremental construction. Let $\langle T_0, T_1, \dots, T_n \rangle$ denote the sequence of trapezoidal maps that result through the randomized incremental process. The point location structure after insertion of the i th segment has one leaf for each trapezoid in T_i . Whenever a segment is inserted, the leaf nodes corresponding to trapezoids that were destroyed are replaced with internal *x*- and *y*-nodes that direct the search to the location of the query point in the newly created trapezoids, after the insertion. (This is illustrated

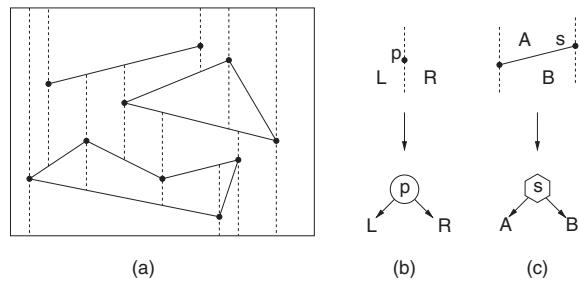

FIGURE 66.6 A trapezoidal map of a set of segments (a), and the two types of internal nodes: *x-node* (b) and *y-node* (c).

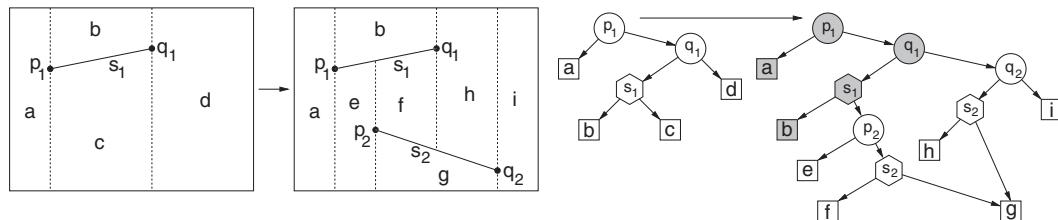

FIGURE 66.7 Example of incremental construction of a trapezoidal map and the associated history DAG. The insertion of segment s_2 replaces the leaves associated with destroyed trapezoids c and d with an appropriate search structure for the new trapezoids $e-i$.

in Figure 66.7.) Through the use of node sharing, the resulting data structure can be shown to have expected size $O(n)$, and its expected depth is $O(\log n)$, where the expectation is over all insertion orders. Details can be found in References 7,11,12.

66.2.5 Worst- and Expected-Case Optimal Point Location

Goodrich, Orletsky and Ramaiyer [13] posed the question of bounding the minimum number of comparisons required, in the worst case, to answer point location queries in a subdivision of n segments. Adamy and Seidel [14] provided a definitive answer by showing that point location queries can be answered with $\log_2 n + 2\sqrt{\log_2 n} + o(\sqrt{\log n})$ primitive comparisons. They also gave a similar lower bound.

Another natural question involves the expected-case complexity of point location. Given a polygonal subdivision S , assume that each cell $z \in S$ is associated with the probability p_z that a query point lies in z . The problem is to produce a point location data structure whose expected search time is as low as possible. The appropriate target bound on the number of comparisons is given by the *entropy* of the subdivision, which is denoted by H and defined:

$$\text{entropy}(S) = H = \sum_{z \in S} p_z \log_2(1/p_z).$$

In the 1-dimensional case, a classical result due to Shannon implies that the expected number of comparisons needed to answer such queries is at least as large as the entropy of the probability distribution [15,16]. Mehlhorn [17] showed that in the 1-dimensional case it is possible to build a binary search tree whose expected search time is at most $H + 2$.

Arya, Malamatos, and Mount [18,19] presented a number of results on this problem in the planar case, and among them they showed that for a polygonal subdivision of size n in which each cell has constant combinatorial complexity, it is possible to answer point location queries with $H + o(H)$ comparisons in the expected case using space that is nearly linear in n . Their results also applied to subdivisions with convex cells, assuming the query distribution is uniform within each cell. Their approach was loosely based on computing a binary space partition (BSP) tree (see Chapter 21) satisfying two properties:

1. The entropy of the subdivision defined by the leaves of the BSP should be close to the entropy of the original subdivision.
2. The depth of a leaf should be close to $\log_2(1/p)$, where p is the probability that a query point lies within the leaf.

Arya, Malamatos, and Mount [20] also presented a simple weighted variant of the randomized incremental algorithm and showed that it can answer queries in $O(H)$ expected time and $O(n)$ space. Iacono [21] presented a deterministic weighted variant based on Kirkpatrick's algorithm.

66.3 Proximity Structures

Proximity structures arise from numerous applications in science and engineering. It is a fundamental fact that nearby objects tend to exert a greater influence and have greater relevance than more distant objects. Proximity structures are discrete geometric and graph structures that encode proximity information. We discuss a number of such structures, including Voronoi diagrams, Delaunay triangulations, and various geometric graph structures, such as the relative neighborhood graph.

66.3.1 Voronoi Diagrams

The *Voronoi diagram* of a set of sites S is a partition of space into regions, one per site, where the region for site s is the set of points that are closer to s than to any other site of S . This structure has been rediscovered and applied in many different branches of science and goes by various names, including Thiessen diagrams and Dirichlet tessellations.

Henceforth, we consider the most common case in which the sites S consist of a set of n points in real d -dimensional space, \mathbb{R}^d , and distances are measured using the Euclidean metric. The set of points of \mathbb{R}^d that are closer to some site $s \in S$ than any other site is called the *Voronoi cell* of s , or $V(s)$. (See Figure 66.8.) The union of the boundaries of the Voronoi cells is the *Voronoi diagram* of S , denoted $\text{Vor}(S)$. Observe that the set of points of \mathbb{R}^d that are closer to s than some other site t consists of the points that lie in the open halfspace defined by a plane that bisects the pair (s, t) . It follows that each Voronoi cell is the intersection of $n - 1$ halfspaces, and hence, it is a (possibly unbounded) convex polyhedron. A Voronoi diagram in dimension d is a cell complex whose faces of all dimensions are convex polyhedra. In the plane a Voronoi diagram is a planar straight line graph with possibly unbounded edges. It can be represented using standard methods for representing polygonal subdivisions and cell complexes (see Chapter 18).

The Voronoi diagram possesses a number of useful geometric properties. For example, for a set of points in the plane, each edge of the Voronoi diagram lies on the perpendicular bisector between two sites. The vertices of the Voronoi diagram lie at the center of an empty circle passing through the incident sites. If the points are in general position (and in particular if no four

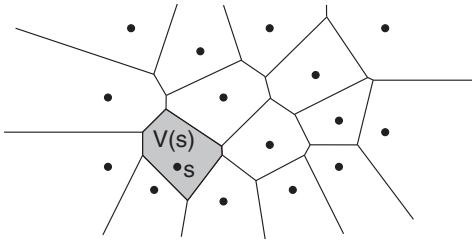

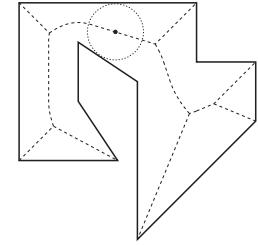

FIGURE 66.8 The Voronoi diagram and a Voronoi cell $V(s)$.

points are cocircular) then every vertex of the diagram is incident to exactly three edges. In fact, it is not hard to show that the largest empty circle whose center lies within the convex hull of a given point set will coincide with a Voronoi vertex. In higher dimensions, each face of dimension k of the Voronoi diagram consists of the points of \mathbb{R}^d that are equidistant from a subset of $d - k + 1$ sites, and all other sites are strictly farther away. In the plane the combinatorial complexity of the Voronoi diagram is $O(n)$, and in dimension d its complexity is $\Theta(n^{\lceil d/2 \rceil})$.

Further information on algorithms for constructing Voronoi diagrams as well as variants of the Voronoi diagram can be found in Chapter 65. Although we defined Voronoi diagrams for point sites, it is possible to define them for any type of geometric object. One such variant involves replacing point sites with line segments or generally the boundary of any region of the plane. Given a region P (e.g., a simple polygon), the *medial axis* is defined to be the set of centers of maximal balls contained in P , that is, balls contained in P that are not contained in another ball in P [22]. The medial axis is frequently used in pattern recognition and shape matching. It consists of a combination of straight-line segments and hyperbolic arcs. It can be computed in $O(n \log n)$ time by a modification of Fortune's sweepline algorithm [23]. Finally, it is possible to generalize Voronoi diagrams to other metrics, such as the L_1 and L_∞ metrics (see Section 66.4).

66.3.2 Delaunay Triangulations

The Delaunay triangulation is a structure that is closely related to the Voronoi diagram. The Delaunay triangulation is defined as follows for a set S of n point sites in the plane. Consider any subset $T \subseteq S$ of sites, such that there exists a circle that passes through all the points of T , and contains no point of S in its interior. Such a subset is said to satisfy the *empty circumcircle property*. For example, in Figure 66.9a, the pair $\{p, q\}$ and triple $\{r, s, t\}$ both satisfy the empty circumcircle property. The *Delaunay triangulation* is defined to be the union of the convex hulls of all such subsets. It can be shown that the result is a cell complex. Furthermore, if the points are in general position, and in particular, no four points are cocircular, then the resulting structure is a triangulation of S . (If S is not in general position, then some faces may have more than three edges, and it is common to *complete* the triangulation by triangulating each such face.) A straightforward consequence of the above definition is that the Delaunay triangulation is dual to the Voronoi diagram. For example, Figure 66.9b shows the overlay of these two structures in the plane.

Delaunay triangulations are widely used in practice, and they possess a number of useful properties. For example, among all triangulations of a planar point set the Delaunay triangulation maximizes the minimum angle. Also, in all dimensions, the Euclidean minimum spanning tree (defined below) is a subgraph of the Delaunay triangulation. Proofs of these facts can be found in Reference 7.

In the plane the Delaunay triangulation of a set of points has $O(n)$ edges and $O(n)$ faces. The above definition can be generalized to arbitrary dimensions. In dimension d , the Delaunay triangulation can have as many as $\Theta(n^{\lceil d/2 \rceil})$ faces. However, it can be much

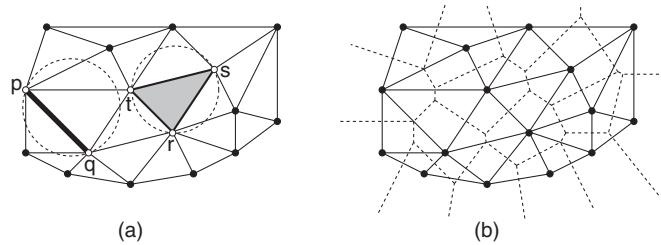

FIGURE 66.9 (a) The Delaunay triangulation of a set of points and (b) its overlay with the Voronoi diagram.

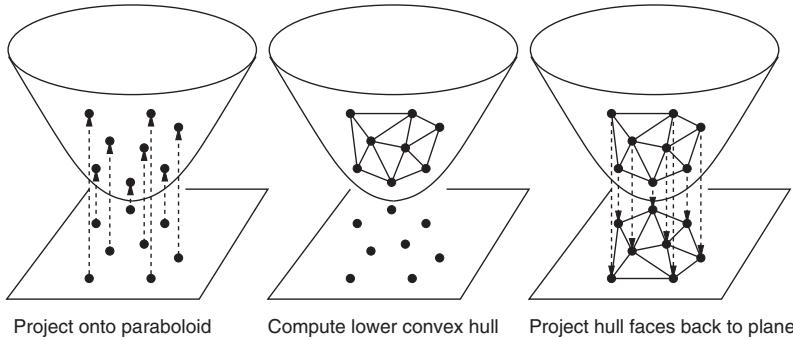

FIGURE 66.10 The Delaunay triangulation can be computed by lifting the points to the paraboloid, computing the lower convex hull, and projecting back to the plane.

smaller. In particular, Dwyer [24] has shown that in any fixed dimension, if n points are drawn from a uniform distribution from within a unit ball, then the expected number of simplices is $O(n)$.

There is an interesting connection between Delaunay triangulations in dimension d and convex hulls in dimension $d + 1$. Consider the *lifting map* $f : \mathbb{R}^2 \rightarrow \mathbb{R}^3$ defined $f(x, y) = (x, y, x^2 + y^2)$. This projects points in the plane onto the paraboloid $z = x^2 + y^2$. Given a planar point set S , let S' denote the set of points of \mathbb{R}^3 that results by applying this map to each point of S . Define the lower hull of S' to be the set of faces whose outward pointing normal has a negative z coordinate. It can be shown that, when projected back to the plane, the edges of the lower convex hull of S' are exactly the edges of the Delaunay triangulation of S . (See Figure 66.10.)

Although there exist algorithms specially designed for computing Delaunay triangulations, the above fact makes it possible to compute Delaunay triangulations in any dimension by computing convex hulls in the next higher dimension. There exist $O(n \log n)$ time algorithms for computing planar Delaunay triangulations, for example, based on divide-and-conquer [25] and plane sweep [23]. Perhaps the most popular method is based on randomized incremental point insertion [26]. In dimension $d \geq 3$, Delaunay triangulations can be computed in $O(n^{[d/2]})$ time through randomized incremental point insertion [27].

66.3.3 Other Geometric Proximity Structures

The Delaunay triangulation is perhaps the best known example of a proximity structure. There are a number of related graph structures that are widely used in pattern recognition, learning, and other applications. Given a finite set S of points in d -dimensional Euclidean space, we can define a graph on these points by joining pairs of points that satisfy certain neighborhood properties. In this section we will consider a number of such neighborhood graphs.

Let us first introduce some definitions. For $p, q \in \mathbb{R}^d$ let $\text{dist}(p, q)$ denote the Euclidean distance from p to q . Given positive $r \in \mathbb{R}$, let $B(p, r)$ be the open ball consisting of points whose distance from point p is strictly less than r . Define the *lune*, denoted $L(p, q)$, to be the intersection of two balls both of radius $\text{dist}(p, q)$ centered at these points, that is,

$$L(p, q) = B(p, \text{dist}(p, q)) \cap B(q, \text{dist}(p, q)).$$

The following geometric graphs are defined for a set S consisting of n points in \mathbb{R}^d . (See Figure 66.11.)

Nearest Neighbor Graph (NNG): The directed graph containing an edge (p, q) if q is the nearest neighbor of p , that is, $B(p, \text{dist}(p, q)) \cap S = \emptyset$.

Euclidean Minimum Spanning Tree (EMST): This is an undirected spanning tree on S that minimizes the sum of the Euclidean edge lengths.

Relative Neighborhood Graph (RNG): The undirected graph containing an edge (p, q) if there is no point $r \in S$ that is simultaneously closer to p and q than $\text{dist}(p, q)$ [28]. Equivalently, (p, q) is an edge if $L(p, q) \cap S = \emptyset$.

Gabriel Graph (GG): The undirected graph containing an edge (p, q) if the ball whose diameter is \overline{pq} does not contain any other points of S [29], that is, if

$$B\left(\frac{p+q}{2}, \frac{\text{dist}(p, q)}{2}\right) \cap S = \emptyset.$$

Delaunay Graph (DT): The 1-skeleton (edges) of the Delaunay triangulation.

These graphs form an interesting hierarchical relationship. If we think of each edge of an undirected graph as consisting of two directed edges, then we have the following hierarchical relationship, which was first established in Reference 28.

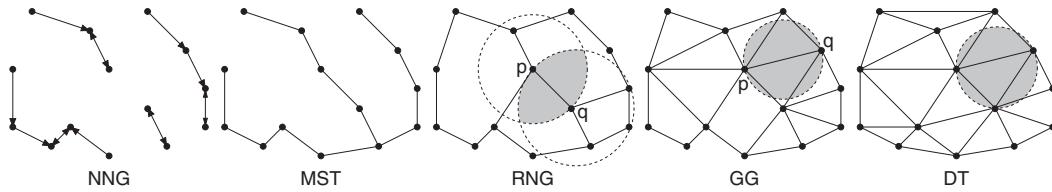

FIGURE 66.11 Common geometric graphs on a point set.

Also see Reference 30.

$$\text{NNG} \subseteq \text{MST} \subseteq \text{RNG} \subseteq \text{GG} \subseteq \text{DT}.$$

This holds in all finite dimensions and generalizes to Minkowski (L_m) metrics, as well.

66.4 Nearest Neighbor Searching

Nearest neighbor searching is an important problem in a variety of applications, including knowledge discovery and data mining, pattern recognition and classification, machine learning, data compression, multimedia databases, document retrieval, and statistics. We are given a set S of objects in some space to be preprocessed, so that given a query object q , the closest object (or objects) of S can be reported quickly.

There are many ways in which to define the notion of similarity. Because the focus of this chapter is on geometric approaches, we shall assume that proximity is defined in terms of the well known Euclidean distance. Most of the results to be presented below can be generalized to any *Minkowski* (or L_m) metric, in which the distance between two points p and q is defined to be

$$\text{dist}_m(p, q) = \left(\sum_{i=1}^d |p_i - q_i|^m \right)^{1/m}$$

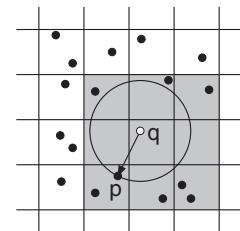

where $m \geq 1$ is a constant. The case $m = 2$ is the Euclidean distance, the case $m = 1$ is the Manhattan distance, and the limiting case $m = \infty$ is the max distance. In typical geometric applications the dimension d is assumed to be a fixed constant. There has also been work on high dimensional proximity searching in spaces of arbitrarily high dimensions [31] and in arbitrary (nongeometric) metric spaces [32], which we shall not cover here.

There are a number of natural extensions to the nearest neighbor problem as described above. One is to report the k nearest neighbors to the query point, for some given integer k . Another is to compute all the points lying within some given distance, that is, a range query in which the range is defined by the distance function.

Obviously, without any preprocessing whatsoever, the nearest neighbor search problem can be solved in $O(n)$ time through simple brute-force search. A number of very simple methods have been proposed which assume minimal preprocessing. For example, points can be sorted according to their projection along a line, and the projected distances can be used as a method to prune points from consideration [33–35]. These methods are only marginally effective, and provide significant improvements over brute-force search only in very low dimensions.

For uniformly distributed point sets, good expected case performance can be achieved by simple decompositions of space into a regular grid of hypercubes. Rivest [36] and later Cleary [37] provided analyses of these methods. Bentley, Weide, and Yao [38] also analyzed a grid-based method for distributions satisfying certain bounded-density assumptions. Intuitively, the points are bucketed into grid cells, where the size of the grid cell is based on the expected distance to the nearest neighbor. To answer a query, the grid cell containing the query point is located, and a spiral-like search working outwards from this cell is performed to identify nearby points. Suppose for example that q is the query point and p is its closest neighbor. Then all the grid cells overlapping a ball centered at q of radius $\text{dist}(p, q)$ would be visited.

Grids are easy to implement, since each bucket can be stored as a simple list of points, and the complete set of buckets can be arranged in a multi-dimensional array. Note that this may not be space efficient, since it requires storage for empty cells. A more space-efficient method is to assign a hash code to each grid cell based on its location, and then store only the nonempty grid buckets in a hash table. In general, grid methods do not work well for nearest neighbor search unless the point distribution is roughly uniform. As will be discussed below, more sophisticated methods are needed to achieve good efficiency for nonuniformly distributed data.

66.4.1 Nearest Neighbor Searching Through Point Location

One of the original motivations for the Voronoi diagram is nearest neighbor searching. By definition, the Voronoi diagram subdivides space into cells according to which site is the closest. So, in order to determine the closest site, it suffices to compute the Voronoi diagram and generate a point location data structure for the Voronoi diagram. In this way, nearest neighbor queries are reduced to point location queries. This provides an optimal $O(n)$ space and $O(\log n)$ query time method for answering point location queries in the plane. Unfortunately, this solution does not generalize well to higher dimensions. The worst-case combinatorial complexity of the Voronoi diagram in dimension d grows as $\Theta(n^{\lceil d/2 \rceil})$, and optimal point location data structures are not known to exist in higher dimensions.

66.4.2 K-d Trees

Perhaps the most popular class of approaches to nearest neighbor searching involves some sort of hierarchical spatial subdivision. Let S denote the set of n points in \mathbb{R}^d for which queries are to be answered. In such an approach, the entire space is subdivided into successively smaller regions, and the resulting hierarchy is represented by a rooted tree. Each node of the tree represents a region of space, called a *cell*. Implicitly, each node represents the subset of points of S that lie within its cell. The root of the tree is associated with the entire space and the entire point set S . For some arbitrary node u of the tree, if the number of points of S associated with u is less than some constant, then this node is declared to be a leaf of the tree. Otherwise, the cell associated with u is recursively subdivided into smaller (possibly overlapping) subcells according to some *splitting rule*. Then the associated points of S are distributed among these children according to which subcell they lie in. These subcells are then associated with the children of u in the tree.

There are many ways in which to define such a subdivision. Perhaps the earliest and best known example is that of the k-d tree data structure. Bentley [39] introduced the *k-d tree* data structure (or *kd-tree*) as a practical general-purpose data structure for many types of geometric retrieval problems. Although it is not the asymptotically most efficient solution for these problems, its flexibility makes it a popular choice for implementation. The cells of a k-d tree are axis-aligned hyperrectangles. Each internal node is associated with an axis-orthogonal splitting hyperplane. This hyperplane splits the rectangular cell into two rectangular subcells, each of which is associated with one of the two children. An example is shown in Figure 66.12.

The choice of the splitting hyperplane is an important issue in the implementation of the k-d tree. For the purpose of nearest neighbor searching, a good split is one that divides the points into subsets of similar cardinalities and which produces cells that are not too skinny, that is, the ratio between the longest and shortest sides is bounded. However, it is not always possible to achieve these goals. A simple and commonly used method is to cycle through the various coordinate axes (i.e., splitting along x , then y , then z , then back to x , and so on). Each time the split is made through the median coordinate along the splitting dimension [7,40]. Friedman, Bentley and Finkel [41] suggested the following method, which is more sensitive to the data distribution. First, compute the minimum axis-aligned bounding box for the set of points associated with the current cell. Next choose the splitting axis to be the one that is parallel to the longest side of this box. Finally, split the points by a hyperplane that is orthogonal to this axis, and which splits the points into two sets of equal size. A number of other splitting rules have been proposed for k-d trees, including the sliding midpoint rule by Arya and Fu [42] and Maneeuwongvatana and Mount [43], variance minimization by White and Jain [44], and methods by Silva Filho [45] and Sproull [46]. We will discuss other subdivision methods in the next section as well.

It is possible to construct the k-d tree of an n -element point set in $O(n \log n)$ time by a simple top-down recursive procedure. The process involves determining the splitting axis and the splitting coordinate along this axis, and then partitioning the point set about this coordinate. If the splitting rule partitions the point set about its median coordinate then it suffices to compute the median by any linear-time algorithm for computing medians [3]. Some splitting methods may not evenly partition the point set.

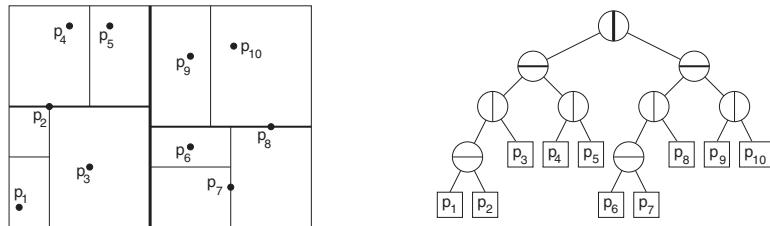

FIGURE 66.12 An example of a k-d tree of a set of points in the plane, showing both the associated spatial subdivision (left) and the binary tree structure (right).

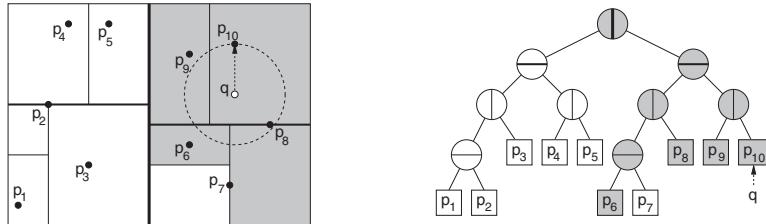

FIGURE 66.13 Nearest neighbor search in a k-d tree. The point p_{10} is the initial closest, and only the shaded cells and nodes are visited. The final answer is p_8 .

In the worst case this can lead to quadratic construction time. Vaidya showed that it is possible to achieve $O(n \log n)$ construction time, even when unbalanced splitting takes place [47]. The total space requirements are $O(n)$ for the tree itself.

Given a query point q , a nearest neighbor search is performed by the following recursive algorithm [41]. Throughout, the algorithm maintains the closest point to q encountered so far in the search, and the distance to this closest point. As the nodes of the tree are traversed, the algorithm maintains the d -dimensional hyperrectangular cell associated with each node. (This is updated incrementally as the tree is traversed.) When the search arrives at a leaf node, it computes the distance from q to the associated point(s) of this node, and updates the closest point if necessary. (See Figure 66.13.) Otherwise, when it arrives at an internal node, it first computes the distance from the query point to the associated cell. If this distance is greater than the distance to the closest point so far, the search returns immediately, since the subtree rooted at this node cannot provide a closer point. Otherwise, it is determined which side of the splitting hyperplane contains the query point. First, the closer child is visited and then the farther child. A somewhat more intelligent variant of this method, called *priority search*, involves storing the unvisited nodes in a priority queue, sorted according to the distance from the query point to the associated cell, and then processes the nodes in increasing order of distance from the query point [48].

66.4.3 Other Approaches to Nearest Neighbor Searching

The k-d tree is but one example of a general class of nearest neighbor search structures that are based on hierarchical space decomposition. A good survey of methods from database literature was given by Böhm, Berchtold, and Keim [49]. These include the R-tree [50] and its variants, the R*-tree [51], the R⁺-tree [52], and the X-tree [53], which are all based on recursively decomposing space into (possibly overlapping) hyperrectangles. (See Chapter 22 for further information.) For the cases studied, the X-tree is reported to have the best performance for nearest neighbor searching in high dimensional spaces [49]. The SS-tree [44] is based on subdividing space using (possibly overlapping) hyperspheres rather than rectangles. The SR-tree [54] uses the intersection of an enclosing rectangle and enclosing sphere to represent a cell. The TV-tree [55] applies a novel approach of considering projections of the data set onto higher dimensional subspaces at successively deeper levels in the search tree.

A number of algorithms for nearest neighbor searching have been proposed in the algorithms and computational geometry literature. Higher dimensional solutions with sublinear worst-case performance were considered by Yao and Yao [56]. Clarkson [57] showed that queries could be answered in $O(\log n)$ time with $O(n^{\lceil d/2 \rceil + \delta})$ space, for any $\delta > 0$. The O -notation hides constant factors that are exponential in d . Agarwal and Matoušek [58] generalized this by providing a tradeoff between space and query time. Meiser [59] showed that queries could be answered in $O(d^5 \log n)$ time and $O(n^{d+\delta})$ space, for any $\delta > 0$, thus showing that exponential factors in query time could be eliminated by using sufficient space.

66.4.4 Approximate Nearest Neighbor Searching

In any fixed dimensions greater than two, no method for exact nearest neighbor searching is known that achieves the simultaneous goals of roughly linear space and logarithmic query time. For methods achieving roughly linear space, the constant factors hidden in the asymptotic running time grow at least as fast as 2^d (depending on the metric). Arya et al. [60] showed that if n is not significantly larger than 2^d , then boundary effects decrease this exponential dimensional dependence. Nonetheless, the so called “curse of dimensionality” is a significant impediment to computing nearest neighbors efficiently in high dimensional spaces.

This suggests the idea of computing nearest neighbors approximately. Consider a set of points S and a query point q . For any $\epsilon > 0$, we say that a point $p \in S$ is an ϵ -approximate nearest neighbor of q if

$$\text{dist}(p, q) \leq (1 + \epsilon)\text{dist}(p^*, q),$$

where p^* is the true nearest neighbor of q in S . The approximate nearest neighbor problem was first considered by Bern [61]. He proposed a data structure that achieved a fixed approximation factor depending on dimension. Arya and Mount [62] proposed a

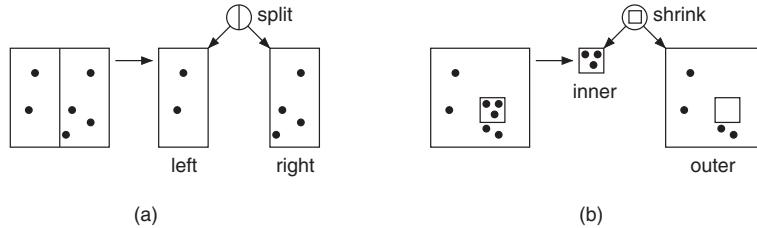

FIGURE 66.14 Splitting nodes (a) and shrinking nodes (b) in a BBD-tree.

randomized data structure that achieves polylogarithmic query time in the expected case, and nearly linear space. Their approach was based on a combination of the notion of neighborhood graphs, as described in Section 66.3.3, and skip lists. In their algorithm the approximation error factor ϵ is an arbitrary positive constant, which is given at preprocessing time.

Arya et al. [63] proposed a hierarchical spatial subdivision data structure, called the *BBD-tree*. This structure has the nice features of having $O(n)$ size, $O(\log n)$ depth, and each cell has bounded aspect ratio, that is, the ratio between its longest and shortest side is bounded. They achieved this by augmenting the axis-aligned splitting operation of the k-d tree (see Figure 66.14a) with an additional subdivision operation called *shrinking* (see Figure 66.14b). A shrinking node is associated with an axis-aligned rectangle, and the two children correspond to the portions of space lying inside and outside of this rectangle, respectively. The resulting cells are either axis-aligned hyperrectangles, or the set-theoretic difference of two axis-aligned hyperrectangles. They showed that, in all fixed dimensions d and for $\epsilon > 0$, it is possible to answer ϵ -nearest neighbor queries in $O(\log n)$ time using the BBD-tree. The hidden asymptotic constants in query time grow as $(1/\epsilon)^d$.

Duncan et al. [64] proposed an alternative structure, called the *BAR tree*, which achieves all of these combinatorial properties and has convex cells. The BAR tree achieves this by using cutting planes that are not necessarily axis-aligned. Clarkson [65] and Chan [66] presented data structures that achieved better ϵ dependency in the query time. In particular, they showed that queries could be answered in $O((1/\epsilon)^{d/2} \log n)$ time.

66.4.5 Approximate Voronoi Diagrams

As mentioned in Section 66.4.1 it is possible to answer nearest neighbor queries by applying a point location query to the Voronoi diagram. However, this approach does not generalize well to higher dimensions, because of the rapid growth rate of the Voronoi diagram and the lack of good point location structures in dimension higher than two.

Har-Peled [67] proposed a method to overcome these problems. Given an error bound $\epsilon > 0$, an *approximate Voronoi diagram* (AVD) of a point set S is defined to be a partition of space into cells, where each cell c is associated with a *representative* $r_c \in S$, such that r_c is an ϵ -nearest neighbor for all the points in c [67]. Arya and Malamatos [68] generalized this by allowing up to some given number $t \geq 1$ representatives to be stored with each cell, subject to the requirement that for any point in the cell, one of these t representatives is an ϵ -nearest neighbor. Such a decomposition is called a (t, ϵ) -AVD. (See Figure 66.15.)

Of particular interest are AVDs that are constructed from hierarchical spatial decompositions, such as quadtrees and their variants, since such structures support fast point location in all dimensions. This yields a very simple method for performing approximate nearest neighbor searching. In particular, a tree descent determines the leaf cell containing the query point and then the closest of the t representatives is reported.

Har-Peled [67] showed that it is possible to construct a $(1, \epsilon)$ AVD in which the number of leaf cells is $O((n/\epsilon^d)(\log n) \log(n/\epsilon))$. Arya and Malamatos [68] and later Arya, Malamatos, and Mount [69] improved these results by showing how to construct more space-efficient AVDs. In all constant dimensions d , their results yield a data structure of $O(n)$ space (including the space for representatives) that can answer ϵ -nearest neighbor queries in $O(\log n + (1/\epsilon)^{(d-1)/2})$ time. This is the best asymptotic result known for approximate nearest neighbor searching in fixed dimensional spaces.

66.5 Sources and Related Material

General information regarding the topics presented in the chapter can be found in standard texts on computational geometry, including those by Preparata and Shamos [8], Edelsbrunner [1], Mulmuley [70], de Berg et al. [7], and Boissonnat and Yvinec [71] as well as Samet's book on spatial data structures [40]. Further information on point location can be found in a survey paper written by Snoeyink [72]. For information on Voronoi diagrams see the book by Okabe, Boots and Sugihara [73] or surveys by Aurenhammer [74], Aurenhammer and Klein [75], and Fortune [76]. For further information on geometric graphs see the survey

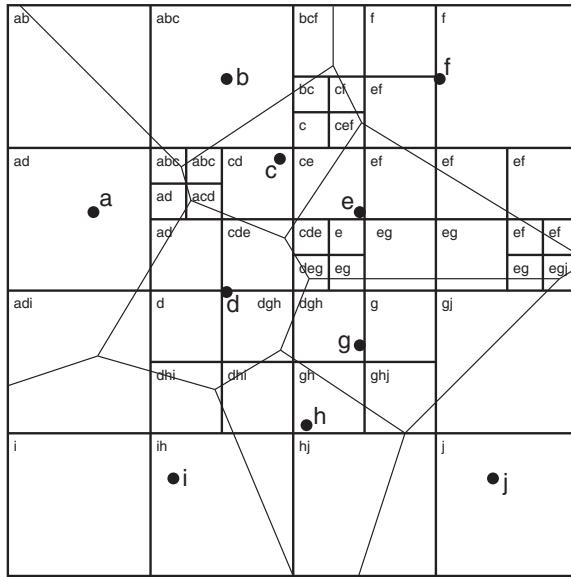

FIGURE 66.15 A (3,0)-AVD implemented as a quadtree subdivision for the set $\{a, b, \dots, j\}$. Each cell is labeled with its representatives. The Voronoi diagram is shown for reference.

by O'Rourke and Toussaint [77]. Further information on nearest neighbor searching can be found in surveys by Böhm et al. [49], Indyk [31], and Chavez et al. [32].

67.1 Geometric Intersection Searching Problems

Problems arising in diverse areas, such as VLSI layout design, database query-retrieval, robotics, and computer graphics can often be formulated as *geometric intersection searching problems*. In a generic instance of such a problem, a set, S , of geometric objects is to be preprocessed into a suitable data structure so that given a query object, q , we can answer efficiently questions regarding the intersection of q with the objects in S . The problem comes in four versions, depending on whether we want to report the intersected objects or simply count their number—the *reporting* version and the *counting* version, respectively—and whether S remains fixed or changes through insertion and deletion of objects—the *static* version and the *dynamic* version, respectively. In the dynamic version, which arises very often owing to the highly interactive nature of the above-mentioned applications, we wish to perform the updates more efficiently than simply recomputing the data structure from scratch after each update, while simultaneously maintaining fast query response times. We call these problems *standard* intersection searching problems in order to distinguish them from the *generalized* intersection searching problems that are the focus of this chapter. Due to their numerous applications, standard intersection searching problems have been the subject of much study and efficient solutions have been devised for many of them (see, for instance, References 1,2 and the references therein).

The efficiency of a standard intersection searching algorithm is measured by the space used by the data structure, the query time, and, in the dynamic setting, the update time. In a counting problem, these are expressed as a function of the input size n (i.e., the size of S); in a reporting problem, the space and update time are expressed as a function of n , whereas the query time is expressed as a function of both n and the output size k (i.e., the number of intersected objects) and is typically of the form $O(f(n) + k)$ or $O(f(n) + k \cdot g(n))$, for some functions f and g . Such a query time is called *output-sensitive*.

67.1.1 Generalized Intersection Searching

In many applications, a more general form of intersection searching arises. Here the objects in S come aggregated in disjoint groups and of interest are questions regarding the intersection of q with the groups rather than with the objects. (q intersects a group if and only if it intersects some object in the group.) In our discussion, it will be convenient to associate with each group a different color and imagine that all the objects in the group have that color. Then, in the *generalized reporting* (resp., *generalized*

counting) problem, we want to report (resp., count) the distinct colors of the objects intersected by q ; in the dynamic setting, an object of some (possibly new) color is inserted in S or an object in S is deleted. Note that the generalized problem reduces to the standard one when each color class has cardinality 1. (We remark that the generalized problems discussed here are also sometimes referred to as *colored* problems; we use the two terms interchangeably.)

We give some examples of such generalized problems:

- Consider a database of mutual funds which contains for each fund its annual total return and its beta (a real number measuring the fund's volatility). Thus each fund can be represented as a point in two dimensions. Moreover, funds are aggregated into groups according to the fund family they belong to. A typical query is to determine the families that offer funds whose total return is between, say, 15% and 20%, and whose beta is between, say, 0.9 and 1.1. This is an instance of the generalized two-dimensional range searching problem. The output of this query enables a potential investor to initially narrow his/her search to a few families instead of having to plow through dozens of individual funds (all from the same small set of families) that meet these criteria. (From a database perspective, this query is similar to an SQL query with a GROUP-BY clause.)
- In the Manhattan layout of a VLSI chip, the wires (line segments) can be grouped naturally according to the circuits they belong to. A problem of interest to the designer is determining which circuits (rather than wires) become electrically connected when a new wire is added. This is an instance of the generalized orthogonal segment intersection searching problem.

One approach to solving a generalized problem is to try to take advantage of solutions known for the corresponding standard problem. For instance, we can solve a generalized reporting problem by first determining the objects intersected by q (a standard reporting problem) and then reading off the distinct colors. However, the query time can be very high since q could intersect $k = \Omega(n)$ objects but only $O(1)$ distinct colors. For a generalized reporting problem, we seek query times that are sensitive to the number, i , of distinct colors intersected, typically of the form $O(f(n) + i)$ or $O(f(n) + i \cdot g(n))$, where f and g are polylogarithmic. (This is attainable using the approach just described if each color class has cardinality $O(1)$. On the other hand, if there are only $O(1)$ different color classes, we could simply run a standard algorithm on each color class in turn, stopping as soon as an intersection is found and reporting the corresponding color. The real challenge is when the number of color classes and the cardinalities of the color classes are not constants, but rather are (unknown) functions of n ; throughout, we will assume this to be the case.) For a generalized counting problem, the situation is worse; it is not even clear how one can extract the answer for such a problem from the answer (a mere count) to the corresponding standard problem. One could, of course, solve the corresponding reporting problem and then count the colors, but this is not efficient. Thus it is clear that different techniques are needed.

In this chapter, we describe the research that has been conducted over the past two decades on generalized intersection searching problems. We begin with a brief review of known results and then discuss a variety of techniques for these problems. For each technique, we give illustrative examples and provide pointers to related work. We conclude with a discussion of possible directions for further research.

67.2 Summary of Known Results

Generalized intersection searching problems were introduced by Janardan and Lopez [3]. Subsequent work in this area may be found in References 4–28, among others. In this section, we give a broad overview of the work on these problems to date; details may be found in the cited references.

67.2.1 Axes-Parallel Objects

In Reference 3, efficient solutions were given for several generalized reporting problems, where the input objects and the query were axes-parallel. Examples of such input/query pairs considered include: points/interval in \mathbb{R}^1 ; line segments/segment, points/rectangle, and rectangles/rectangle, all in \mathbb{R}^2 ; and rectangles/points in \mathbb{R}^d , where $d \geq 2$ is a constant. Several of these results were further extended in Reference 13 to include counting and/or dynamic reporting, and new results were presented for input/query pairs such as intervals/interval in \mathbb{R}^1 , points/quadrant in \mathbb{R}^2 , and points/rectangle in \mathbb{R}^3 . Furthermore, a new type of counting problem, called a *type-2 counting problem* was also introduced, where the goal was to count for each color intersected the number of objects of that color that are intersected. In Reference 6, improved solutions were given for counting and/or reporting problems involving points/interval in \mathbb{R}^1 , points/rectangle in \mathbb{R}^2 , and line segments/segment in \mathbb{R}^2 .

In References 9 and 10, variants of the reporting problem were considered for points/rectangle in \mathbb{R}^2 , with the goal of reporting those colors that appeared “many” times in the output. Specifically, in Reference 10, an efficient dynamic algorithm was given for reporting each color for which the number of points of that color in the query rectangle was more than a user-specified fraction of the total number points in the query rectangle. On the other hand, in Reference 9, an efficient (approximation) algorithm was

given for reporting each color such that the number of points of that color in the query rectangle was at least a user-specified fraction of the total number of points of that color in the input set. More recently, interesting connections have been shown between generalized counting problems and other problems. For instance, as shown in Reference 21, standard range counting involving points/rectangle in \mathbb{R}^2 can be solved using an algorithm for generalized range counting on points/interval in \mathbb{R}^1 . Also, as discussed at length in Reference 18, it is possible to use an “offline” version of the generalized counting problem on points/rectangle in \mathbb{R}^2 to do sparse matrix multiplication.

67.2.2 Arbitrarily Oriented Objects

Efficient solutions were given in Reference 3 for generalized reporting on nonintersecting line segments using a query line segment. Special, but interesting, cases of intersecting line segments, such as when each color class forms a polygon or a connected component, were considered in Reference 5. Efficient solutions were given in Reference 14 for input/query pairs consisting of points/half-space in \mathbb{R}^d , points fat-triangle, and fat-triangles/point in \mathbb{R}^2 . (A *fat-triangle* is a triangle where each internal angle is at least a user-specified constant, hence “well-shaped.”) Some of these results were improved subsequently in Reference 6. In Reference 15, alternative bounds were obtained for the fat-triangle problems within the framework of a general technique for adding range restriction capability to a generalized data structure. Results were presented in Reference 8 for querying, with a polygon, a set of polygons whose sides are oriented in at most a constant number of different directions, with a polygon. In Reference 28, a general method was given for querying intersecting line segments with a segment and for querying points in \mathbb{R}^d with a half-space or a simplex. Generalized problems involving various combinations of circular objects (circles, discs, annuli) and points, lines, and line segments were considered in Reference 16.

67.2.3 Problems on the Grid

Problems involving document retrieval or string manipulation can often be cast in the framework of generalized intersection searching. For example, in the context of document retrieval, the following problem (among others) was considered in Reference 22. Preprocess an array of colored nonnegative integers (i.e., points on the one-dimensional grid) such that, given two indices into the array, each distinct color for which there is a pair of points in the index range at distance less than a specified constant can be reported efficiently. In the context of substring indexing, the following problem was considered in Reference 11. Preprocess a set of colored points on the one-dimensional grid, so that given two nonoverlapping intervals, the list of distinct colors that occurs in both intervals can be reported efficiently. I/O efficient algorithms were given in the standard external memory model [29] for this problem. See References 23 and 30 and references therein for a discussion of more recent work on document retrieval and string manipulation problems. Other grid-related work in this area includes Reference 4, where efficient solutions were given for the points/rectangle and rectangles/point problems, under the condition that the input and query objects lie on a d -dimensional grid.

67.2.4 Single-Shot Problems

In this class of problems, we are given a collection of geometric objects and the goal is to report all pairs that intersect. Note that there is no query object as such here and no notion of preprocessing the input. As an example, suppose that we are given a set of convex polygons with a total of n vertices in \mathbb{R}^2 , and we wish to report or count all pairs that intersect, with the goal of doing this in time proportional to the number of intersecting pairs (i.e., output-sensitively). If the number of polygons and their sizes are both functions of n (instead of one or the other being a constant), then, as discussed in Reference 17, standard methods (e.g., testing each pair of polygons or computing all boundary intersections and polygon containments in the input) are inefficient. In Reference 17, an efficient and output-sensitive algorithm is given for this problem. Each polygon is assigned a color and then decomposed into simpler elements, that is, trapezoids, of the same color. The problem then becomes one of reporting all distinct color pairs (c_1, c_2) such that a trapezoid of color c_1 intersects one of color c_2 . An improved algorithm was given subsequently in Reference 31 for both \mathbb{R}^2 and \mathbb{R}^3 . Other related work on such colored single-shot problems may be found in References 7 and 19. In Reference 19, interesting connections between sparse matrix multiplication and colored single-shot problems are established.

67.2.5 External Memory and Word-RAM Algorithms

The results discussed earlier (and in the rest of this chapter) are in the well-known RAM model or pointer machine model. Recently, generalized problems have also been considered in other machine models such as the external memory model and the word-RAM model. In the external memory model [32], the data resides primarily on disk, in blocks of some fixed size, data transfer (I/O) between disk and main memory happens in blocks, and space and query time are measured in terms of the number of blocks used and the number of I/O operations, respectively. In this model, efficient algorithms were first given in Reference 24 (see also Reference 25) for generalized range search in \mathbb{R}^2 , where the query rectangle is grounded, that is, three-sided. These

results have been improved subsequently in Reference 21. A limitation of these results is that they report each color $O(1)$ times, instead of exactly once, which results in an additional overhead in the external memory model for removal of duplicate colors via sorting. (This is in contrast to internal memory algorithms, where duplicate removal is easy.) This limitation has recently been removed in Reference 26 where each color is reported exactly once. The above papers also present results in the word-RAM model [33], where it is assumed that standard arithmetic and bitwise operations can be done in constant time on a computer word of some fixed length.

67.3 Techniques

We describe in some detail several techniques that have emerged over the past several years for generalized intersection searching. Briefly, these include: a geometric transformation-based approach, an approach based on generating a sparse representation of the input, an approach based on persistent data structures, a generic method that is applicable to any reporting problem, an approach for searching on a subset of the input satisfying a specified range restriction, and an approach that exploits the output size to gain efficiency. We illustrate each method with examples. Finally, we also discuss a “reverse” transformation method that shows an interesting connection between a standard counting and a generalized counting problem.

67.3.1 A Transformation-Based Approach

We describe an approach for certain reporting and counting problems, which transforms the original generalized reporting/counting problem to an instance of a related standard reporting/counting problem on which efficient known solutions can be brought to bear. We illustrate this approach by considering the *generalized one-dimensional range searching* problem, where the input consists of a set, S , of n colored points in \mathbb{R}^1 and the query, q , is an interval. Let S be a set of n colored points on the x -axis. We show how to preprocess S so that for any query interval q , we can solve efficiently the dynamic reporting problem, the static and dynamic counting problems, and the static type-2 counting problem. The solutions for the dynamic reporting problem and the static and dynamic counting problems are from Reference 13. The type-2 counting solution is from Reference 6.

We now describe the transformation. For each color c , we sort the distinct points of that color by increasing x -coordinate. For each point p of color c , let $\text{pred}(p)$ be its predecessor of color c in the sorted order; for the leftmost point of color c , we take the predecessor to be the point $-\infty$. We then map p to the point $p' = (p, \text{pred}(p))$ in the plane and associate with it the color c . Let S' be the resulting set of points. Given a query interval $q = [l, r]$, we map it to the grounded rectangle $q' = [l, r] \times (-\infty, l)$.

Lemma 67.1

There is a point of color c in S that is in $q = [l, r]$ if and only if there is a point of color c in S' that is in $q' = [l, r] \times (-\infty, l)$. Moreover, if there is a point of color c in q' , then this point is unique.

Proof. Let p' be a c -colored point in q' , where $p' = (p, \text{pred}(p))$ for some c -colored point $p \in S$. Since p' is in $[l, r] \times (-\infty, l)$, it is clear that $l \leq p \leq r$ and so $p \in [l, r]$.

For the converse, let p be the leftmost point of color c in $[l, r]$. Thus $l \leq p \leq r$ and since $\text{pred}(p) \notin [l, r]$, we have $l > \text{pred}(p)$. It follows that $p' = (p, \text{pred}(p))$ is in $[l, r] \times (-\infty, l)$. We prove that p' is the only point of color c in q' . Suppose for a contradiction that $t' = (t, \text{pred}(t))$ is another point of color c in q' . Thus we have $l \leq t \leq r$. Since $t > p$, we also have $\text{pred}(t) \geq p \geq l$. Thus $t' = (t, \text{pred}(t))$ cannot lie in q' —a contradiction. ■

Lemma 67.1 implies that we can solve the generalized one-dimensional range reporting (resp., counting) problem by simply reporting the points in q' (resp., counting the number of points in q'), without regard to colors. In other words, we have reduced the generalized reporting (resp., counting) problem in \mathbb{R}^1 to the standard grounded range reporting (resp., counting) problem in \mathbb{R}^2 . In the dynamic case, we also need to update S' when S is updated. We discuss these issues in more detail below.

67.3.1.1 The Dynamic Reporting Problem

Our data structure consists of the following: For each color c , we maintain a balanced binary search tree, T_c , in which the c -colored points of S are stored in increasing x -order. We maintain the colors themselves in a balanced search tree CT and store with each color c in CT a pointer to T_c . We also store the points of S' in a *balanced priority search tree* (PST) [34]. (Recall that a PST on m points occupies $O(m)$ space, supports insertions and deletions in $O(\log m)$ time, and can be used to report the k points lying inside a grounded query rectangle in $O(\log m + k)$ time [34]. Although this query is designed for query ranges of the form $[l, r] \times (-\infty, l]$, it can be trivially modified to ignore the points on the upper edge of the range without affecting its performance.) Clearly, the space used by the entire data structure is $O(n)$, where $n = |S|$.

To answer a query $q = [l, r]$, we simply query the *PST* with $q' = [l, r] \times (-\infty, l)$ and report the colors of the points found. Correctness follows from Lemma 67.1. The query time is $O(\log n + k)$, where k is the number of points inside q' . By Lemma 67.1, $k = i$, and so the query time is $O(\log n + i)$.

Suppose that a c -colored point p is to be inserted into S . If $c \notin CT$, then we create a tree T_c containing p , insert $p' = (p, -\infty)$ into the *PST*, and insert c , with a pointer to T_c , into CT . Suppose that $c \in CT$. Let u be the successor of p in T_c . If u exists, then we set $\text{pred}(p)$ to $\text{pred}(u)$ and $\text{pred}(u)$ to p ; otherwise, we set $\text{pred}(p)$ to the rightmost point in T_c . We then insert p into T_c , $p' = (p, \text{pred}(p))$ into the *PST*, delete the old u' from the *PST*, and insert the new one. If T_c becomes empty in the process, then we delete c from CT . By Lemma 67.1, the update operations are correct and take $O(\log n)$ time.

Deletion of a point p of color c is essentially the reverse. We delete p from T_c . Then we delete p' from the *PST* and if p had a successor, u , in T_c then we reset $\text{pred}(u)$ to $\text{pred}(p)$, delete the old u' from the *PST*, and insert the new one. If T_c becomes empty in the process, then we delete c from CT . Clearly, the update operations are correct and take $O(\log n)$ time.

Theorem 67.1

Let S be a set of n colored points on the real line. S can be preprocessed into a data structure of size $O(n)$ such that the i distinct colors of the points of S that are contained in any query interval can be reported in $O(\log n + i)$ time and points can be inserted and deleted online in S in $O(\log n)$ time.

For the static reporting problem, we can dispense with CT and the T_c 's and simply use a static form of the *PST* to answer queries. This provides a simple $O(n)$ -space, $O(\log n + i)$ -query time alternative to another solution given in Reference 3.

67.3.1.2 The Static Counting Problem

We store the points of S' in nondecreasing x -order at the leaves of a balanced binary search tree, T , and store at each internal node t of T an array A_t containing the points in t 's subtree in nondecreasing y -order. The total space is clearly $O(n \log n)$. To answer a query, we determine $O(\log n)$ canonical nodes v in T such that the query interval $[l, r]$ covers v 's range but not the range of v 's parent. Using binary search we determine in each canonical node's array the highest array position containing an entry less than l (and thus the number of points in that node's subtree that lie in q') and add up the positions thus found at all canonical nodes. The correctness of this algorithm follows from Lemma 67.1. The total query time is $O(\log^2 n)$.

We can reduce the query time to $O(\log n)$ as follows: At each node t we create a linked list, B_t , which contains the same elements as A_t and maintain a pointer from each entry of B_t to the same entry in A_t . We then apply the technique of fractional cascading [35] to the B -lists, so that after an initial $O(\log n)$ -time binary search in the B -list of the root, the correct positions in the B -lists of all the canonical nodes can be found directly in $O(\log n)$ total time. (To facilitate binary search in the root's B -list, we build a balanced search tree on it after the fractional cascading step.) Once the position in a B -list is known, the appropriate position in the corresponding A -array can be found in $O(1)$ time.

It is possible to reduce the space slightly (to $O(n \log n / \log \log n)$) at the expense of a larger query time ($O(\log^2 n / \log \log n)$), by partitioning the points of S' recursively into horizontal strips of a certain size and doing binary search, augmented with fractional cascading, within the strips. Details can be found in Reference 13.

Theorem 67.2

Let S be a set of n colored points on the real line. S can be preprocessed into a data structure of size $O(n \log n)$ (resp., $O(n \log n / \log \log n)$) such that the number of distinctly colored points of S that are contained in any query interval can be determined in $O(\log n)$ (resp., $O(\log^2 n / \log \log n)$) time.

67.3.1.3 The Dynamic Counting Problem

We store the points of S' using the same basic two-level tree structure as in the first solution for the static counting problem. However, T is now a $BB(\alpha)$ tree [36] and the auxiliary structure, $D(t)$, at each node t of T is a balanced binary search tree where the points are stored at the leaves in left to right order by nondecreasing y -coordinate. To facilitate the querying, each node v of $D(t)$ stores a count of the points in its subtree. Given a real number, l , we can determine in $O(\log n)$ time the number of points in $D(t)$ that have y -coordinate less than l by searching for l in $D(t)$ and adding up the count for each node of $D(t)$ that is not on the search path but is the left child of a node on the path. It should be clear that $D(t)$ can be maintained in $O(\log n)$ time under updates.

In addition to the two-level structure, we also use the trees T_c and the tree CT , described previously, to maintain the correspondence between S and S' . We omit further discussion about the maintenance of these trees.

Queries are answered as in the static case, except that at each auxiliary structure we use the above-mentioned method to determine the number of points with y -coordinate less than l . Thus the query time is $O(\log^2 n)$. (We cannot use fractional cascading here.)

Insertion/deletion of a point is done using the worst-case updating strategy for $BB(\alpha)$ trees, and take $O(\log^2 n)$ time.

Theorem 67.3

Let S be a set of n colored points on the real line. S can be preprocessed into a data structure of size $O(n \log n)$ such that the number of distinctly colored points of S that are contained in any query interval can be determined in $O(\log^2 n)$ time and points can be inserted and deleted online in S in $O(\log^2 n)$ worst-case time.

67.3.1.4 The Static Type-2 Problem

We wish to preprocess a set S of n colored points on the x -axis, so that for each color intersected by a query interval $q = [l, r]$, the number of points of that color in q can be reported efficiently. The solution for this problem originally proposed in Reference 13 takes $O(n \log n)$ space and supports queries in $O(\log n + i)$ time. The space bound was improved to $O(n)$ in Reference 6, as follows.

The solution consists of two priority search trees, PST_1 and PST_2 . PST_1 is similar to the priority search tree built on S' in the solution for the dynamic reporting problem, with an additional count stored at each node. Let $p' = (p, pred(p))$ be the point that is stored at a node in PST_1 and c the color of p . Then at this node, we store an additional number $t_1(p')$, which is the number of points of color c to the right of p .

PST_2 is based on a transformation that is symmetric to the one used for PST_1 . For each color c , we sort the distinct points of that color by increasing x -coordinate. For each point p of color c , let $next(p)$ be its successor in the sorted order; for the rightmost point of color c , we take the successor to be the point $+\infty$. We then map p to the point $p'' = (p, next(p))$ in the plane and associate with it the color c . Let S'' be the resulting set of points. We build PST_2 on S'' , with an additional count stored at each node. Let $p'' = (p, next(p))$ be the point that is stored at a node in PST_2 and c the color of p . Then at this node, we store an additional number $t_2(p'')$, which is the number of points of color c to the right of $next(p)$.

We also maintain an auxiliary array A of size n . Given a query $q = [l, r]$, we query PST_1 with $q' = [l, r] \times (-\infty, l)$ and for each color c found, we set $A[c] = t_1(p')$, where p' is the point stored at the node where we found c . Then we query PST_2 with $q'' = [l, r] \times (r, +\infty)$ and for each color c found, we report c and $A[c] - t_2(p'')$, where p'' is the point stored at the node where we found c . This works because the queries on PST_1 and PST_2 effectively find the leftmost and rightmost points of color c in $q = [l, r]$ (cf. proof of Lemma 67.1). Thus $A[c] - t_2(p'')$ gives the number of points of color c in q .

Theorem 67.4

A set S of n colored points on the real line can be preprocessed into a data structure of size $O(n)$ such that for any query interval, a type-2 counting query can be answered in $O(\log n + i)$ time, where i is the output size.

Finally, we note that Theorem 67.1 combined with the notion of persistence (which is discussed in detail in Section 67.3.3) yields an efficient solution to the *generalized grounded range reporting* problem in \mathbb{R}^2 . In this problem, we wish to preprocess a set of n colored points in \mathbb{R}^2 so that the distinct colors of the points lying in any three-sided axes-parallel query rectangle can be reported efficiently. The solution uses $O(n \log n)$ and $O(\log n + i)$ query time. As shown in Reference 27, the space bound can be further improved to $O(n)$ by using persistence in conjunction with a transformation that maps the colored points in \mathbb{R}^1 to colored points in \mathbb{R}^2 such that the y -coordinates are integers in the range $[0 : \lceil \log n \rceil]$. (This transformation is different from the one underlying Lemma 67.1.) We refer the reader to Reference 27 for details. In Section 67.3.6, we describe another solution to this problem which has the same bounds but is based on a different technique.

67.3.2 A Sparsification-Based Approach

The idea behind this approach is to generate from the given set, S , of colored objects a colored set, S' —possibly consisting of different objects than those in S —such that a query object q intersects an object in S if and only if it intersects an object in S' . Moreover, if q intersects objects in S' then it intersects at most a constant number of them. This allows us to use a solution to a standard problem on S' to solve the generalized reporting problem on S . (In the case of a generalized counting problem, the requirement is more stringent: exactly one object in S' must be intersected.) We illustrate this method with the generalized half-space range searching problem in \mathbb{R}^d , $d = 2, 3$.

67.3.2.1 Generalized Half-Space Range Searching in \mathbb{R}^2 and \mathbb{R}^3

Let S be a set of n colored points in \mathbb{R}^d , $d = 2, 3$. In the *generalized half-space range searching* problem we wish to preprocess S so that for any query hyperplane Q , the i distinct colors of the points lying in the closed half-space Q^- (i.e., below Q) can be reported or counted efficiently. Without loss of generality, we may assume that Q is nonvertical since vertical queries are easy to handle. The approach described here is from Reference 14.

We denote the coordinate directions by x_1, x_2, \dots, x_d . Let \mathcal{F} denote the well-known point-hyperplane duality transform [37]: If $p = (p_1, \dots, p_d)$ is a point in \mathbb{R}^d , then $\mathcal{F}(p)$ is the hyperplane $x_d = p_1x_1 + \dots + p_{d-1}x_{d-1} - p_d$. If $H: x_d = a_1x_1 + \dots + a_{d-1}x_{d-1} + a_d$ is a (nonvertical) hyperplane in \mathbb{R}^d , then $\mathcal{F}(H)$ is the point $(a_1, \dots, a_{d-1}, -a_d)$. It is easily verified that p is above (resp., on, below) H , in the x_d -direction, if and only if $\mathcal{F}(p)$ is below (resp., on, above) $\mathcal{F}(H)$. Note also that $\mathcal{F}(\mathcal{F}(p)) = p$ and $\mathcal{F}(\mathcal{F}(H)) = H$.

Using \mathcal{F} , we map S to a set S' of hyperplanes and map Q to the point $q = \mathcal{F}(Q)$, both in \mathbb{R}^d . Our problem is now equivalent to: “Report or count the i distinct colors of the hyperplanes lying on or above q , that is, the hyperplanes that are intersected by the vertical ray r emanating upwards from q .”

Let S_c be the set of hyperplanes of color c . For each color c , we compute the *upper envelope* E_c of the hyperplanes in S_c . E_c is the locus of the points of S_c of maximum x_d -coordinate for each point on the plane $x_d = 0$. E_c is a d -dimensional convex polytope which is unbounded in the positive x_d -direction. Its boundary is composed of j -faces, $0 \leq j \leq d-1$, where each j -face is a j -dimensional convex polytope. Of particular interest to us are the $(d-1)$ -faces of E_c , called *facets*. For instance, in \mathbb{R}^2 , E_c is an unbounded convex chain and its facets are line segments; in \mathbb{R}^3 , E_c is an unbounded convex polytope whose facets are convex polygons.

Let us assume that r is well behaved in the sense that for no color c does r intersect two or more facets of E_c at a common boundary—for instance, a vertex in \mathbb{R}^2 and an edge or a vertex in \mathbb{R}^3 . (This assumption can be removed; details can be found in Reference 14.) Then, by definition of the upper envelope, it follows that (i) r intersects a c -colored hyperplane if and only if r intersects E_c and, moreover, (ii) if r intersects E_c , then r intersects a unique facet of E_c (in the interior of the facet). Let \mathcal{E} be the collection of the envelopes of the different colors. By the above discussion, our problem is equivalent to: “Report or count the facets of \mathcal{E} that are intersected by r ,” which is a standard intersection searching problem. We will show how to solve efficiently this ray-envelope intersection problem in \mathbb{R}^2 and in \mathbb{R}^3 . This approach does not give an efficient solution to the generalized half-space searching problem in \mathbb{R}^d for $d > 3$; for this case, we will give a different solution in Section 67.3.4.

To solve the ray-envelope intersection problem in \mathbb{R}^2 , we project the endpoints of the line segments of \mathcal{E} on the x -axis, thus partitioning it into $2n+1$ *elementary intervals* (some of which may be empty). We build a *segment tree* T which stores these elementary intervals at the leaves. Let v be any node of T . We associate with v an x -interval $I(v)$, which is the union of the elementary intervals stored at the leaves in v 's subtree. Let $Strip(v)$ be the vertical strip defined by $I(v)$. We say that a segment $s \in \mathcal{E}$ is *allocated* to a node $v \in T$ if and only if $I(v) \neq \emptyset$ and s crosses $Strip(v)$ but not $Strip(parent(v))$. Let $\mathcal{E}(v)$ be the set of segments allocated to v . Within $Strip(v)$, the segments of $\mathcal{E}(v)$ can be viewed as lines since they cross $Strip(v)$ completely. Let $\mathcal{E}'(v)$ be the set of points dual to these lines. We store $\mathcal{E}'(v)$ in an instance $D(v)$ of the standard half-plane reporting (resp., counting) structure for \mathbb{R}^2 given in Reference 38 (resp., [39]). This structure uses $O(m)$ space and has a query time of $O(\log m + k_v)$ (resp., $O(m^{1/2})$), where $m = |\mathcal{E}(v)|$ and k_v is the output size at v .

To answer a query, we search in T using q 's x -coordinate. At each node v visited, we need to report or count the lines intersected by r . But, by duality, this is equivalent to answering, in \mathbb{R}^2 , a half-plane query at v using the query $\mathcal{F}(q)^- = Q^-$, which we do using $D(v)$. For the reporting problem, we simply output what is returned by the query at each visited node; for the counting problem, we return the sum of the counts obtained at the visited nodes.

Theorem 67.5

A set S of n colored points in \mathbb{R}^2 can be stored in a data structure of size $O(n \log n)$ so that the i distinct colors of the points contained in any query half-plane can be reported (resp., counted) in time $O(\log^2 n + i)$ (resp., $O(n^{1/2})$).

Proof. Correctness follows from the preceding discussion. As noted earlier, there are $O(|S_c|)$ line segments (facets) in E_c ; thus $|\mathcal{E}| = O(\sum_c |S_c|) = O(n)$ and so $|T| = O(n)$. Hence each segment of \mathcal{E} can get allocated to $O(\log n)$ nodes of T . Since the structure $D(v)$ has size linear in $m = |\mathcal{E}(v)|$, the total space used is $O(n \log n)$. For the reporting problem, the query time at a node v is $O(\log m + k_v) = O(\log n + k_v)$. When summed over the $O(\log n)$ nodes visited, this gives $O(\log^2 n + i)$. To see this, recall that the ray r can intersect at most one envelope segment of any color; thus the terms k_v , taken over all nodes v visited, sum to i .

For the counting problem, the query time at v is $O(m^{1/2})$. It can be shown that if v has depth j in T , then $m = |\mathcal{E}(v)| = O(n/2^j)$ [40, page 675]. Thus, the overall query time is $O(\sum_{j=0}^{O(\log n)} (n/2^j)^{1/2})$, which is $O(n^{1/2})$. ■

The (standard) problem of reporting the segments in \mathbb{R}^2 that are intersected by a vertical query ray has been revisited recently in Reference 41, in the context of solving a different problem defined on so-called “uncertain points.” For a set of n segments, the solution in Reference 41 uses $O(n)$ space and has a query time of $O(\log n + k)$, where k is the number of reported segments. The approach is based on using a combination of a segment tree and an interval tree together with some other ideas; we refer the reader to Reference 41 for details. By the preceding discussion, this result implies an $O(n)$ -space and $O(\log n + i)$ -query time solution to the generalized half-space range reporting problem in \mathbb{R}^2 .

In \mathbb{R}^3 , the approach is similar, but somewhat more complex. Our goal is to solve the ray–envelope intersection problem in \mathbb{R}^3 . As shown in Reference 14, this problem can be reduced to certain standard half-space range queries in \mathbb{R}^3 on a set of triangles (obtained by triangulating the E_c ’s). This problem can be solved by building a segment tree on the x -spans of the triangles projected to the xy -plane and augmenting each node of this tree with a data structure based on partition trees [42] or cutting trees [43] to answer the half-plane queries. Details may be found in Reference 14.

Theorem 67.6

The reporting version of the generalized half-space range searching problem for a set of n colored points in \mathbb{R}^3 can be solved in $O(n \log^2 n)$ (resp., $O(n^{2+\epsilon})$) space and $O(n^{1/2+\epsilon} + i)$ (resp., $O(\log^2 n + i)$) query time, where i is the output size and $\epsilon > 0$ is an arbitrarily small constant. The counting version is solvable in $O(n \log n)$ space and $O(n^{2/3+\epsilon})$ query time.

Additional examples of the sparsification-based approach may be found in Reference 3. (An example also appears in the next section, enroute to a persistence-based solution of a generalized problem.)

67.3.3 A Persistence-Based Approach

Roughly speaking, we use persistence as follows: To solve a given generalized problem we first identify a different, but simpler, generalized problem and devise a data structure for it that also supports updates (usually just insertions). We then make this structure partially persistent [44] and query this persistent structure appropriately to solve the original problem.

We illustrate this approach for *generalized three-dimensional range searching*, where we are required to preprocess a set, S , of n colored points in \mathbb{R}^3 so that for any query box $q = [a, b] \times [c, d] \times [e, f]$ the i distinct colors of the points inside q can be reported efficiently. We first show how to build a semidynamic (i.e., insertions-only) data structure for the generalized versions of the quadrant searching and two-dimensional range searching problems. These two structures will be the building blocks of our solution for the three-dimensional problem.

67.3.3.1 Generalized Semidynamic Quadrant Searching

Let S be a set of n colored points in the plane. For any point $q = (a, b)$, the *northeast quadrant* of q , denoted by $NE(q)$, is the set of all points (x, y) in the plane such that $x \geq a$ and $y \geq b$. We show how to preprocess S so that for any query point q , the distinct colors of the points of S contained in $NE(q)$ can be reported, and how points can be inserted into S . This is the *generalized two-dimensional quadrant range searching* problem supporting insertions. The data structure uses $O(n)$ space, has a query time of $O(\log^2 n + i)$, and an amortized insertion time of $O(\log n)$. This solution is based on the sparsification approach described previously.

For each color c , we determine the c -maximal points. (A point p is called c -*maximal* if it has color c and there are no points of color c in p ’s northeast quadrant.) We discard all points of color c that are not c -maximal. In the resulting set, let the predecessor, $pred(p)$, of a c -colored point p be the c -colored point that lies immediately to the left of p . (For the leftmost point of color c , the predecessor is the point $(-\infty, \infty)$.) With each point $p = (a, b)$, we associate the horizontal segment with endpoints (a', b) and (a, b) , where a' is the x -coordinate of $pred(p)$. This segment gets the same color as p . Let S_c be the set of such segments of color c . The data structure consists of two parts, as follows.

The first part is a structure T storing the segments in the sets S_c , where c runs over all colors. T supports the following query: given a point q in the plane, report the segments that are intersected by the upward-vertical ray starting at q . Moreover, it allows segments to be inserted and deleted. We implement T as the structure given in Reference 45. This structure uses $O(n)$ space, supports insertions and deletions in $O(\log n)$ time, and has a query time of $O(\log^2 n + l)$, where l is the number of segments intersected.

The second part is a balanced search tree CT , storing all colors. For each color c , we maintain a balanced search tree, T_c , storing the segments of S_c by increasing y -coordinate. This structure allows us to dynamically maintain S_c when a new c -colored point p is inserted. The general approach (omitting some special cases; see Reference 13) is as follows: By doing a binary search in T_c we can determine whether or not p is c -maximal in the current set of c -maximal points, that is, the set of right endpoints of the segments of S_c . If p is not c -maximal, then we simply discard it. If p is c -maximal, then let s_1, \dots, s_k be the segments of S_c

whose left endpoints are in the southwest quadrant of p . We do the following: (i) delete s_2, \dots, s_k from T_c ; (ii) insert into T_c the horizontal segment which starts at p and extends leftwards up to the x -coordinate of the left endpoint of s_k ; and (iii) truncate the segment s_1 by keeping only the part of it that extends leftwards up to p 's x -coordinate. The entire operation can be done in $O(\log n + k)$ time.

Let us now consider how to answer a quadrant query, $NE(q)$, and how to insert a point into S . To answer $NE(q)$, we query \mathcal{T} with the upward-vertical ray from q and report the colors of the segments intersected. The correctness of this algorithm follows from the easily proved facts that (i) a c -colored point lies in $NE(q)$ if and only if a c -maximal point lies in $NE(q)$ and (ii) if a c -maximal point is in $NE(q)$, then the upward-vertical ray from q must intersect a segment of S_c . The correctness of \mathcal{T} guarantees that only the segments intersected by this ray are reported. Since the query can intersect at most two segments in any S_c , we have $l \leq 2i$, and so the query time is $O(\log^2 n + i)$.

Let p be a c -colored point that is to be inserted into S . If c is not in CT , then we insert it into CT and insert the horizontal, leftward-directed ray emanating from p into a new structure T_c . If c is present already, then we update T_c as just described. In both cases, we then perform the same updates on \mathcal{T} . Hence, an insertion takes $O((k+1)\log n)$ time.

What is the total time for n insertions into an initially empty set S ? For each insertion, we can charge the $O(\log n)$ time to delete a segment s_i , $2 \leq i \leq k$, to s_i itself. Notice that none of these segments will reappear. Thus each segment is charged at most once. Moreover, each of these segments has some previously inserted point as a right endpoint. It follows that the number of segments existing over the entire sequence of insertions is $O(n)$ and so the total charge to them is $O(n \log n)$. The rest of the cost for each insertion ($O(\log n)$ for the binary search plus $O(1)$ for steps (ii) and (iii)) we charge to p itself. Since any p is charged in this mode only once, the total charge incurred in this mode by all the inserted points is $O(n \log n)$. Thus the time for n insertions is $O(n \log n)$, which implies an amortized insertion time of $O(\log n)$.

Lemma 67.2

Let S be a set of n colored points in the plane. There exists a data structure of size $O(n)$ such that for any query point q , we can report the i distinct colors of the points that are contained in the northeast quadrant of q in $O(\log^2 n + i)$ time. Moreover, if we do n insertions into an initially empty set then the amortized insertion time is $O(\log n)$.

67.3.3.2 Generalized Semidynamic Two-Dimensional Range Searching

Our goal here is to preprocess a set S of n colored points in the plane so that for any axes-parallel query rectangle $q = [a, b] \times [c, d]$, we can report efficiently the distinct colors of the points in q and moreover perform insertions in S . This is the *generalized two-dimensional range reporting* problem supporting insertions.

Our solution is based on the quadrant reporting structure of Lemma 67.2. We first show how to solve the problem for query rectangles $q' = [a, b] \times [c, \infty)$. We store the points of S in sorted order by x -coordinate at the leaves of a $BB(\alpha)$ tree T' . At each internal node v , we store an instance of the structure of Lemma 67.2 for NE -queries (resp., NW -queries) built on the points in v 's left (resp., right) subtree. Let $X(v)$ denote the average of the x -coordinate in the rightmost leaf in v 's left subtree and the x -coordinate in the leftmost leaf of v 's right subtree; for a leaf v , we take $X(v)$ to be the x -coordinate of the point stored at v .

To answer a query q' , we do a binary search down T' , using $[a, b]$, until either the search runs off T' or a (highest) node v is reached such that $[a, b]$ intersects $X(v)$. In the former case, we stop. In the latter case, if v is a leaf, then if v 's point is in q' we report its color. If v is a nonleaf, then we query the structures at v using the NE -quadrant and the NW -quadrant derived from q' (i.e., the quadrants with corners at (a, c) and (b, c) , respectively), and then combine the answers. Updates on T' are performed using the amortized-case updating strategy for $BB(\alpha)$ trees [36]. The correctness of the method should be clear. The space and query time bounds follow from Lemma 67.2. Since the amortized insertion time of the quadrant searching structure is $O(\log n)$, the insertion in the $BB(\alpha)$ tree takes amortized time $O(\log^2 n)$ [36].

To solve the problem for general query rectangles $q = [a, b] \times [c, d]$, we use the above approach again, except that we store the points in the tree by sorted y -coordinates. At each internal node v , we store an instance of the data structure above to answer queries of the form $[a, b] \times [c, \infty)$ (resp., $[a, b] \times (-\infty, d]$) on the points in v 's left (resp., right) subtree. The query strategy is similar to the previous one, except that we use the interval $[c, d]$ to search in the tree. The query time is as before, while the space and update times increase by a logarithmic factor.

Lemma 67.3

Let S be a set of n colored points in the plane. There exists a data structure of size $O(n \log^2 n)$ such that for any query rectangle $[a, b] \times [c, d]$, we can report the i distinct colors of the points that are contained in it in $O(\log^2 n + i)$ time. Moreover, points can be inserted into this data structure in $O(\log^3 n)$ amortized time.

67.3.3.3 Generalized Three-Dimensional Range Searching

The semidynamic structure of Lemma 67.3 coupled with persistence allows us to go up one dimension and solve the original problem of interest: Preprocess a set S of n colored points in \mathbb{R}^3 so that for any query box $q = [a, b] \times [c, d] \times [e, f]$ the i distinct colors of the points inside q can be reported efficiently.

First consider queries of the form $q' = [a, b] \times [c, d] \times [e, \infty)$. We sort the points of S by nonincreasing z -coordinates, and insert them in this order into a partially persistent version of the structure of Lemma 67.3, taking only the first two coordinates into account. To answer q' , we access the version corresponding to the smallest z -coordinate greater than or equal to e and query it with $[a, b] \times [c, d]$.

To see that the query algorithm is correct, observe that the version accessed contains the projections on the xy -plane of exactly those points of S whose z -coordinate is at least e . Lemma 67.3 then guarantees that among these only the distinct colors of the ones in $[a, b] \times [c, d]$ are reported. These are precisely the distinct colors of the points contained in $[a, b] \times [c, d] \times [e, \infty)$. The query time follows from Lemma 67.3. To analyze the space requirement, we note that the structure of Lemma 67.3 satisfies the conditions given in Reference 44. Specifically, it is a pointer-based structure, where each node is pointed to by only $O(1)$ other nodes. As shown in Reference 44, any modification made by a persistent update operation on such a structure adds only $O(1)$ amortized space to the resulting persistent structure. By Lemma 67.3, the total time for creating the persistent structure, via insertions, is $O(n \log^3 n)$. This implies the same bound for the number of modifications in the structure, so the total space is $O(n \log^3 n)$.

To solve the problem for general query boxes $q = [a, b] \times [c, d] \times [e, f]$, we follow an approach similar to that described for the two-dimensional case: We store the points in a balanced binary search tree, sorted by z -coordinates. We associate with each internal node v in the tree the auxiliary structure described above for answering queries of the form $[a, b] \times [c, d] \times [e, \infty)$ (resp., $[a, b] \times [c, d] \times (-\infty, f]$) on the points in v 's left (resp., right) subtree. (Note that since we do not need to do updates here the tree need not be a $BB(\alpha)$ tree.) Queries are done by searching down the tree using the interval $[e, f]$. The query time is as before, but the space increases by a logarithmic factor.

Theorem 67.7

Let S be a set of n colored points in 3-space. S can be stored in a data structure of size $O(n \log^4 n)$ such that for any query box $[a, b] \times [c, d] \times [e, f]$, we can report the i distinct colors of the points that are contained in it in $O(\log^2 n + i)$ time.

Additional applications of the persistence-based approach to generalized intersection problems can be found in References 13, 14, 16, 27.

67.3.4 A General Approach for Reporting Problems

We describe a general method from Reference 16 for solving any generalized reporting problem given a data structure for a “related” standard decision problem.

Let S be a set of n colored geometric objects and let q be any query object. In preprocessing, we store the distinct colors in S at the leaves of a balanced binary tree CT (in no particular order). For any node v of CT , let $C(v)$ be the set of colors stored in the leaves of v 's subtree and let $S(v)$ be the set of those objects of S colored with the colors in $C(v)$. At v , we store a data structure $DEC(v)$ to solve the following *standard decision* problem on $S(v)$: “Decide whether or not q intersects any object of $S(v)$.” $DEC(v)$ returns “true” if and only if there is an intersection.

To answer a generalized reporting query on S , we do a depth-first search in CT and query $DEC(v)$ with q at each node v visited. If v is a nonleaf node then we continue searching below v if and only if the query returns “true”; if v is a leaf, then we output the color stored there if and only if the query returns “true.”

Theorem 67.8

Assume that a set of n geometric objects can be stored in a data structure of size $M(n)$ such that it can be decided in $f(n)$ time whether or not a query object intersects any of the n objects. Assume that $M(n)/n$ and $f(n)$ are nondecreasing functions for nonnegative values of n . Then a set S of n colored geometric objects can be preprocessed into a data structure of size $O(M(n) \log n)$ such that the i distinct colors of the objects in S that are intersected by a query object q can be reported in time $O(f(n) + i \cdot f(n) \log n)$.

Proof. We argue that a color c is reported if and only if there is a c -colored object in S intersecting q . Suppose that c is reported. This implies that a leaf v is reached in the search such that v stores c and the query on $DEC(v)$ returns “true.” Thus, q intersects some object in $S(v)$. Since v is a leaf, all objects in $S(v)$ have the same color c and the claim follows.

For the converse, suppose that q intersects a c -colored object p . Let v be the leaf storing c . Thus $p \in S(v')$ for every node v' on the root-to- v path in CT . Thus, for each v' , the query on $DEC(v')$ will return “true,” which implies that v will be visited and c will be output.

If v_1, v_2, \dots, v_r are the nodes at any level, then the total space used by CT at that level is $\sum_{i=1}^r M(|S(v_i)|) = \sum_{i=1}^r |S(v_i)| \cdot (M(|S(v_i)|)/|S(v_i)|) \leq \sum_{i=1}^r |S(v_i)| \cdot (M(n)/n) = M(n)$, since $\sum_{i=1}^r |S(v_i)| = n$ and since $|S(v_i)| \leq n$ implies that $M(|S(v_i)|)/|S(v_i)| \leq M(n)/n$. Now since there are $O(\log n)$ levels, the overall space is $O(M(n) \log n)$. The query time can be upper bounded as follows: If $i = 0$, then the query on $DEC(\text{root})$ returns “false” and we abandon the search at the root itself; in this case, the query time is just $O(f(n))$. Suppose that $i \neq 0$. Call a visited node v fruitful if the query on $DEC(v)$ returns “true” and fruitless otherwise. Each fruitful node can be charged to some color in its subtree that gets reported. Since the number of times any reported color can be charged is $O(\log n)$ (the height of CT) and since i colors are reported, the number of fruitful nodes is $O(i \log n)$. Since each fruitless node has a fruitful parent and CT is a binary tree, it follows that there are only $O(i \log n)$ fruitless nodes. Hence the number of nodes visited by the search is $O(i \log n)$. At each such node, v , we spend time $f(|S(v)|)$, which is $O(f(n))$ since $|S(v)| \leq n$ and f is nondecreasing. Thus the total time spent in doing queries at the visited nodes is $O(i f(n) \log n)$. The claimed query time follows. ■

As an application of this method, consider the generalized half-space range searching problem in \mathbb{R}^d , for any fixed $d \geq 2$. For $d = 2, 3$, we discussed a solution for this problem in Section 67.3.2. For $d > 3$, the problem can be solved by extending (significantly) the ray-envelope intersection algorithm outlined in Section 67.3.2. However, the bounds are not very satisfactory— $O(n^{d\lfloor d/2 \rfloor + \epsilon})$ space and logarithmic query time or near-linear space and superlinear query time. The solution we give below has more desirable bounds.

The colored objects for this problem are points in \mathbb{R}^d and the query is a closed half-space in \mathbb{R}^d . We store the objects in CT , as described previously. The standard decision problem that we need to solve at each node v of CT is “Does a query half-space contain any point of $S(v)$?” The answer to this query is “true” if and only if the query half-space is nonempty. We take the data structure, $DEC(v)$, for this problem to be the one given in Reference 46. If $|S_v| = n_v$, then $DEC(v)$ uses $O(n_v^{\lfloor d/2 \rfloor}) / (\log n_v)^{\lfloor d/2 \rfloor - \epsilon}$ space and has query time $O(\log n_v)$ [46]. The conditions in Theorem 67.8 hold, so applying it gives the following result.

Theorem 67.9

For any fixed $d \geq 2$, a set S of n colored points in \mathbb{R}^d can be stored in a data structure of size $O(n^{\lfloor d/2 \rfloor}) / (\log n)^{\lfloor d/2 \rfloor - 1 - \epsilon}$ such that the i distinct colors of the points contained in a query half-space Q^- can be reported in time $O(\log n + i \log^2 n)$. Here $\epsilon > 0$ is an arbitrarily small constant.

Other applications of the general method may be found in Reference 16.

67.3.5 Adding Range Restrictions

We describe the general technique of Reference 15 that adds a range restriction to a generalized intersection searching problem.

Let PR be a generalized intersection searching problem on a set S of n colored objects and query objects q belonging to a class Q . We denote the answer to a query by $PR(q, S)$. To add a *range restriction*, we associate with each element $p \in S$ a real number k_p . In a range-restricted generalized intersection searching problem, denoted by TPR , a query consists of an element $q \in Q$ and an interval $[l, r]$, and

$$TPR(q, [l, r], S) := PR(q, \{p \in S : l \leq k_p \leq r\}).$$

For example, if PR is the generalized $(d-1)$ -dimensional range searching problem, then TPR is the generalized d -dimensional version of this problem, obtained by adding a range restriction to the d th dimension.

Assume that we have a data structure DS that solves PR with $O((\log n)^u + i)$ query time using $O(n^{1+\epsilon})$ space and a data structure TDS that solves TPR for generalized (semi-infinite) queries of the form $TPR(q, [l, \infty), S)$ with $O((\log n)^v + i)$ query time using $O(n^w)$ space. (Here u and v are positive constants, $w > 1$ is a constant, and $\epsilon > 0$ is an arbitrarily small constant.) We will show how to transform DS and TDS into a data structure that solves generalized queries $TPR(q, [l, r], S)$ in $O((\log n)^{\max(u, v, 1)} + i)$ time, using $O(n^{1+\epsilon})$ space.

Let $S = \{p_1, p_2, \dots, p_n\}$, where $k_{p_1} \geq k_{p_2} \geq \dots \geq k_{p_n}$. Let m be an arbitrary parameter with $1 \leq m \leq n$. We assume for simplicity that n/m is an integer. Let $S_j = \{p_1, p_2, \dots, p_{jm}\}$ and $S'_j = \{p_{jm+1}, p_{jm+2}, \dots, p_{(j+1)m}\}$ for $0 \leq j < n/m$.

The transformed data structure consists of the following. For each j with $0 \leq j < n/m$, there is a data structure DS_j (of type DS) storing S_j for solving generalized queries of the form $PR(q, S_j)$, and a data structure TDS_j (of type TDS) storing S'_j for solving generalized queries of the form $TPR(q, [l, \infty), S'_j)$.

To answer a query $TPR(q, [l, \infty), S)$, we do the following. Compute the index j such that $k_{p(j+1)m} < l \leq k_{pjm}$. Solve the query $PR(q, S_j)$ using DS_j , solve the query $TPR(q, [l, \infty), S'_j)$ using TDS_j , and output the union of the colors reported by these two queries. It is easy to see that the query algorithm is correct. The following lemma gives the complexity of the transformed data structure.

Lemma 67.4

The transformed data structure uses $O(n^{2+\epsilon}/m + nm^{w-1})$ space and can be used to answer generalized queries $TPR(q, [l, \infty), S)$ in $O((\log n)^{\max(u,v,1)} + i)$ time.

Theorem 67.10

Let S , DS , and TDS be as above. There exists a data structure of size $O(n^{1+\epsilon})$ that solves generalized queries $TPR(q, [l, r], S)$ in $O((\log n)^{\max(u,v,1)} + i)$ time.

Proof. We will use Lemma 67.4 to establish the claimed bounds for answering generalized queries $TPR(q, [l, \infty), S)$. The result for queries $TPR(q, [l, r], S)$ then follows from a technique, based on $BB(\alpha)$ trees, that we used in Section 67.3.3.

If $w > 2$, then we apply Lemma 67.4 with $m = n^{1/w}$. This gives a data structure having size $O(n^2)$ that answers queries $TPR(q, [l, \infty), S)$ in $O((\log n)^{\max(u,v,1)} + i)$ time. Hence, we may assume that $w = 2$.

By applying Lemma 67.4 repeatedly, we obtain, for each integer constant $a \geq 1$, a data structure of size $O(n^{1+\epsilon+1/a})$ that answers queries $TPR(q, [l, \infty), S)$ in $O((\log n)^{\max(u,v,1)} + i)$ time. This claim follows by induction on a ; in the inductive step from a to $a + 1$, we apply Lemma 67.4 with $m = n^{a/(a+1)}$. ■

Using Theorem 67.10, we can solve efficiently, for instance, the generalized orthogonal range searching problem in \mathbb{R}^d . (Examples of other problems solvable via this method may be found in Reference 15.)

Theorem 67.11

Let S be a set of n colored points in \mathbb{R}^d , where $d \geq 1$ is a constant. There exists a data structure of size $O(n^{1+\epsilon})$ such that for any query box in \mathbb{R}^d , we can report the i distinct colors of the points that are contained in it in $O(\log n + i)$ time.

Proof. The proof is by induction on d . For $d = 1$, the claim follows from Theorem 67.1. Let $d \geq 2$, and let DS be a data structure of size $O(n^{1+\epsilon})$ that answers generalized $(d - 1)$ -dimensional range queries in $O(\log n + i)$ time. Observe that for the generalized d -dimensional range searching problem, there are only polynomially many distinct semi-infinite queries. Hence, there exists a data structure TDS of polynomial size that answers generalized d -dimensional semi-infinite range queries in $O(\log n + i)$ time. Applying Theorem 67.10 to DS and TDS proves the claim. ■

67.3.6 Exploiting the Output Size

In this approach, the design of the data structure and the query algorithm is based on the (unknown) size of the output (i.e., i). It involves building and querying two structures, one to handle “large” output size and the other to handle “small” output size. The definition of “large” and “small” depends on the problem at hand and will become clear in the discussion below.

Suppose that we have designed a low-space data structure, \mathcal{D}_L , to handle the case where the output size is large; let the query time of this be $O(f(n) + i)$. Then the crucial observation is that if i is $\Omega(f(n))$ (i.e., i is large), then the query time is $O(i)$, which is the best one can hope for since it takes this much time to merely output the query results. However, if i is $O(f(n))$ (i.e., i is small), then the query time is $O(f(n))$ which is undesirable if $f(n)$ is large. The challenge now is to design a separate data structure, \mathcal{D}_S , that can handle efficiently the case where the output size is small, by taking advantage of this very fact. Intuitively, this step involves “precomputing” and storing the answers to certain carefully chosen queries; the space used for this is kept small by exploiting the fact that the output size is small. Note that an additional challenge is that one does not know *a priori* whether i is small or large for a given query instance. Therefore, the overall query algorithm proceeds as follows: First, \mathcal{D}_S is queried with the given query object. If this succeeds in returning all of the query results (i.e., the output size is small) then the query algorithm terminates. Otherwise, the query on \mathcal{D}_S aborts and the algorithm proceeds to reissue the query on \mathcal{D}_L to compute the query result.

We illustrate this approach by presenting an optimal algorithm for generalized grounded range reporting in \mathbb{R}^2 , where the input is a set of n colored points and the query is a rectangle $q = [x_l, x_r] \times [y_0, \infty)$. This algorithm uses $O(n)$ space and answers

queries in $O(\log n + i)$ time. The following description is based on ideas from References 24 and 25, where the problem is solved in external memory.

For \mathcal{D}_L , we use a data structure presented in Reference 3 which, for a set of n colored points in \mathbb{R}^2 , occupies $O(n)$ space and answers a generalized grounded range query in $O(\log^2 n + i)$ time. Thus $f(n) = \log^2 n$ and we take the output size to be large if $i \geq \log^2 n$. We build an instance of \mathcal{D}_L on the given set S .

We design the structure \mathcal{D}_S as follows: We sort the points of S in nondecreasing order of their x -coordinates and partition them into groups consisting of $\log^3 n$ consecutive points each. For each group we build an instance of \mathcal{D}_L . Next, we build a balanced binary search tree, T , based on the left-to-right ordering of the groups and associate a leaf with each group. Let v be a proper ancestor of a leaf u and let $\Pi(u, v)$ be the path from u to v (excluding u and v). Let $S_l(u, v)$ (resp., $S_r(u, v)$) be the union of the sets of points in the subtrees rooted at nodes that are left (resp., right) children of nodes on $\Pi(u, v)$ but not themselves on the path. For each distinct color in $S_l(u, v)$, we select from among the points of that color in $S_l(u, v)$ the one with the highest y -coordinate. Let $S'_l(u, v)$ be the set of such points selected. Let $S''_l(u, v)$ be the subset of $S'_l(u, v)$ consisting of the $\log^2 n$ points with largest y -coordinate (ties broken arbitrarily). If fewer than $\log^2 n$ points are in $S'_l(u, v)$, then we include all of them in $S''_l(u, v)$. A symmetric discussion for $S_r(u, v)$ yields a set $S''_r(u, v)$. For each pair (u, v) , we store $S''_l(u, v)$ and $S''_r(u, v)$ in linked lists, in nonincreasing order of the y -coordinates of their points (ties broken arbitrarily). The number of (u, v) -pairs stored is $O((n/\log^3 n) \times (\log n)) = O(n/\log^2 n)$, so the space occupied by all sets $S''_l(u, v)$ and $S''_r(u, v)$ is $O(n)$. The space occupied by T and the \mathcal{D}_L structures at all leaves is also $O(n)$.

To answer a query $q = [x_l, x_r] \times [y_0, \infty)$, we first determine the leaf u_l (resp., u_r) of T whose range of x -coordinates contains x_l (resp., x_r). If $u_l = u_r$, then we query the \mathcal{D}_L structure of that leaf and stop. Otherwise, we find the lowest common ancestor, v , of u_l and u_r and do the following:

- First, we report the distinct colors of the points in the groups associated with u_l and u_r that lie in q . This is done by querying the \mathcal{D}_L structure of u_l (resp., u_r) with $[x_l, \infty) \times [y_0, \infty)$ (resp., $(-\infty, x_r] \times [y_0, \infty)$).
- Next, we scan the list for $S''_r(u_l, v)$ and report the colors in it until either (a) we find a point with y -coordinate less than y_0 or (b) all the points in the list have been scanned. If case (a) holds, then the distinct colors of the points of $S_r(u_l, v)$ that lie in q have been reported. If case (b) holds, then we check the size of $S''_r(u_l, v)$. If $|S''_r(u_l, v)| < \log^2 n$, then again the distinct colors of the points of $S_r(u_l, v)$ that lie in q have been reported. (Recall that, by construction, if $S_r(u_l, v)$ has fewer than $\log^2 n$ distinctly colored points, then all of them are included in $S''_r(u_l, v)$.) However, if $|S''_r(u_l, v)| \geq \log^2 n$, then we conclude that i is $\Omega(\log^2 n)$. Similarly, we also scan the list for $S''_l(u_r, v)$ and either report the distinct colors of the points of $S_l(u_r, v)$ that lie in q or conclude that i is $\Omega(\log^2 n)$. If we conclude i is $\Omega(\log^2 n)$ at least once in the above process, then we discard the reported colors and proceed to query the structure \mathcal{D}_L built on the entire set S with q .

The time to find u_l , u_r , and v is $O(\log n)$. If $u_l = u_r$, then querying the \mathcal{D}_L structure at that leaf node takes $O((\log(\log^3 n))^2 + i) = O(\log n + i)$ time. If $u_l \neq u_r$, then, as above, querying the \mathcal{D}_L structure at the two leaves takes $O(\log n + i)$ time. The time to scan $S''_r(u_l, v)$ and $S''_l(u_r, v)$ is $O(i)$. Finally, the time to query the \mathcal{D}_L structure for S is $O(\log^2 n + i) = O(i)$, since at this point we know that i is $\Omega(\log^2 n)$. Therefore, the overall query time is $O(\log n + i)$.

Theorem 67.12

Let S be a set of n colored points in \mathbb{R}^2 . S can be preprocessed into a data structure of size $O(n)$ such that the i distinct colors of the points of S lying in any grounded query rectangle can be reported in $O(\log n + i)$ time.

We remark that the idea of exploiting the output size to gain efficiency can be traced back to Reference 47, where it was used within the framework of filtering search. It has manifested itself in various forms in several subsequent papers on standard and generalized range search, including References 21,24,25,41,48–53 among others.

67.3.7 A Reverse Transformation

In Section 67.3.1, we discussed how the generalized range counting problem in \mathbb{R}^1 can be transformed to a standard range counting problem in \mathbb{R}^2 (with a grounded query rectangle). In this section, we show a reverse transformation which maps a standard range counting problem in \mathbb{R}^2 to a generalized range counting problem in \mathbb{R}^1 . The approach, which is based on Reference 21, shows that the two problems (i.e., generalized range counting in \mathbb{R}^1 and standard range counting in \mathbb{R}^2) are in fact equivalent and it also yields a lower bound for the former problem based on a known lower bound for the latter (in the word-RAM model). This reverse transformation is not a solution technique for generalized problems per se, but it does reveal an interesting connection between a generalized problem and a standard problem and prompts the question of whether other pairs of generalized and standard problems might share a similar connection.

We begin by noting that a standard range counting query in \mathbb{R}^2 with a four-sided (i.e., nongrounded) query rectangle can be answered by doing four standard quadrant counting queries, where each quadrant is defined by one of the vertices of the rectangle, and then adding and subtracting the counts returned using the principle of inclusion/exclusion. Therefore, in what follows, it suffices to focus on standard quadrant counting queries. Specifically, we wish to preprocess a set S of n points in \mathbb{R}^2 so that given any query quadrant $q = (-\infty, a] \times (-\infty, b]$, we can count efficiently the number of points of S that are in q . We assume, without loss of generality, that all coordinates are positive.

We map each point $p = (x(p), y(p)) \in S$ to two points in \mathbb{R}^1 , one with coordinate $-x(p)$ and the other with coordinate $y(p)$. We give each of these points the color p (any unique identifier associated with p). Let S_1 be the set of these newly constructed $2n$ points in \mathbb{R}^1 . Next we make a copy, S_2 , of S_1 and recolor the points so that all of them have distinct colors. For each of S_1 and S_2 , we build a data structure for answering generalized range counting queries in \mathbb{R}^1 . (Note that the structure on S_2 is actually a standard structure since all colors in S_2 are distinct, but it is convenient for our purposes to view it as a generalized structure.)

Given q , we query the two data structures with $q' = [-a, b]$ to obtain two integers t_1 and t_2 , where t_1 is the the number of distinct colors among the points of S_1 in q' and t_2 is the number of distinct colors among the points of S_2 in q' (hence also the number of points of S_2 in q' , since the points in S_2 have distinct colors). We report $t_2 - t_1$ as the answer to the query q on S , that is, the number of points of S that are in q .

The correctness of this can be seen as follows: If p is in q , then we have $x(p) \leq a$ and $y(p) \leq b$, that is, $-a \leq -x(p)$ and $y(p) \leq b$, that is, $-a \leq -x(p) < b$ and $-a < y(p) \leq b$ (since all coordinates are positive). Hence the points $-x(p)$ and $y(p)$ are both in $q' = [-a, b]$. Thus this pair contributes 2 to t_2 and 1 to t_1 , and it follows that $t_2 - t_1$ correctly returns the count of the points of S that are in q . On the other hand, if p is not in q , then we have $-a > -x(p)$ or $y(p) > b$ (or both). In this case, the pair contributes the same amount to both t_2 and t_1 (1, if exactly one inequality holds, and 0 if both hold), so $t_2 - t_1$ again returns the correct overall count.

67.4 Conclusion and Future Directions

We have reviewed research on a class of geometric query-retrieval problems, where the objects to be queried come aggregated in disjoint groups and of interest are questions concerning the intersection of the query object with the groups (rather than with the individual objects). These problems include the well-studied standard intersection problems as a special case and have many applications. We have described several general techniques that have been identified for these problems and have illustrated them with examples.

Some potential directions for future work include: (i) extending the transformation-based approach to higher dimensions; (ii) improving the time bounds for some of the problems discussed here—for instance, can the generalized orthogonal range searching problem in \mathbb{R}^d , for $d \geq 4$, be solved with $O(\text{polylog}(n) + i)$ query time and $O(n(\log n)^{O(1)}n)$ space; (iii) developing general dynamization techniques for generalized problems, along the lines of, for instance, Reference 54 for standard problems; (iv) developing efficient solutions to generalized problems where the objects may be in time-dependent motion; (v) identifying other pairs of standard and generalized problems (beyond the pair discussed in Section 67.3.7) that are equivalent; and (vi) implementing and testing experimentally some of the solutions presented here.
